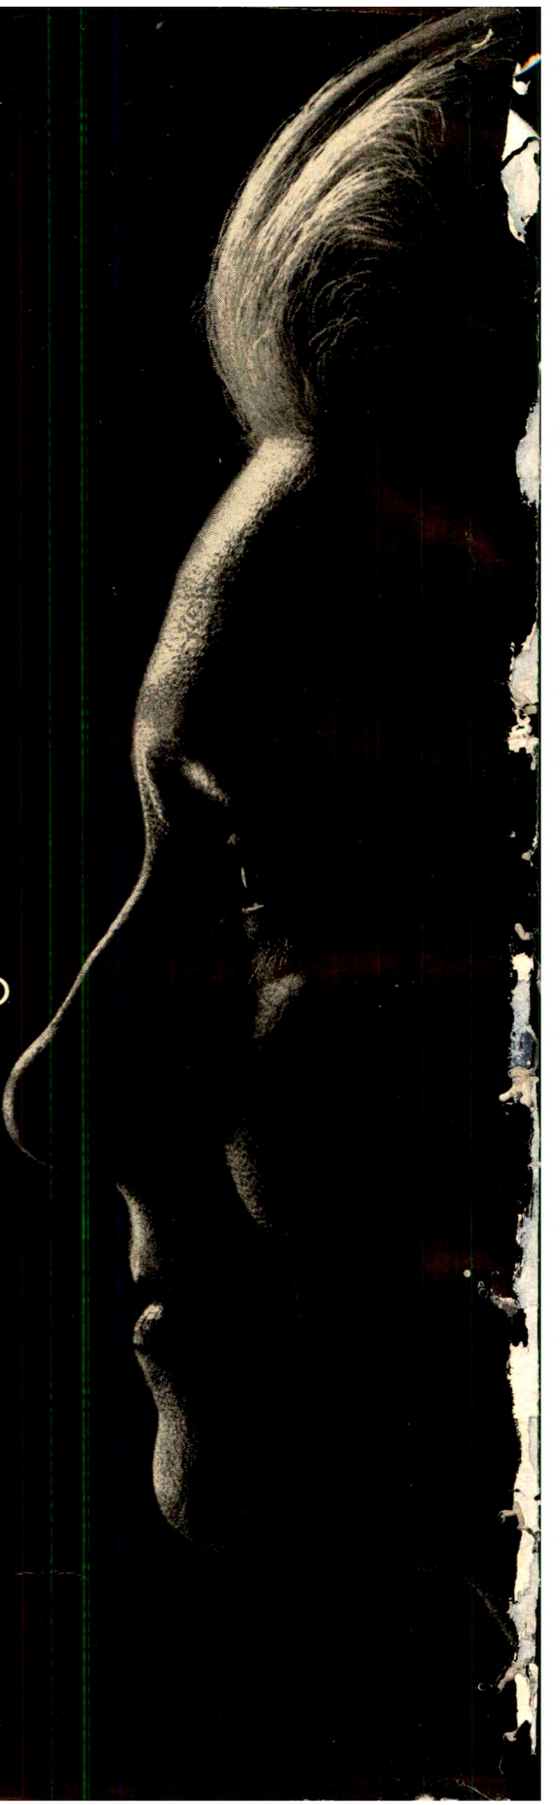
VOLUME 72 NUMBER 1 JULY, 1971

Cur-HQ1639-2:P024393

# AMERICAN JOURNAL OF OPHTHALMOLOGY



THIRD SERIES FOUNDED BY EDWARD JACKSON

The extraocular muscle ..... *Goodwin M. Breinin* 1
Cover test limitations ..... *Paul E. Romano and Gunter K. von Noorden* 10
Pathogenesis of retinal dysplasia ..... *Arthur M. Silverstein, Bennie I. Osburn, and Robert A. Prendergast* 13
Experimental retinal dysplasia ..... *Arthur M. Silverstein, Charles J. Parshall, Jr., Bennie I. Osburn, and Robert A. Prendergast* 22
Ischemia after scleral buckling ..... *Stephen J. Ryan and Morton F. Goldberg* 35
Catgut in detachment surgery ..... *A. Dellaporta and R. Yukins* 51
Segmental retinal periarteritis ..... *Nicola Orzalesi and Luigi Ricciardi* 55
Electroretinogram wavelets ... *Yutaka Tsuchida, Kazuo Kawasaki, and Jerry H. Jacobson* 60
Ocular pigmentation ..... *Harrout E. Melikian, Theodore W. Lieberman, and Irving H. Leopold* 70
Systemic vasodilators ..... *José D. Peczon, W. Morton Grant, and Brent W. Lambert* 74
Pressure and optic nerve transection ..... *Steven M. Podos, Theodore Krupin, and Bernard Becker* 79
Corneal hemochromatosis ..... *Alberto Urrets-Zavalia, Jr., and Celia Katz* 88
Spontaneous congenital iris cyst ..... *Frederick H. Roy and Calvin Hanna* 97
Keratoplasty in Fuchs' dystrophy ..... *Max Fine and Carole E. West* 109
Wound dehiscence ..... *Stuart I. Brown and Michael P. Tragakis* 115
Tonometry following keratoplasty ..... *Chiel A. Wind and Herbert E. Kaufman* 117
Corneal graft reaction ..... *Atsushi Kanai and Frank M. Polack* 119
New pachymeter ..... *Hernando Cardona and A. Gerard DeVoe* 127
Calcific deposition in uremia ..... *Laurence S. Harris, Kenneth Cohn, Hidenao Toyofuku, Edmund Lonergan, and Miles A. Galin* 130
Cryotherapy in keratitis ..... *Peter D'Alena, Masao Okumoto, and Brooks Crawford* 134
Tear film thinning ..... *James E. McDonald and Stephen Brubaker* 139
Corneal lymphatic drainage ..... *Gilbert Smolin and Robert A. Hyndiuk* 147
Spectacle glass injuries ..... *Arthur H. Keeney and Bert R. Estlow* 152
Eye injuries in Nigeria ..... *Oyin Olurin* 159
Atypical mycobacteria and uveitis ..... *Janet C. Weber, T. F. Schlaegel, Jr., and John S. Chapman* 167
Diagnosis of cryptococcal uveitis ..... *Michael H. Grieco, Dennis B. Freilich, and Donald B. Louria* 171
Ocular toxin of pneumococcus ..... *Mary K. Johnson and James H. Allen* 175
Angular conjunctivitis ..... *O. P. van Bijsterveld* 181
Ocular nematodiasis ..... *Robert C. Tudor and Edwin Blair* 185
Orbital exenteration ..... *J. Earl Rathbun, Crowell Beard, and Marvin H. Quickert* 191
Ultrasonic dacryocystorhinostomy ..... *M. M. Krasnov* 200
Median cleft syndrome ... *William C. Edwards, Wallace Askew, and Bernard Weisskopf* 202

*Table of Contents pages 3 and 4*

# SUBJECT INDEX

## VOLUME 72, JULY-DECEMBER, 1971

## ORIGINAL ARTICLES, AND NOTES, CASES, INSTRUMENTS

**Note:** Abstract Index follows Author Index

A

Achromatopsia in genetic isolate, 746
Amaurosis, congenital, of retinal origin, 724
Amblyopia, tropical, in Nigerians, 708
Aneurysm of ophthalmic artery with drusen of optic nerve head, 743
Aqueous outflow, resistance to, 445

B

Blepharoptosis, blepharophimosis, epicanthus inversus, and telecanthus, 625
  traumatic, surgical treatment of, 691
BOOK REVIEWS:
  Babel, Jean; Bischoff, Albert; and Spoendlin, Heinrich: Ultrastructure of the peripheral nervous system and sense organs. Atlas of normal and pathologic anatomy, 660
  Bach-Y-Rita, Paul; Collins, Carter, C.; and Hyde, Jane E.: The control of eye movements, 1019
  Bergsma, Daniel (ed.): The second conference on the clinical delineation of birth defects. Part VIII. Eye, 1020
  Bier, Norman: Correction of subnormal vision, 1020
  Bishop, Virginia E.: Teaching the visually limited child, 1020
  Brindley, G. S.: Physiology of the retina and visual pathway, 2nd ed., 495
  Bronson, Nathaniel R., II, and Paton, R. Townley: Advances in keratoplasty, 840
  Conant, Norman F.; Smith, David Tillerson; Baker, Roger Denio; and Callaway, Jasper Lamar: Manual of clinical mycology, 1160
  Daton, John G.: Markets for the medical author, 1162
  Fells, Peter (ed.): The first congress of the international strabismological association, 841
  Goodman, Louis S., and Gilman, Alfred: The pharmacological basis of therapeutics, 4th ed., 498
  Grayson, Merrill, and Keates, Richard H.: Manual of diseases of the cornea, 494
  Guillaumat, L.; Paufique, L.; and De Saint-Martin, R.: Traitment chirugical des affections oculaires, 1161
  Harrington, David O.: The visual fields. A textbook and atlas of clinical perimetry, 1158
  Hill, George J., II: Leprosy in five young men, 497
  Irinoda, Kimiho: Colour atlas and criteria of fundus changes in hypertension, 839
  Jensen, H. E.: Stereoscopic atlas of clinical ophthalmology of domestic animals, 840
  Kolker, Allan E., and Hetherington, John, Jr.: Becker-Shaffer's diagnosis and therapy of the glaucomas, 3rd ed., 499
  Lang, J.: Strabismus-Diagnostik-Schielformen Therapie, 1159
  Martenet, A. Catherine: Virus et uveites, 1020
  Martin-Doyle, J. L. C.: A symposia of ophthalmology, 1161
  Members of the departments of neurology, physiology, and biophysics of the Mayo Clinic: Clinical examinations in neurology, 839
  Miller, James N. (ed.): Spirochetes in body fluids and tissues, 1161
  Moreau, P. J.; Haut, J.; Alfieri, R.; Brihaye, M.; Payray, P.; Pouliquen, Y.; Simatos, D.; and Sole, P.: Cryophthalmolgie, 494
  Motokawa, K.: Physiology of color and pattern vision, 498
  Radnót, Magda: Famous Hungarian ophthalmologists, 497
  Shaffer, Robert N., and Weiss, Daniel I.: Congenital and pediatric glaucomas, 497
  Sterling, T. D.; Bering, E. A., Jr.; Pollack, S. B.; and Vaughn, H. G., Jr.: Visual prosthesis—The interdisciplinary dialogue, 495
BOOK REVIEWS *(Continued)*
  Stocker, Frederick W.: The endothelium of the cornea and its clinical implications, 1018
  Storz, Johannez: Chlamydia and chlamydia-induced diseases, 215
  Trevor-Roper, Patrick: The world through blunted sight, 493
  Turner, Paul: Clinical aspects of autonomic pharmacology, 499
Buckling procedure, suture for segmental, 51

C

Calcific deposits, conjunctival and corneal, in uremic patients, 130
Carcinoid syndrome with bilateral orbital metastasis, 1118
CATARACT extraction, integrity and position of anterior hyaloid membrane following, 390
  in Smith-Lemli-Opitz syndrome, 955
  keratome blade, disposable, in, 1012
  with iridogoniodysgenesis, 949
Cholinesterase isoenzymes in ocular tissue homogenates, 460
Choroidal atrophies, classification of, 562
  melanoma, and rhegmatogenous retinal detachment, 351
Ciliary body, bilateral inflammatory pseudotumors in, 586
  epithelium border layers, aging changes of, and significance in intraocular pressure, 1079
  melanoma, 592
Coloboma of iris, heterochromia associated with, 827
  of optic disk, intrascleral smooth muscle in, 452
Conjunctival and corneal calcific deposits in uremic patients, 130
Conjunctivitis, ligneous, histology of, 909
  moraxella angular, bacterial proteases in, 181
Conjunctivo-dacryocystorhinostomy, technique for, 931
CONTACT LENS, bionite hydrophilic, as cosmetic devices, 527
  hydrophilic, in management of corneal problems, 521
  hydrophilic, therapeutic evaluation of, 532
  migration of, blepharoptosis as a complication of, 536
CORNEA, and conjunctiva, calcific deposits in, 130
  clouding, normal intellect and mucopolysaccharidosis, disorders related to, 1106
  dystrophy, 88
  epithelium, microcystic dystrophy of, 381
  graft, penetrating keratoplasty in, (Suppl.) 205 (See erratum, xiii)
  grafts, ultramicroscopic alterations in corneal epithelium, 119
  hemochromatosis, with dystrophy involving anterior stroma and both limiting membranes, 88
  homograft rejection and uveitis, thickness during, 383
  inflammation, isolation of stromal collagenase in, 1139
  laceration, trephine for primary transplant in repair of, 1147
  opacity, congenital, central (Peter's anomaly), 801
  permeability, influence of various agents on, 897
  thickness during homograft rejection, 383
  ulcer, sequelae of cyanoacrylate therapy of perforated, 538
  vascularized, lymphatic drainage from, 147
CORRESPONDENCE:
  Aphakic detachment, 1157
  Blow-out fractures, 837
  Eye pad flammability, 660
  Gonioscopic evaluation of the narrow angle, 492
  Jaw-winking blepharoptosis, 216
  Metastatic endophthalmitis, 838
  Protective moist dressing, 1018
  Reply to Dr. Becker, 492
  Transpupillary cyclophotocoagulation, 660

CORRESPONDENCE (*Continued*)
Treatment of anterior chamber obliteration after surgery, 493
Cover test, limitations of, in strabismus, 10
Cryopreservation, incorporation of radioactive sulphate by corneal stroma during, 906
Cryotherapy of stromal herpes simplex keratitis, 134
Cyanoacrylate adhesive therapy of perforated corneal ulcer, sequelae of, 538
Cyst, giant, of pars plana, 481

D

Dacryocystorhinostomy, external, modified technique, 679
Degeneration, posterior polymorphous, histopathology of, 879
Depression biomicroscopy, results of, in posterior chamber, 1073
Dermatophytosis affecting periorbital region, 934
Descemet's membrane, acquired autosensitivity to degenerating, 782
Diabetic retinopathy, photocoagulation in, 299
Double occluder, modification of, 1146
Drusen of optic nerve head with aneurysm of ophthalmic artery, 743
Duality concept, structure and function of extraocular muscle, 1
Dysplasia, retinal, experimental, virus-induced, 22
retinal, pathogenesis of, 13
DYSTROPHY, corneal, 88
endothelial, pathogenesis of congenital hereditary corneal, 787
Fuchs' corneal, epithelial changes in, 542
Fuchs', late results of keratoplasty in, 109
Reis-Bücklers, ultrastructure of, 549

E

Ectropion, tarsal, correction of, 615
EDITORIALS:
A memento, 1157
Herpes simplex corneae—Its centennial of recognition, 212
The cause of the Argyll Robertson pupil, 488
The International Eye Foundation, 657
The need for standards in tests of vision, 836
The section is dead. Long live the section council, 656
The semicentenary of insulin, 1155
The 1971 Academy, 1015
Electrocautery puncture of trabecular meshwork in enucleated eyes, 1094
Electroretinogram, positive and negative deflections in responses, 367
rhythmic wavelets in, 60
Endophthalmitis, late, after filering surgery, 1097
Serratia marcescens, 1102
Enucleated eyes, electrocautery puncture of trabecular meshwork in, 1094
Epicanthus procedure, 1144
Epithelium, changes, in Fuchs' corneal dystrophy, 542
corneal, microcystic dystrophy of, 381
Exenteration, orbital, 191
Exophthalmos and posterior frontocele with fibrous wall, 701
Eyelid, paradoxical elevation of, on smiling, 207

F

Fiber optics coagulator for macular holes, 1143
Filtering surgery, late endophthalmitis after, 1097
Fluorescein, intravenous, reactions following, 861
Foreign body, metallic, removal of, from tear duct, 483
Frontocele, posterior, and exophthalmos, 701
Fuchs' dystrophy, late results of keratoplasty in, 109

G

Glaucoma, absolute, with pigment dispersion phenomena and contusion angle deformity, 420
atypical band keratopathy in, 917
systemic vasodilators, intraocular pressure, and chamber depth in, 74
Gnathostoma spinigerum, cause of ocular nematodiasis, 185
Goldenhar's syndrome and phocomelia, 618

H

Hemangiomatosis, diffuse congenital, 633
Hemochromatosis with corneal dystrophy, 88
Hemodialysis, intraocular pressure changes during, 926
Herpes simplex infection, chronic, long-term topical poly I:C in, 821
keratitis, stromal, cryotherapy of, 134
Herpes zoster ophthalmicus in absence of immunoglobulin A and deficiency of delayed hypersensitivity, 555
Heterochromia associated with iris coloboma, 827
Horner's syndrome, adrenergic mydriasis in, 472
Human evoked response, localization of, early components specific to visual stimulation, 988
Hyphema, delayed spontaneous, following sclerotomy, 458
Hypersensitivity, deficiency of delayed, in viral ophthalmicus, 555
Hypertension, intracranial, and tetracycline therapy, 981

I

Immunoglobulin A, absence of, 555
E in tear drops, 558
Instrument carrying case, surgical, 827
INTRAOCULAR PRESSURE changes during hemodialysis, 926
drug effects on, 773
pigmentation, and outflow response to drug therapy, 70
response to optic nerve transection, 79
significance of aging changes in ciliary epithelium border layers, 1079
systemic vasodilators, chamber depth, in glaucoma, 74
Iridectomies, laser, 393
Iridogoniodysgenesis with cataract, 949
Iris and ciliary body, catecholamine metabolite formation in, 939
coloboma, heterochromia associated with, 827
hemangioma and abnormal retinal vasculature in diffuse congenital hemangiomatosis, 633
cyst, spontaneous congenital, 97

K

Kepler, Johannes, 869
KERATITIS, granulomatous, after cyanoacrylate adhesive therapy of perforated corneal ulcer, 538
interstitial, testing for congenital syphilis in, 816
Nocardia asteroides, 813
stromal, herpes simplex, cryotherapy in, 134
Keratome blade, disposable, in cataract surgery, 1012
Keratopathy, atypical band, in glaucoma, 917
bullous, bandage lenses in, 376
KERATOPLASTY for aphakic bullous keratopathy, corneal histopathology following, 888
late results of, in Fuchs' dystrophy, 109
penetrating, in corneal graft, (Suppl.) 205 (See erratum, xiii)
penetrating, validity of MacKay-Marg applanation tonometry following, 117
wound dehiscence with, complication of the continuous-suture technique, 115

L

Lacrimal canaliculus repair, French-eye pigtail probe for, 1145
Landolt rings and Sloan letter in adult visual acuity screening, 983
Laser iridectomies, 393
Lens and zonular fibers, scanning electron microscopy, of, 604
Lens, pseudo-exfoliation of, among Navajos, 206
L-epinephrine, early effects of single and repeated doses, 1058
Leukemia, chronic myelocytic, peripheral retinal neovascularization in, 975
Lignocaine, and other drugs, effects on intraocular pressure, 773
Lincomycin levels in ocular fluids and serum, 464
Lymphatic drainage from vascularized cornea, 147

M

Macular holes, fiber optics coagulator for, 1143
Median cleft face syndrome, 202
MEETINGS, CONFERENCES, AND SYMPOSIA:
American Ophthalmological Society Meeting—1971, 485

MEETINGS, CONFERENCES, AND SYMPOSIA *(Continued)*:
Association for Research in Vision and Ophthalmology Spring Meeting, 211
Bascom Palmer Eye Institute seventh annual residents' day, 1153
Combined meeting of the European Ophthalmic Pathology Society and the Verhoeff Society, 486
Fifth annual meeting of the Horacio Ferrer Eye Institute International Symposium on Ocular Motility, 830
The Iowa Eye Association, 647
Japanese Medical Association, 834
Kresge Eye Institute Alumni 1971 Clinic Day Program, 653
Lens symposium at Utrecht, 1149
New York Medical College Ophthalmology Seminar, 833
Ninety-first Congress of the Ophthalmological Society of the United Kingdom, 209
Second conference of International Society of Geographical Ophthalmology and Jerusalem Seminar, 1150
Society of Eye Surgeons meeting, 832
University of Toronto annual research meeting, 648
Melanoma, choroidal, and retinal detachment, 351
ciliary body, 592
conjunctival malignant, originating in acquired melanosis sine pigmento, 595
malignant, corneal, in African, 796
Mental retardation, technique for visual appraisal of children with, 622
Muscle, extraocular, duality concept in structure and function of, 1
intrascleral smooth, in coloboma of optic disk, 452
Mydriasis, adrenergic, in Horner's syndrome, 472
Myotonic dystrophy, pigmentary retinopathy of, 720

N

Needle with wire loop for drawing sutures through tissues, 1012
Nematodiasis, ocular, Gnathostoma spinigerum as cause of, 185
Neovascularization, peripheral, in chronic leukemia, 975
NEWS ITEMS: 227, 519, 677, 859, 1035, 1174
Norrie's disease, congenital progressive oculo-acousticocerebral degeneration in, 947
Nystagmus, periodic alternating, 757

O

OBITUARIES:
Archimede Busacca, 215
Clarence H. Graham, 1018
Everett Logan Goar, 214
William A. Mann, 489
Occlusion of central retinal vessels, pathogenesis in, 998
Ocular field defects, peripheral nasal, 415
Oculo-acoustico-cerebral degeneration, congenital, progressive, in Norrie's disease, 947
Ophthalmia, sympathetic, and lymphocyte transformation, 960
Ophthalmitis, sympathetic, 967
Operating microscope, modified ceiling-mounted zoom, 972
Optic disk, intrascleral smooth muscle in coloboma of, 452
Optic nerve, evulsion of, 969
pathophysiology of distal portion of, 435
transection, mechanism of intraocular pressure response in, 79
Orbital exenteration, 191
floor fractures, complications of, 699

P

Pachymeter for measuring corneal thickness, 127
Paresis, oculosympathetic, associated with cluster headaches, 763
Pars plana, giant cyst of, 481
Periarteritis, retinal, 55
Peter's anomaly (corneal opacity, congenital, central), histopathology of, 801
Photocoagulation in diabetic retinopathy, 299
Pigmentation, ocular, pressure and outflow responses to pilocarpine and epinephrine, 70
Pilocarpine, effect of ocular pigmentation on hypotensive response to, 923
Pneumococcus, ocular toxin of, 175
Poikiloderma, congenital, retinal changes in, 981
Poly I:C, long-term, in chronic viral infection, 821
Posterior chamber, results of depression biomicroscopy in, 1073
Prilocaine as local ophthalmic surgery anesthetic, 468
Propranolol and other drugs, effects on intraocular pressure, 773
Pseudotumors, bilateral inflammatory, in ciliary body, 586
Pupillary membrane, hyperplastic persistent, 717

R

Refsum's syndrome, 342
Reis-Bücklers' dystrophy, ultrastructure of, 549
RETINA, albinotic spots, peripheral, 729
detachment, experimental, photoreceptor protein renewal in early reattachment, 356
detachment, rhegmatogenous, and choroidal melanoma, 351
detachment secondary to vitreous loss at cataract surgery, 705
detachment, surgical catgut for segmental buckle 51
dysplasia, experimental, virus-induced, 22
dysplasia, pathogenesis in, 13
hemorrhages, pale centered, association with intracranial bleeding in infancy, 348
periarteritis, 55
Retinitis pigmentosa, inverse, deafness, and hypogenitalism, 332
Retinopathy, diabetic, photocoagulation in, 299
Retrolental fibroplasia, ophthalmoscopic monitoring of oxygen therapy in, 322

S

Saccadic velocities in infants and children, 1130
Scleral depressor as marker in retinal detachment surgery, 1013
Sclerostomy, guarded thermal, 769
Sclerotomy, delayed spontaneous hyphema following, 458
Scopolamine with physostigmine salicylate, reversal of toxic effects of, 1136
Serratia marcescens endophthalmitis, 1102
Sickle cell hemoglobinopathy, anterior segment ischemia, 35
Sloan letter and Landolt rings in vision screening, 983
Smith-Lemli-Opitz syndrome, cataracts in, 955
Spectacle glass injuries, 152
Sphenoid fissure syndrome, orbital venography in, 600
Strabismus, limitations of cover test in, 10
Stromal collagenase in corneal inflammation, isolation of, 1139
Surgery system, ophthalmic, at Jules Stein Eye Institute, 403
Surgical light, 645
Sutures, for segmental buckling, 51
needle with wire loop for, 1012
wound dehiscence after technique of continuous, 115

T

Tear duct, removal of metallic, foreign body from, 483
film, immunoglobulin E in, 558
film, meniscus-induced thinning of, 139
Terato-neuroma (Verhoeff's), reappraisal of, 1039
Tetracycline and intracranial hypertension, 981
Tomography, axial, diagnostic, of optic canals in children's eye and optic nerve defects, 1122
Tonometry, MacKay-Marg, validity of, following penetrating keratoplasty, 117
Toxoplasma gondii toxin, effects of, 733
Trauma, eye, in Nigerians, 159
Tritiated digoxin, localization of, 608

U

Uveitis, atypical microbacteria in, 167
cryptococcal, diagnosis of, with hypertonic media, 171

V

Venography, orbital, in sphenoid fissure syndrome, 600
Verhoeff's "terato-neuroma," reappraisal of, 1039
Vision, testing in mentally retarded children, 622
Visual evoked response, human, localization of, 988

W

Wound dehiscence after continuous suture technique, 115

# ABSTRACT INDEX

A

Abducens palsy, bilateral traumatic, 668
Acetazolamide therapy, aplastic anemia as complication of, 507
Adrenergic neurone and receptor activity in iris of neonate, 856
Aging, ocular changes in man, 503
Agnosia, associative visual, 847
Alcohol, effects on nystagmus, 226
Amaurotic idiocy, ultrastructural studies in, 1172
Angiokeratoma corporis diffusum, ocular findings in, 1925
Aniridia, hamartoma, and Wilm's tumor, simultaneous occurrence of, 667
Anophthalmia, congenital and surgical, 1169
Anterior chamber, biometry of normal, 662
  sagittal growth from birth to puberty, 1026
Antibody-producing cells, corneal and conjunctival, 222
Aphakia, flat anterior chamber and choroidal detachment in, 665
  unilateral, hydrophilic contact lenses in children with, 854
AQUEOS HUMOR, concentration after oral tetracycline, 512
  dynamics, 1029
  dynamics and pilocarpine therapy, 1167
  effect of mydriatics and miotics on out-flow resistance, 668
  formation in primate, effect of changes in arterial blood pressure on, 514
  insulin in, in man, 220
Argon laser, multiline, 505
Asteroid hyalopathy, experimental, 850
  vascular factors in, 1167
Ataxia, myoclonic, syndrome of dancing eyes in, 1020
Atrophy, dominant juvenile, 217

B

Bacteria on eyelashes, 1022
Behçet's disease, 844
  electroretinography in, 854
Beta-radiation therapy, long-term complications, 1033
Blepharoptosis, jaw-winking, surgical treatment of, 1034
  minimal, levator resection for, 1170
  therapeutic rationale, 1170
Blepharospasm, resection of facial nerve for, 1165
Blindness, causes of, in mentally defective children, 222
  cortical, and cerebellar ataxia, 506
  cortical, transient, 513
Bloch-Sulz-Berger syndrome with ocular involvement, familial incidence of, 672
Brainstem tumors, internuclear ophthalmoplegia with, 513
Bruch's membrane, holes in, 504

detachment surgery, intolerance to silicone sponges in, 661
detachment, treatment of, 1022
hemorrhages in newborn infants, 850
ischemia, effect of hyperbaric oxygenation on, 1171
outer limiting membrane of, 661
periphlebitis, photocoagulation in, 1030
photocoagulation using Goldmann contact lens, 1164
photography in premature infants, 1173
surgical reattachment of, 671
tears, 1031
tears, giant, treatment by intraocular air tamponade, 668
thermal effect generated by photocoagulation, 846
vascular obstructions, 1026
vasculitis of marginal zone, 662
Retinitis pigmentosa, cerebellar ataxia, skeletal abnormalities, familial nephropathy associated with, 844
light deprivation for early, 847
punctata albescens, fluorescein angiographic findings in, 669
Retinoblastoma, cause of radioresistance in, 517
chromosomal analysis of, 843
epidemiologic characteristics, 851
lactic dehydrogenase activity of aqueous humor in, 666
Retinopathy, central serous, electroretinography in, 667
diabetic, prevention of, 663
ischemic, due to carbon monoxide poisoning, 1165
proliferative sickle, treatment of, 848
Retrolental fibroplasia, oxygen studies in, 218
Rubella, congenital, high frequency of diabetes mellitus in young adults with, 1173
embryopathy, 669
Rubeosis iridis in diabetic patients, frequency of, 1027

S

Schiøtz tonometer, care of, 669
Schistosomiasis, ocular, experimental 666
Schlemm's canal, pores of trabecular wall of, 667
Sclera, peripheral iridectomy with cauterization of, 671
rupture of, after electrocoagulation of, 503
Sclerosing panencephalitis, subacute, 1165
Silverman's battered child syndrome, 501
Stevens-Johnson Syndrome, Lyell's disease, and exfoliative dermatitis, 674
STRABISMUS, comitant, dystrophic lesions of horizontal recti in, 846
examination of children for, 516
optimal age for surgery in, 856
treatment of, by slanting muscle insertions, 1168
Superior eyelid sulcus, correction of with subperiosteal implants, 218
Superior oblique tendon sheath syndrome, 849
Supraclinoid carotid artery, aneurysm, of, 225
Surgical adhesives, experience with, 1031
Sutures, comparison of tensile strength of glue and, 662

T

Tay-Sachs disease, 513
Thermography and ophthalmology, 518
Tonography during treatment with local dexamethasone, 671
Trauma, air-blast, ocular changes following, 1164
burns, 1170
Tritanopia, congenital, hereditary dominant, 1028
Tumors, lymphatic, of eye and adnexa, 670

Tumors *(Continued)*
metastatic choroidal, effect of radiation therapy on, 675
orbital region, 1169

U

Ultrasound echography in retinal detachment surgery, 672
Unnecessary mistakes, 224
Upward gaze, restriction in with advancing age, 1033
Uveitis, endogenous, mediastinoscopy with lymph node biopsy, 1023
retrobulbar, administration of corticosteroids in, 505

V

Ventriculography, bilateral homonymous hemianopsia following, 1025
Visual acuity of national sample, 1028
field, extent of accommodation phosphene, 856
Vitrectomy, pars plana approach, 1032

W-X-Y-Z

Wegener's granuloma, marginal corneal ulcer as presenting manifestation of, 675
Wegener's granulomatosis, pseudotumor of, 226

## ERRATUM

The legends for five illustrations in color in "The Corneal Graft," by Thomas E. Moore, Jr., M.D., and Samuel B. Aronson, M.D., which appeared in a special supplement in July, 1971 (72:205, 1971) were incorrect. Readers may wish to clip the correct labels reprinted below and paste them on the appropriate pages.

Page 219:

Fig. 9 (Moore and Aronson). Postoperative morphologic classification. (A) Absent host neovascularization following keratoplasty in keratoconus. (B) Mild host neovascularization following grafting in aphakic bullous keratoplasty. Note superficial vessels in the host cornea at four and 10 o'clock positions. (C) Moderate host neovascularization following grafting in herpes simplex keratitis (3+). Note superficial and deep vessels throughout the host cornea. (D) Moderate host neovascularization following graft for alkali keratitis. Note sequential distribution of neovascularization.

Fig. 11 (Moore and Aronson). Surgery-induced inflammation (early graft reaction). (A) Patient 5, preoperatively demonstrates a large central descemetocele below a partially retracted flap. (B) Postoperative endophthalmitis (photograph taken eight weeks following surgery). (C) Histology of ciliary body demonstrates a low-grade cyclitis. (D) Histology of posterior eye shows perivascular cellular cuffing of a retinal vessel with minimal-to-absent vitreous involvement.

Page 226:

Fig. 10 (Moore and Aronson). A-B. Primary donor failure (early graft reaction). (A) Patient 1, histology of donor cornea demonstrating endothelial stripping (×40). (B) Same patient, demonstrating sub- and intraepithelial edema. C-H. Surgery-induced early graft reaction. (C) Patient 2, graft failure following wound dehiscence, pictured 10 weeks after surgery. (D) Same patient four months after subsequent keratoplasty. (E) Patient 3, descemetocele following wound dehiscence at the time of suture removal. (F) Same patient, demonstrating a subsequently clear graft six months postoperatively. (G) Patient 4, demonstrating wound dehiscence following cutting of the continuous nylon suture (three weeks postoperation). (H) Same patient at six months after surgery with a clear graft. Note the area of inferior scarring.

Page 229:

Fig. 12 (Moore and Aronson). Suture toxicity (early graft reaction). (A) Patient 6 demonstrates early failure as a result of silk suture toxicity six weeks following surgery. (B) Same patient with subsequent keratoplasty in which 10-0 Ethilon suture was used, demonstrating a clear graft 10 weeks after surgery. (C) Patient 7 demonstrates early graft failure secondary to silk suture toxicity 12 weeks after surgery. (D) same patient demonstrating a clean graft one year after surgery. 10-0 Ethilon suture was used. (E) Patient 8 at four weeks postsurgery demonstrates reaction to 8-0 silk suture, with no reaction to nylon suture. (F) Another patient with penetrating keratoplasty demonstrates reaction to 9-0 virgin silk with relative lack of reaction to nylon. (G) Another patient with keratoconus in whom continuous nylon suture was used. Suture tracts are free of infiltrate. (H) Same patient (higher magnification), demonstrating the lack of infiltrate.

Page 236:

Fig. 13 (Moore and Aronson). A-F. Microbial toxicity (early graft reaction). G-H. Tissue incompatibility (early graft reaction). (A) Patient 9, demonstrating severe pseudomonas infection. (B) Same patient following inflammatory inactivation with combined corticosteroid Polysporin therapy. (C) Same patient four days after surgery, demonstrating a pseudomonas, suture-tract abscess following penetrating keratoplasty. (D) Same patient 12 weeks after surgery, demonstrating a clear graft. Note area of corneal scarring in the eight o'clock meridian. (E) Patient 10, three weeks postsurgery, demonstrating inflammatory infiltrate and neovascularization around interrupted sutures. The continuous suture is free of reaction. (F) Same patient one week after removal of interrupted suture. Note involution of conjunctival neovascularization. (G) Patient 11, demonstrating graft failure seven months after surgery. (H) Same patient (high magnification). Note that many superficial and deep vessels enter the donor cornea between suture tracts.

The JOURNAL regrets these errors.

**One drop of Isopto® Carbachol 3% keeps IOP down for 8 hours.** Administer it at bedtime and control IOP through the early morning hours—without the side effects of the more potent cholinesterase inhibitor. Consider Isopto Carbachol, also, for extended IOP control *during the day*, in cases where the patient no longer responds to pilocarpine.

One recent study* in glaucoma patients showed Isopto Carbachol 3% effective for a full 8 hours. A single instillation of the solution was administered in one eye; the fellow eye served as a control. IOP in the treated eye was still significantly lower than the control at 8 hours. Use it for assured all night glaucoma control.

**Variation in IOP after instillation of a single dose of Carbachol 3%**

An increase in the log value corresponds to a drug induced fall in IOP

| | | | |
|---|---|---|---|
| Mean Log | Baseline outflow pressure treated eye | X | Outflow pressure control eye at same time after instillation as treated eye. |
| | Baseline outflow pressure control | X | Outflow pressure treated eye at same time after instillation as control eye. |

*Drance, S.M. and Flindall, R. J.; Canad. J. of Ophth. *1*:#4:292-296, Oct. 1966

**Contraindicated** in presence of corneal abrasion or when constriction is undesirable, as in acute iritis. **Precaution & Side Effects:** Avoid overdose. Transient ciliary and conjunctival injection, headache and ciliary spasm with resultant temporary decrease of visual acuity may occur. Systemic symptoms of cholinesterase inhibitors may occur even when epithelium is intact. **Available:** Isopto Carbachol 0.75%, 1.5%, 2.25%, 3%. **Supplied** in 15cc and 30cc Drop-Tainer® Dispensers. Rx only.

**All Strengths now in Economy Packages—30cc.**

**STEREOSCOPE? MICROSCOPE? BOTH!**

The XONIX new* head-mounted MICROSCOPE gives superb Stereopsis (hence, STEREOSCOPE), fiber-optics illumination, an excellent working distance, better than average field of view, AND, it is portable and lightweight. A few specifications and applications are:

## *OPHTHALMOLOGICAL USES:*

All eye surgical procedures for both surgeon and assistant:

Glaucoma — filtering procedures, sinusotomy, trabeculotomy, goniotomy

Cataract extraction • Keratoplasty

Repair of anterior segment trauma, including lacerated cornea, foreign body removal, etc.

Iris surgery

Plastic procedures, including blowout fractures and orbital surgery where coaxial light is important

Retina • Strabismus • Suture removal

Gonioscopy • Funduscopy

Research surgery and general microscopic laboratory manipulations

Low vision aid

*The XONIX STEREOSCOPE was first introduced at the AAOO National Meeting in Las Vegas, October, 1970.

## *FEATURES:*

Head-mounted for freedom of movement and ease of focus

Coaxial fiber-optics illumination with variable light intensity

Large field: 28mm @ 6X magnification
18mm @ 12X magnification

Zoom magnification oculars 6X, 8X, 10X, 12X

Light weight — 13 oz. (without headband)

Comfortably worn for extended periods of time

Can be worn over glasses

Exceptional optical clarity and resolution

Working distance: 10″ from objective; 13″ from eye

Variable P.D. with lock setting — range 51 to 80mm

Superior depth of field and excellent stereopsis

Gaze below ocular gives unmagnified view

Completely adjustable rigid locking linkage

All magnesium construction

Priced for individual rather than institutional ownership

*XONIX'S PRODUCTS INCLUDE:*

• XONIX BINOCULAR INDIRECT OPHTHALMOSCOPE • XONIX PORTA-PAK • XONIX STEREOSCOPE

## TABLE OF CONTENTS

**COLOR PLATES**

Illustrating paper by Alberto Urrets-Zavalía, Jr., and Celia Katz ..... *facing pages 92 and 95*

**ORIGINAL ARTICLES**

The structure and function of extraocular muscle—An appraisal of the duality concept. Goodwin M. Breinin ..... 1
Limitations of cover test in detecting strabismus. Paul E. Romano and Gunter K. von Noorden 10
The pathogenesis of retinal dysplasia. Arthur M. Silverstein, Bennie I. Osburn, and Robert A. Prendergast ..... 13
An experimental, virus-induced retinal dysplasia in the fetal lamb. Arthur M. Silverstein, Charles J. Parshall, Jr., Bennie I. Osburn, and Robert A. Prendergast ..... 22
Anterior segment ischemia following scleral buckling in sickle cell hemoglobinopathy. Stephen J. Ryan and Morton F. Goldberg ..... 35
Surgical catgut for segmental buckle in retinal detachment. A. Dellaporta and R. Yukins .... 51
Segmental retinal periarteritis. Nicola Orzalesi and Luigi Ricciardi ..... 55
Rhythmic wavelets of the positive off effect in the human electroretinogram. Yutaka Tsuchida, Kazuo Kawasaki, and Jerry H. Jacobson ..... 60
Ocular pigmentation and pressure and outflow responses to pilocarpine and epinephrine. Harrout E. Melikian, Theodore W. Lieberman, and Irving H. Leopold ..... 70
Systemic vasodilators, intraocular pressure, and chamber depth in glaucoma. José D. Peczon, W. Morton Grant, and Brent W. Lambert ..... 74
Mechanism of intraocular pressure response after optic nerve transection. Steven M. Podos, Theodore Krupin, and Bernard Becker ..... 79
Corneal hemochromatosis. A unique type of corneal dystrophy involving the anterior stroma and both limiting membranes. Alberto Urrets-Zavalía, Jr., and Celia Katz ..... 88
Spontaneous congenital iris cyst. Frederick H. Roy and Calvin Hanna ..... 97
Late results of keratoplasty for Fuchs' dystrophy. Max Fine and Carole E. West ..... 109
Wound dehiscence with keratoplasty: Complication of the continuous-suture technique. Stuart I. Brown and Michael P. Tragakis ..... 115
Validity of MacKay-Marg applanation tonometry following penetrating keratoplasty in man. Chiel A. Wind and Herbert E. Kaufman ..... 117
Ultramicroscopic alterations in corneal epithelium in corneal grafts. Atsushi Kanai and Frank M. Polack ..... 119
New pachymeter to measure corneal thickness. Hernando Cardona and A. Gerard DeVoe .... 127
Conjunctival and corneal calcific deposits in uremic patients. Laurence S. Harris, Kenneth Cohn, Hidenao Toyofuku, Edmund Lonergan, and Miles A. Galin ..... 130
Cryotherapy of stromal herpes simplex keratitis in rabbits. Peter D'Alena, Masao Okumoto, and Brooks Crawford ..... 134
Meniscus-induced thinning of tear films. James E. McDonald and Stephen Brubaker ..... 139
Lymphatic drainage from vascularized rabbit cornea. Gilbert Smolin and Robert A. Hyndiuk . 147
Spectacle glass injuries to the eye. Arthur H. Keeney and Bert R. Estlow ..... 152
Eye injuries in Nigeria. A review of 433 cases. Oyin Olurin ..... 159
Atypical mycobacteria and uveitis. Janet C. Weber, T. F. Schlaegel, Jr., and John S. Chapman 167
Diagnosis of cryptococcal uveitis with hypertonic media. Michael H. Grieco, Dennis B. Freilich, and Donald B. Louria ..... 171
Ocular toxin of the pneumococcus. Mary K. Johnson and James H. Allen ..... 175
Bacterial proteases in moraxella angular conjunctivitis. O. P. van Bijsterveld ..... 181

## General

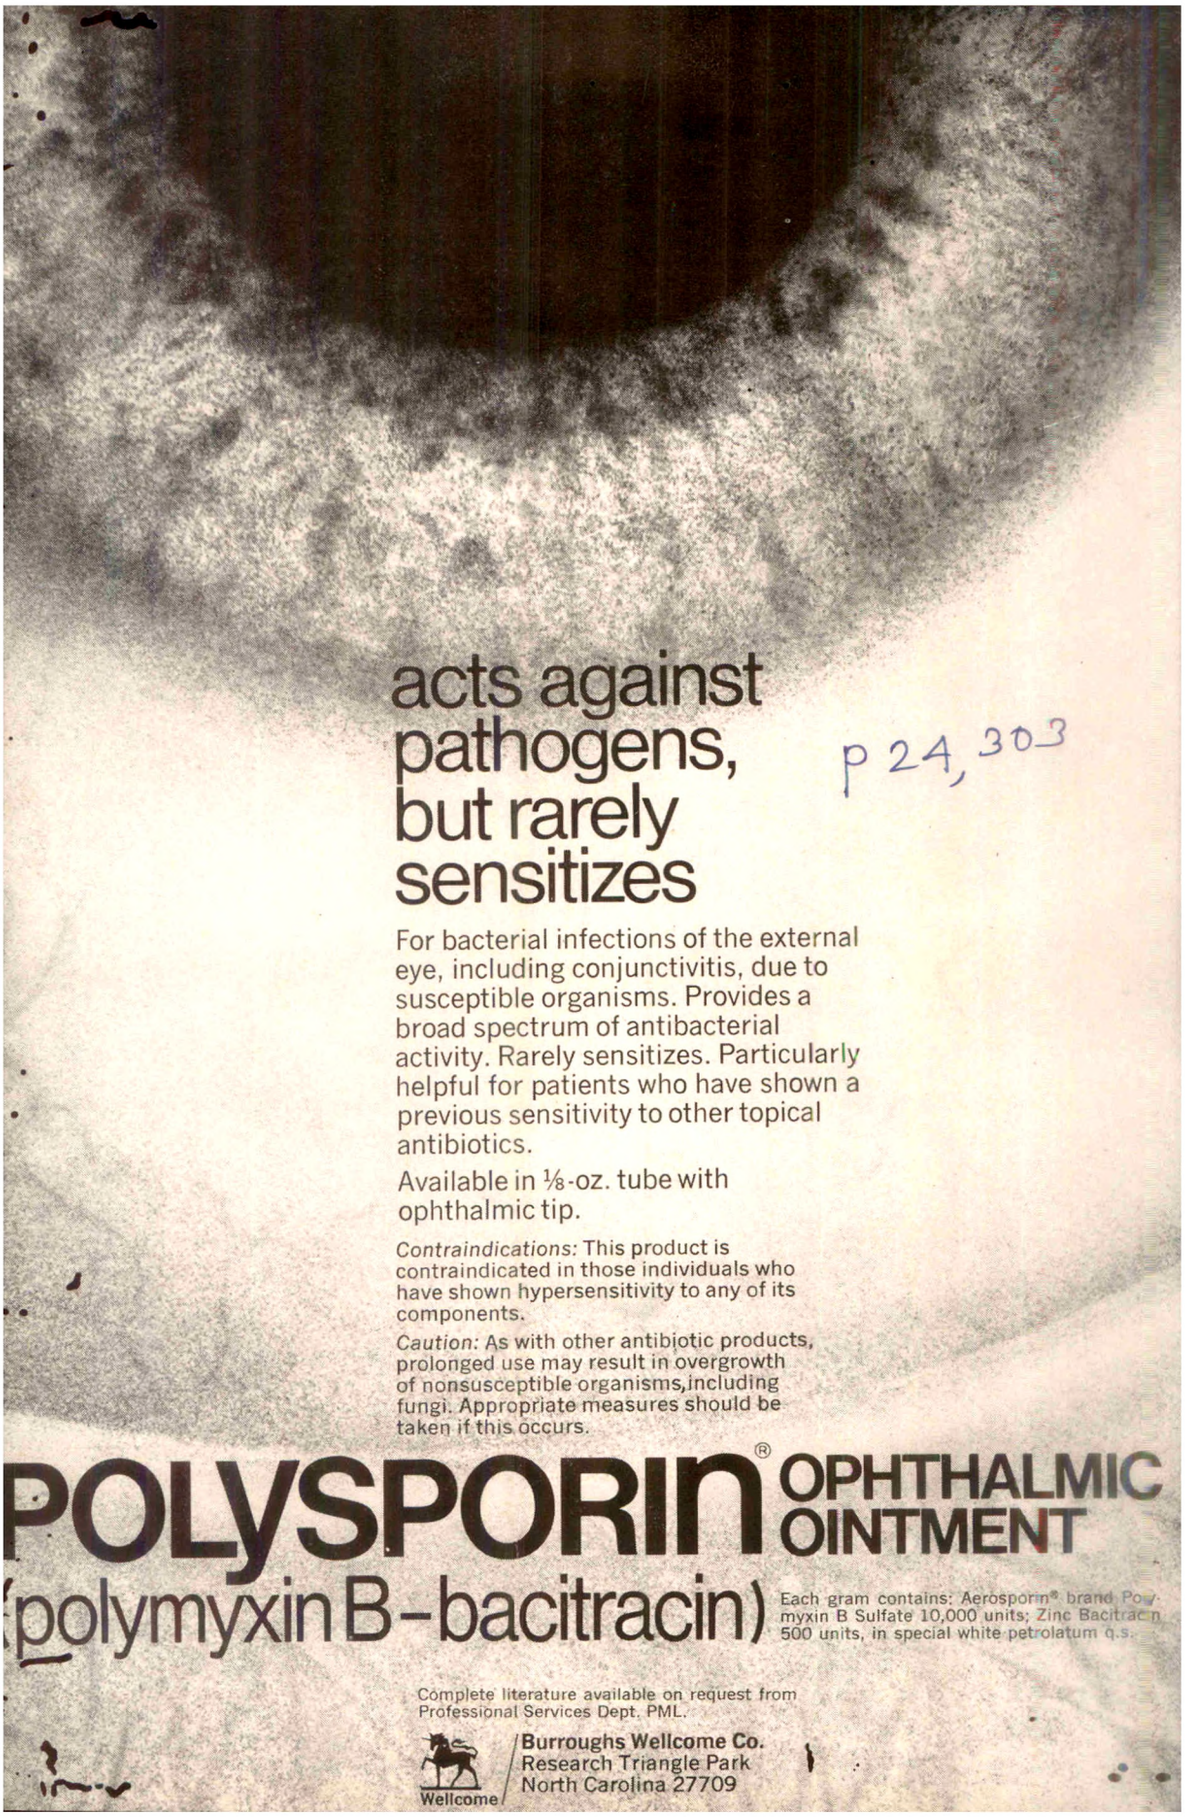
Address manuscripts and other scientific communications to Frank W. Newell, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Manuscripts must be original material submitted solely to the American Journal of Ophthalmology. Two original typed copies must be submitted. The entire manuscript, including case reports, footnotes and references, must be typed in double space, with wide margins, on 8½ by 11-inch heavy white bond paper. See Suggestions to Authors (Am. J. Ophth. 70: Advertising pages 85–88, December, 1970).

Author's proofs must be corrected and returned with 48 hours to Manuscript Editor, 160 East Grand Avenue, Chicago, Illinois 60611.

Fifty reprints of each article will be supplied to the senior author without charge. Additional reprints may be obtained from Ophthalmic Publishing Company, 160 East Grand Avenue, Chicago, Illinois 60611, if ordered at the time proofs are returned.

Address news items and society proceedings to Thomas Chalkley, M.D., 700 North Michigan Avenue, Chicago, Illinois 60611.



Exchange copies of medical journals should be sent to David Shoch, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Subscriptions, requests for single issues, notices of changes of addresses, advertising, and other communications should be sent to 160 East Grand Avenue, Chicago, Illinois 60611.

Change of address notices must be received at least 60 days in advance and must include both old and new addresses.

Claims for copies lost in the mail must be received within 60 days from the date of issue.

Advertisement insertion orders and copy must be received before the first day of the preceding month for which the advertisement is scheduled.

# acts against pathogens, but rarely sensitizes

p 24,303

For bacterial infections of the external eye, including conjunctivitis, due to susceptible organisms. Provides a broad spectrum of antibacterial activity. Rarely sensitizes. Particularly helpful for patients who have shown a previous sensitivity to other topical antibiotics.

Available in ⅛-oz. tube with ophthalmic tip.

*Contraindications:* This product is contraindicated in those individuals who have shown hypersensitivity to any of its components.

*Caution:* As with other antibiotic products, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

## POLYSPORIN® OPHTHALMIC OINTMENT

(polymyxin B–bacitracin)

Each gram contains: Aerosporin® brand Polymyxin B Sulfate 10,000 units; Zinc Bacitracin 500 units, in special white petrolatum q.s.

Complete literature available on request from Professional Services Dept. PML.

# you can't protect your patient's contact lenses once they're out of your office.

# RLI can!

And we can do it simply, with no paperwork for you. Complete loss and damage protection for your patient's lenses, 24 hours a day, and there are no exclusions for any sports activities or occupations.

Coverage is always renewable. No premium increases, cancellations or additional charges because of excessive claims. One premium for all types of lenses, including bifocals and spare pairs.

Plus an 80% effective recall system (optional) for you—and we do all the paperwork and mailing of notices for you.

A smooth, no involvement program that not only protects lenses, but as a by-product protects the success of your own lens wearing patients.

Your questions are RLI's favorite subject—contact us, any time.

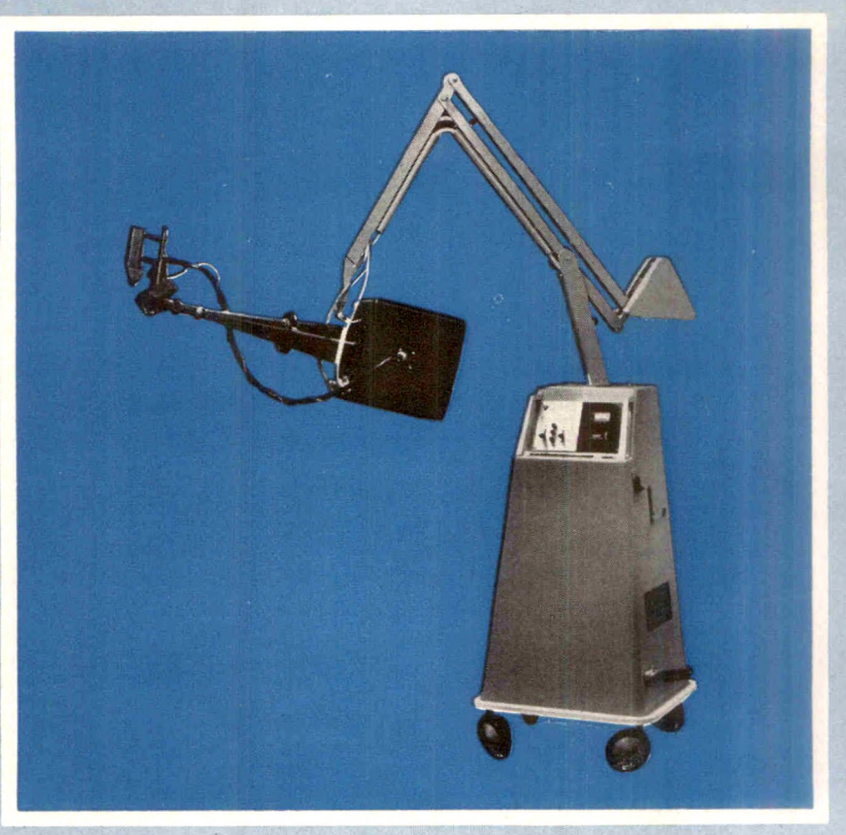
# LIGHT COAGULATOR MF 1000

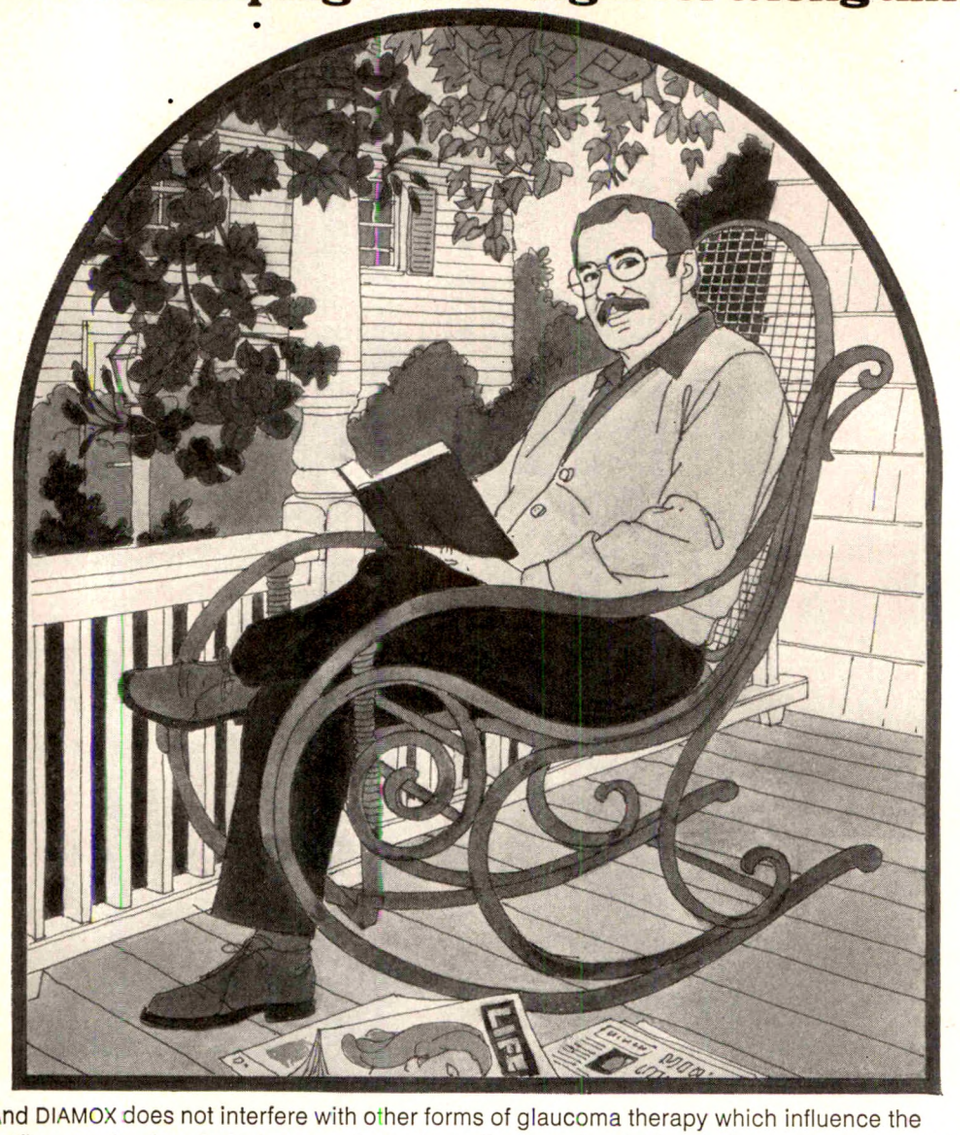
■ The **Light Coagulator MF 1000** is the result of modern techniques. It has been **clinically tested** for the past several years.



■ Viewing of the fundus is possible with either a **Direct or Indirect Ophthalmoscope.**

■ One surgeon can operate and move the instrument. The light source and optical system, suspended from a balanced, fully articulated arm, afford **fingertip manipulation to any position.**

■ The Xenon Arc Lamp is driven by a reliable and **compact solid state power supply.**



■ The Light Coagulator MF 1000 is useful in the treatment of **retinal detachment, retinal and choroidal tumors, abnormal retinal blood vessels and aphakic pupils** too small for adequate fundus examination.

■ The heat energy provided by the light beam is easily adjusted and can reach **very high levels extremely valuable** when treating **retinal or choroidal tumors** and when extremely small burns are desirable.

MEDICAL INSTRUMENT RESEARCH ASSOCIATES, INC.
150 Causeway Street, Boston, Mass. 02114 / Tel. 523-5031

# It's been helping to save sight for a long time

And DIAMOX does not interfere with other forms of glaucoma therapy which influence the outflow mechanism. In fact, a complementary effect may be obtained when DIAMOX is used in conjunction with miotics.

Treatment with DIAMOX may retard progress of glaucoma by reducing secretion of aqueous humor and thus intraocular pressure. With DIAMOX SEQUELS, acetazolamide is slowly released, and concentrations peak at 8 to 12 hours. A single dose may provide a therapeutic effect for as long as 18 to 24 hours. It is thus possible to maintain the inhibitory effect on aqueous humor formation with a twice-daily regimen . . . an important consideration for the patient's rest and for minimization of side effects.

**DIAMOX®**
ACETAZOLAMIDE
**SEQUELS®** 500 mg
Sustained Release Capsules

**Contraindications**—Situations in which sodium and/or potassium serum levels are depressed, in kidney and liver disease or dysfunction, suprarenal gland failure and hyperchloremic acidosis. Long-term administration is contraindicated in chronic noncongestive angle closure glaucoma.

**Warning**—Although teratogenic and embryocidal effects demonstrated in mice at more than ten times the equivalent therapeutic doses have not been evidenced in humans, DIAMOX Acetazolamide should not be used in pregnancy, especially during the first trimester, unless the expected benefits outweigh these potential adverse effects.

**Precautions**—Increasing the dose may increase drowsiness and paresthesia and decrease diuresis. Reactions common to sulfonamides may occur: fever, rash, crystalluria, renal calculus, bone marrow depression, thrombocytopenic purpura, hemolytic anemia, leukopenia, pancytopenia, agranulocytosis. If such occur, discontinue drug and institute appropriate therapy.

**Side Effects**—During short-term therapy: paresthesias, loss of appetite, polyuria, drowsiness, confusion. In long-term therapy an acidotic state may supervene. Transient myopia has been reported. Other occasional reactions: urticaria, melena, hematuria, glycosuria, hepatic insufficiency, flaccid paralysis, convulsions.

# Cryophake®

...sterile, disposable cryoextractor. Developed by R. David Sudarsky, M.D.

## minimizes complications in cataract surgery

Actual Size

Experience has shown that the incidence of capsule rupture and vitreous loss is considerably lower when the lens is removed by cryoextraction rather than with forceps or erisiphake.

**Cryophake® offers all these additional important benefits...**

- accidental ahesions easily freed without loosening bond on lens
- instantly ready for use
- small, fits the hand comfortably
- designed with a small tip, gives good visibility
- light in weight, easily maneuverable
- pre-sterilized, less chance of infection
- inexpensive

Available only from Alcon Surgical Products Division

Ask for Cryophake® at your hospital.

Surgical Products Division, Alcon Laboratories, Inc.

Nancy's classmates won't call her names now...

## and her accommodative esotropia no longer affects her grades

Over two years ago, Nancy showed an esophoria of 6 △ at distance and an intermittent esotropia of 15 △ at near, with imperfect fusion. She was put on PHOSPHOLINE IODIDE 0.125% O.U., at first once a day. This dosage regimen was reduced gradually to once a week. Orthoptic measures were employed to increase binocular control. Nancy now has an esophoria of 12 △ at near, no tropia, and excellent stereopsis. Fusion is still variable for near. Vision is 20/20 in each eye. She no longer requires eyedrops.*

## for diagnosis

One drop of PHOSPHOLINE IODIDE 0.125% instilled in both eyes for two or three weeks can help determine if there is an accommodative basis for the esotropia.

## in treatment

If there is a significant accommodative factor present, the continued use of PHOSPHOLINE IODIDE alone is often sufficient for treatment.

If surgery is necessary, postoperative use of PHOSPHOLINE IODIDE may help correct a residual deviation.

*Case history courtesy of Orthoptic Clinic, Department of Ophthalmology, N.Y.U. Medical Center, N.Y. School of Medicine, New York, N.Y. Other children are professional models.

**BRIEF SUMMARY**
**(For full prescribing information, see package circular.)**

**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, browache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local):* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have also been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic):* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

in the management of accommodative esotropia

# Phospholine Iodide®

(echothiophate iodide for ophthalmic solution)

Redness and burning can't be wiped out with a beach towel. Surfside eyes need Vasocon-A. Long-lasting vasoconstrictor-decongestant, antihistamine. Reduces conjunctival hyperemia in minor eye irritations and ocular allergies. Relieves burning and itching. Vasocon-A. Keeps eyes in the swim.

CAUTION: Federal law prohibits dispensing without prescription. See package insert before prescribing.

COMPOSITION: Naphazoline HCL, 0.05%; antazoline phosphate, 0.5%; boric acid, 1.2%; sodium carbonate anhydrous; sodium chloride; phenylmercuric acetate (preservative) 0.002%.

SIDE EFFECTS: Except for transitory stinging, side effects have rarely been encountered.

CONTRAINDICATIONS: Should not be used by patients with narrow angle glaucoma. If irritation persists or increases, patient should be advised to discontinue use and return to physician.

SUPPLIED: 15 cc plastic dropper-tip vials.

Smith, Miller & Patch, Inc.
New York, N.Y. 10010

**Vasocon-A®**

# CONTACT LENSES AND RESIDUAL ASTIGMATISM

## Part 2: Ultra-Thin & Astigmatic Lenses

When the practitioner anticipates a residual astigmatism of 1.00 diopter or more with the use of conventional spherical contact lenses, he should consider *ultra-thin lenses* instead as a means of reducing this error. The following rules (applying to minus lenses only) may enable him to determine in advance if there will be any visual advantage in ultra-thin lenses:

a. If the spectacle cylinder is *smaller* than the corneal cylinder, the residual astigmatism *will be reduced* with ultra-thin lenses, and they should be prescribed.

b. If the spectacle cylinder is *greater* than the corneal cylinder, the residual astigmatism will *not* be reduced, and may actually be increased with ultra-thin lenses.

c. If the corneas are *spherical,* the residual astigmatism *will not be affected* by the use of ultra-thin lenses.

A more complete discussion of these factors appears in my monograph "More About Small, Thin Contact Lenses: Visual Considerations". When it is found that ultra-thin lenses are visually contraindicated, or do not sufficiently reduce the residual astigmatism, we must turn to *astigmatic lenses:*

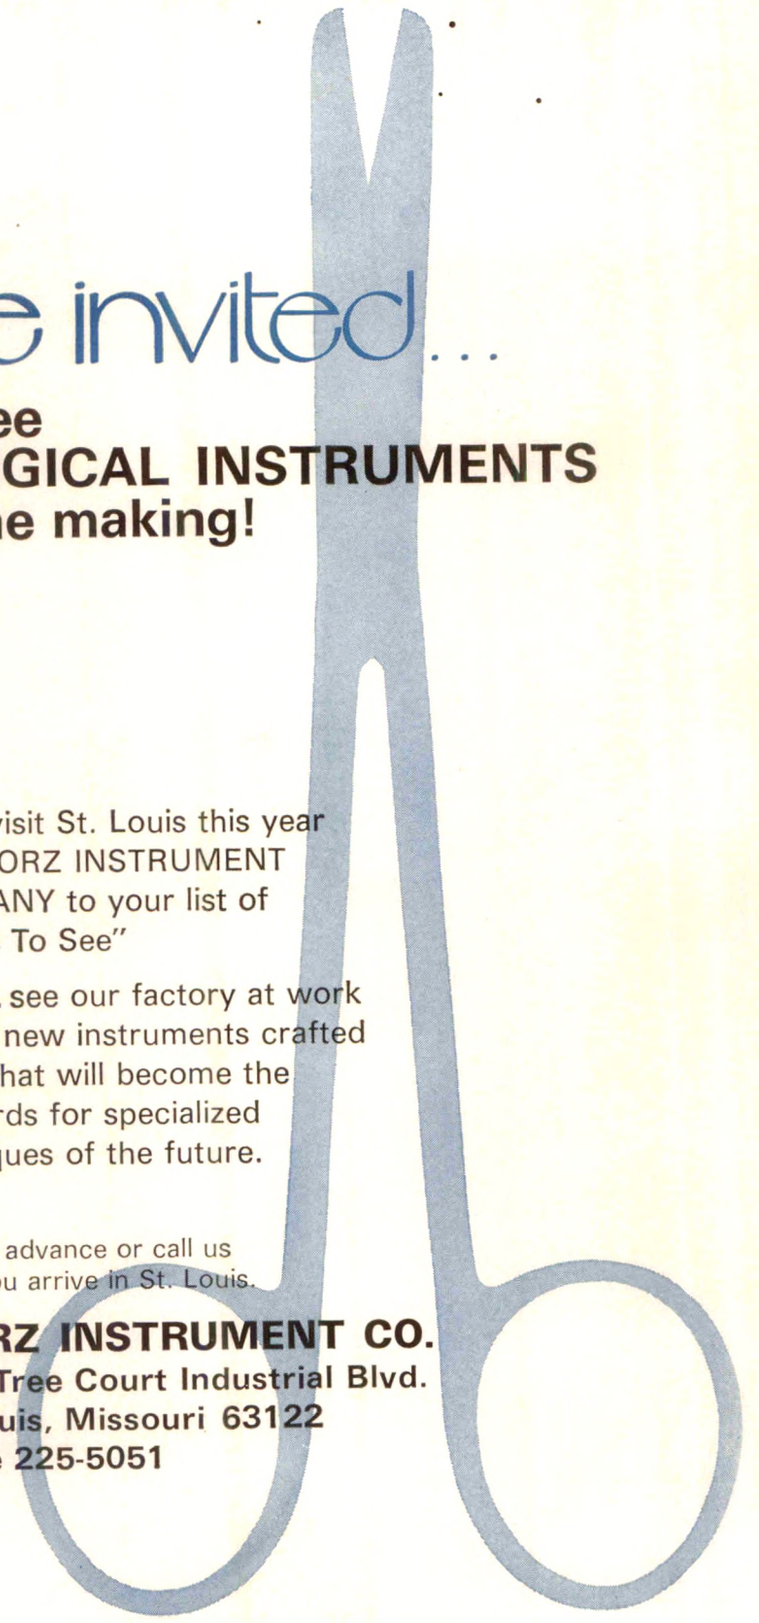
1. ASTIGMACON "O": Outside toric and inside spherical. This is the most frequently used type of astigmatic lens for correcting residual astigmatism, and has given the best results of all available types. To retard lens rotation, prism ballast is used, often in conjunction with lower truncation and with slight nasal decentration of the prism. Contraindications: (a) If patient has a low lower lid; (b) If the corneal cylinder exceeds 2.00 diopters 'with the rule' or 1.00 diopter 'against the rule'.

2. ASTIGMACON "B": Inside toric and outside spherical. This type of lens seldom corrects residual astigmatism and often results in a greater residual error, which is induced by the inside cylinder. The exceptions are those cases where the *spectacle cylinder* is greater than the *corneal cylinder.* To prevent rotation, the inside cylinder must be at least 1.50 diopters, preferably more. Prism ballast gives further stability, but is seldom needed when the inside cylinder is greater than 2.00 diopters.

3. ASTIGMACON "C": Bitoric (inside toric and outside toric). Prescribed in most cases where the Astigmacon "O" type is contraindicated. The physical fit and the conditions for prescribing these lenses are the same as for the Astigmacon "B" lenses. The outside cylinder required to give best vision is the sum of the residual astigmatic error found with a conventional spherical contact lens and the residual astigmatism induced by the inside cylinder.

The practitioner should not hesitate to call upon his laboratory for technical assistance in making the best possible lens selection.

STANLEY GORDON, *President*



P.S. *If I can be of assistance to you with your problem cases, please write to my personal attention.*

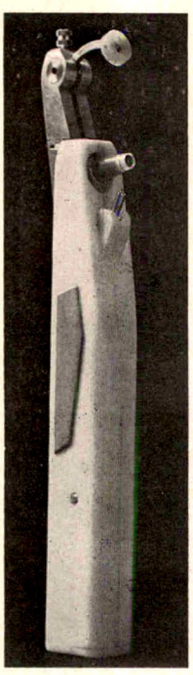
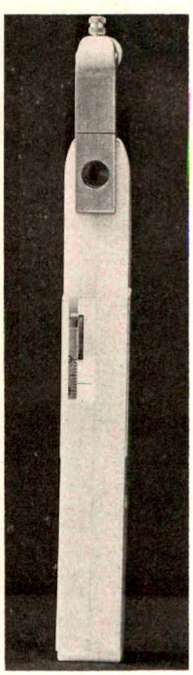
# NEW DEVELOPMENTS . . .





## ORA SERRATA ATTACHMENT TO THE GOLDMANN 3 MIRROR LENS

The periphery of the fundus near the ora serrata and the ciliary body cannot be examined under normal conditions with the 3-mirror lens alone. The ora serrata attachment along with the 3-mirror lens allows the observation of these most peripheral parts in its entire circumference.

The attachment is shaped like the 3-mirror lens. Half a steel-ball is fixed to the scleral part of the attachment which presses on the sclera above the ora serrata so that the fundus at its periphery near the ora serrata can be seen in the gonio mirror of the 3-mirror lens. The ora attachment can be used either with the 3-mirror lens in a locked or moveable position.

Most ophthalmic solutions start out sterile. But the OCUMETER® helps this one stay that way.
OCUMETER helps steroid solution stay sterile by eliminating a major cause of contamination —the eye dropper. Sterile, highly stable
Ophthalmic Solution
DECADRON®
Phosphate
(Dexamethasone Sodium Phosphate|MSD)
for mild acute iritis and conjunctivitis
For prescribing information, please see next page.

# for mild acute iritis and conjunctivitis

Not all steroid ophthalmic solutions stay sterile during the days and weeks of therapy. But this one is more apt to—Ophthalmic Solution DECADRON Phosphate (Dexamethasone Sodium Phosphate, MSD) in the OCUMETER® eliminates a common source of contamination—the eye dropper.

*Uniform dosage, drop after drop*

Each drop of Ophthalmic Solution DECADRON Phosphate contains the same dosage of steroid. And, with a gentle squeeze, the OCUMETER measures out one drop at a time. So your patient can conveniently get the steroid dose you want her to have, wherever she is.

Each cc. contains dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate. Also available as DECADRON® Phosphate Ophthalmic Ointment (0.05%); and as NeoDECADRON® Ophthalmic Solution containing dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base in each cc.; and NeoDECADRON® Ophthalmic Ointment, containing dexamethasone sodium phosphate equivalent to 0.5 mg. (0.05%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base per gram.

Sterile, highly stable
Ophthalmic Solution
**DECADRON®** Phosphate
(Dexamethasone Sodium
Phosphate|MSD)

CONTRAINDICATIONS: DECADRON and NeoDECADRON should not be used in the presence of infectious tuberculous lesions of the eye, chickenpox, early acute herpes simplex, vaccinia, the early acute stages of most viral diseases of the cornea and conjunctiva, acute purulent untreated infections of the conjunctiva and lids, suspected ocular or aural fungal infection, perforated ear drum. Sensitivity to components is also a contraindication.

PRECAUTIONS: DECADRON: Like all adrenal corticosteroids, may sometimes mask, activate, or enhance incipient infection. Whenever possibility of infection exists, suitable antibiotic agents or a steroid-antibiotic preparation (such as NeoDECADRON) should be considered. If infections do not respond promptly, therapy should be discontinued until the infection has been adequately controlled by other measures.

Systemic side effects may occur with extensive use of steroids. Rarely, ocular herpes simplex has been reported in patients receiving adrenocortical steroids systemically or locally in the eye for other conditions.

As with other corticosteroids, increased intraocular tension can follow extended local use (1-2 weeks or more) of dexamethasone sodium phosphate. Since increased intraocular tension can lead to loss of vision, this possibility should be kept in mind and topical administration used only under adequate tonometric supervision, particularly in patients known to have glaucoma, or whose family history includes glaucoma.

In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids. Reports in the literature indicate that, rarely, protracted use of topical corticosteroids in the eye may be associated with the development of posterior subcapsular cataracts. Hereditary and degenerative eye diseases in general do not show any response to treatment with these preparations.

Stubborn cases of anterior segment eye disease may require systemic adrenocortical hormone therapy. When the deeper ocular structures are involved, systemic therapy is necessary.

NeoDECADRON: A few individuals may be sensitive to one or more of the components of NeoDECADRON. If any reaction indicating sensitivity is observed, discontinue use. Sensitivity to neomycin may occasionally develop, especially when it is applied to abraded skin. Some reports in the current literature point to an increase in the number of persons sensitive to neomycin.

Use of any antibiotic agent may result in overgrowth of fungi or other organisms not susceptible to the antibiotic, necessitating prompt medical attention for such new infections.

As the safety of topical steroids during pregnancy has not been confirmed, they should not be used for extended periods during pregnancy.

# from the Nikon collection

The Nikon Aspherical Hand Lenses like all Nikon lenses are truly exceptional. Compared to other hand lenses, these two Nikon lenses give a broader, undistorted view, greater optical clarity, unusual image quality and have unequaled light gathering power. In fact, once an ophthalmologist uses one, he willingly pays more for this superior lens.

So that you may experience the uncommon qualities of a Nikon Aspheric Hand Lens first hand, we will send one to you, in either 14D or 20D magnification, on a two week trial basis. Once you experience its clear superiority, we feel sure you will be counted among the ranks of the Nikon Collectors. Call or write:

Nikon Instrument Division, Subsidiary of Ehrenreich Photo-Optical Industries, Inc. Garden City, New York. 11530 (In Canada: Anglophoto, Ltd., Ont.)

**Nikon Aspherical Ophthalmoscopic Lens**

**Composition:**

**Inflamase**

*Prednisolone Sodium Phosphate .....0.125%
(Equivalent to Prednisolone 0.1%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

**Inflamase Forte**

*Prednisolone Sodium Phosphate 1.0%
(Equivalent to Prednisolone 0.8%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

Prednisolone Sodium Phosphate is a water soluble inorganic ester of prednisolone. It is approximately 2,000 times as soluble in water at 25°C. as is hydrocortisone.

*Licensed under patent #3,134,718.

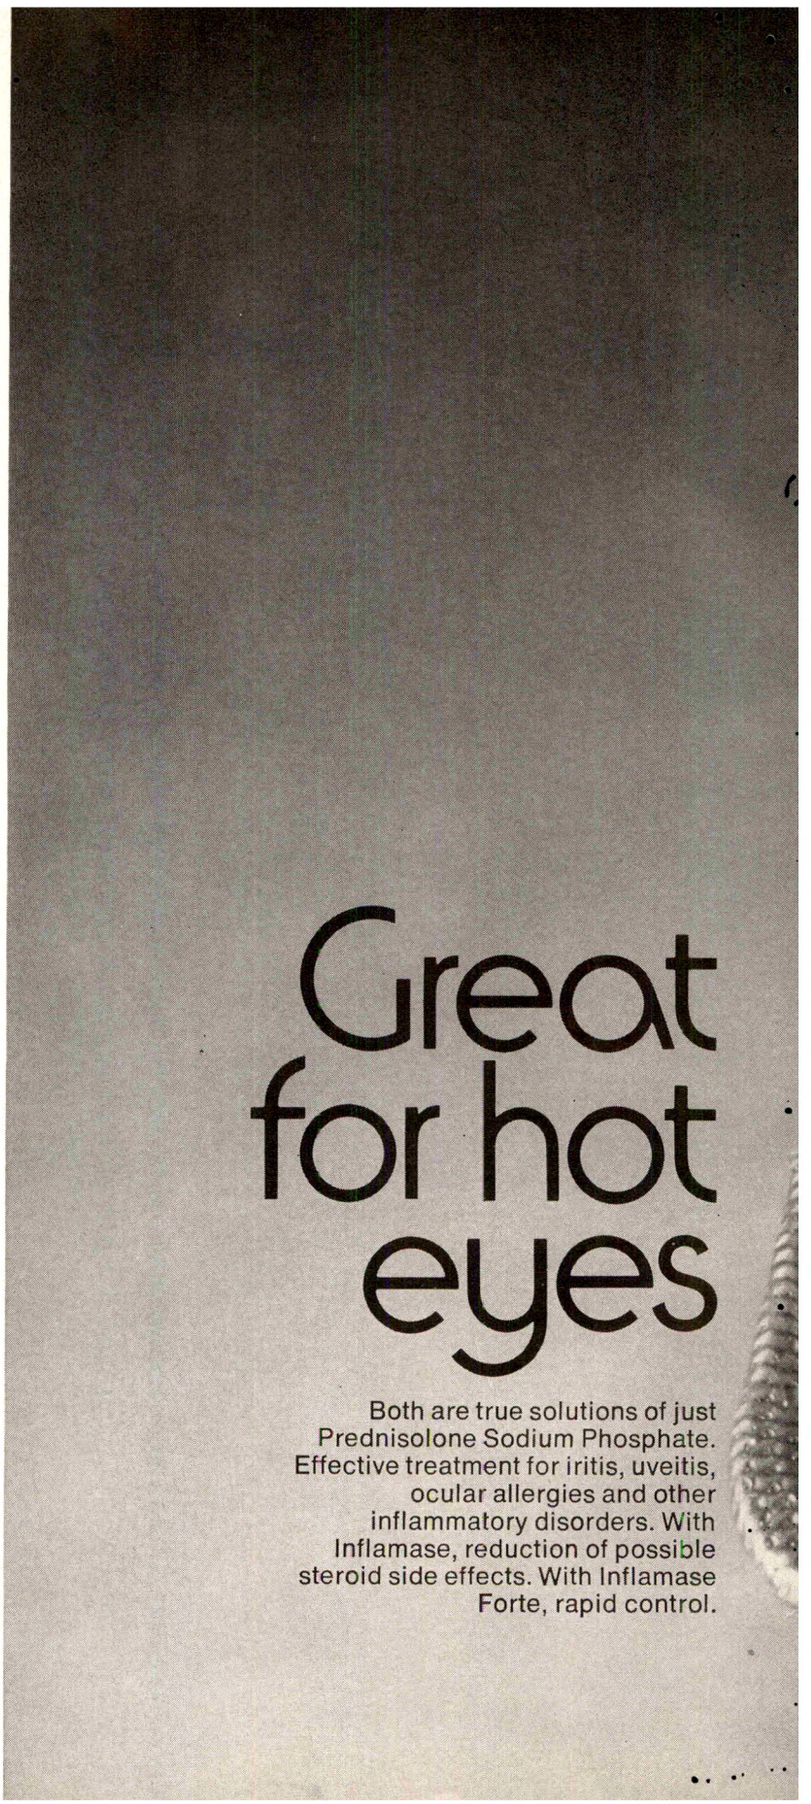
**Indications:** Inflamase and Inflamase Forte ophthalmic solutions may be used effectively in the following conditions of the anterior segment of the eye: superficial keratitis, including punctate epithelial lesions (Thygeson type), phlyctenular keratoconjunctivitis, and Sjogren's keratoconjunctivitis (with systemic steroids); deep keratitis, including interstitial or parenchymatous keratitis, acne rosacea, sclerosing keratitis; herpes zoster opthalmicus (do not use in herpes simplex); non-purulent conjunctivitis, including vernal, allergic, catarrhal; iridocyclitis; acute iritis; recurrent marginal ulceration, whether endogenous or due to atopic or contact allergies, or microbial allergy; corneal injuries, such as aseptic thermal, radiation, or chemical burns and corneal injuries following surgery or the penetration of foreign bodies; lid allergy; and non-purulent blepheritis, including catarrhal and allergic.

Inflamase and Inflamase Forte ophthalmic solutions have their principal effect on the anterior segment of the eye (cornea and the anterior uvea), with acute disorders responding more favorably than chronic disorders. Inflamase Forte 1% solution is recommended for moderate to severe inflammations particularly when rapid control is desired. In stubborn cases of anterior segment eye disease, systemic adrenocortical hormone therapy may be required. When the deeper ocular structures are involved, systemic therapy is necessary.

**Dosage:** Initially, 1 or 2 drops placed in conjunctival sac every hour during day and every 2 hours during night until improvement occurs. Thereafter, 1 or 2 drops 2 to 4 times daily.

**Contraindications:** Contraindicated in acute herpes simplex, ocular tuberculosis, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva; fungal diseases of the eye. Purulent conjunctivitis, purulent blepharitis, and infectious conditions are contraindications to the use of steroids.

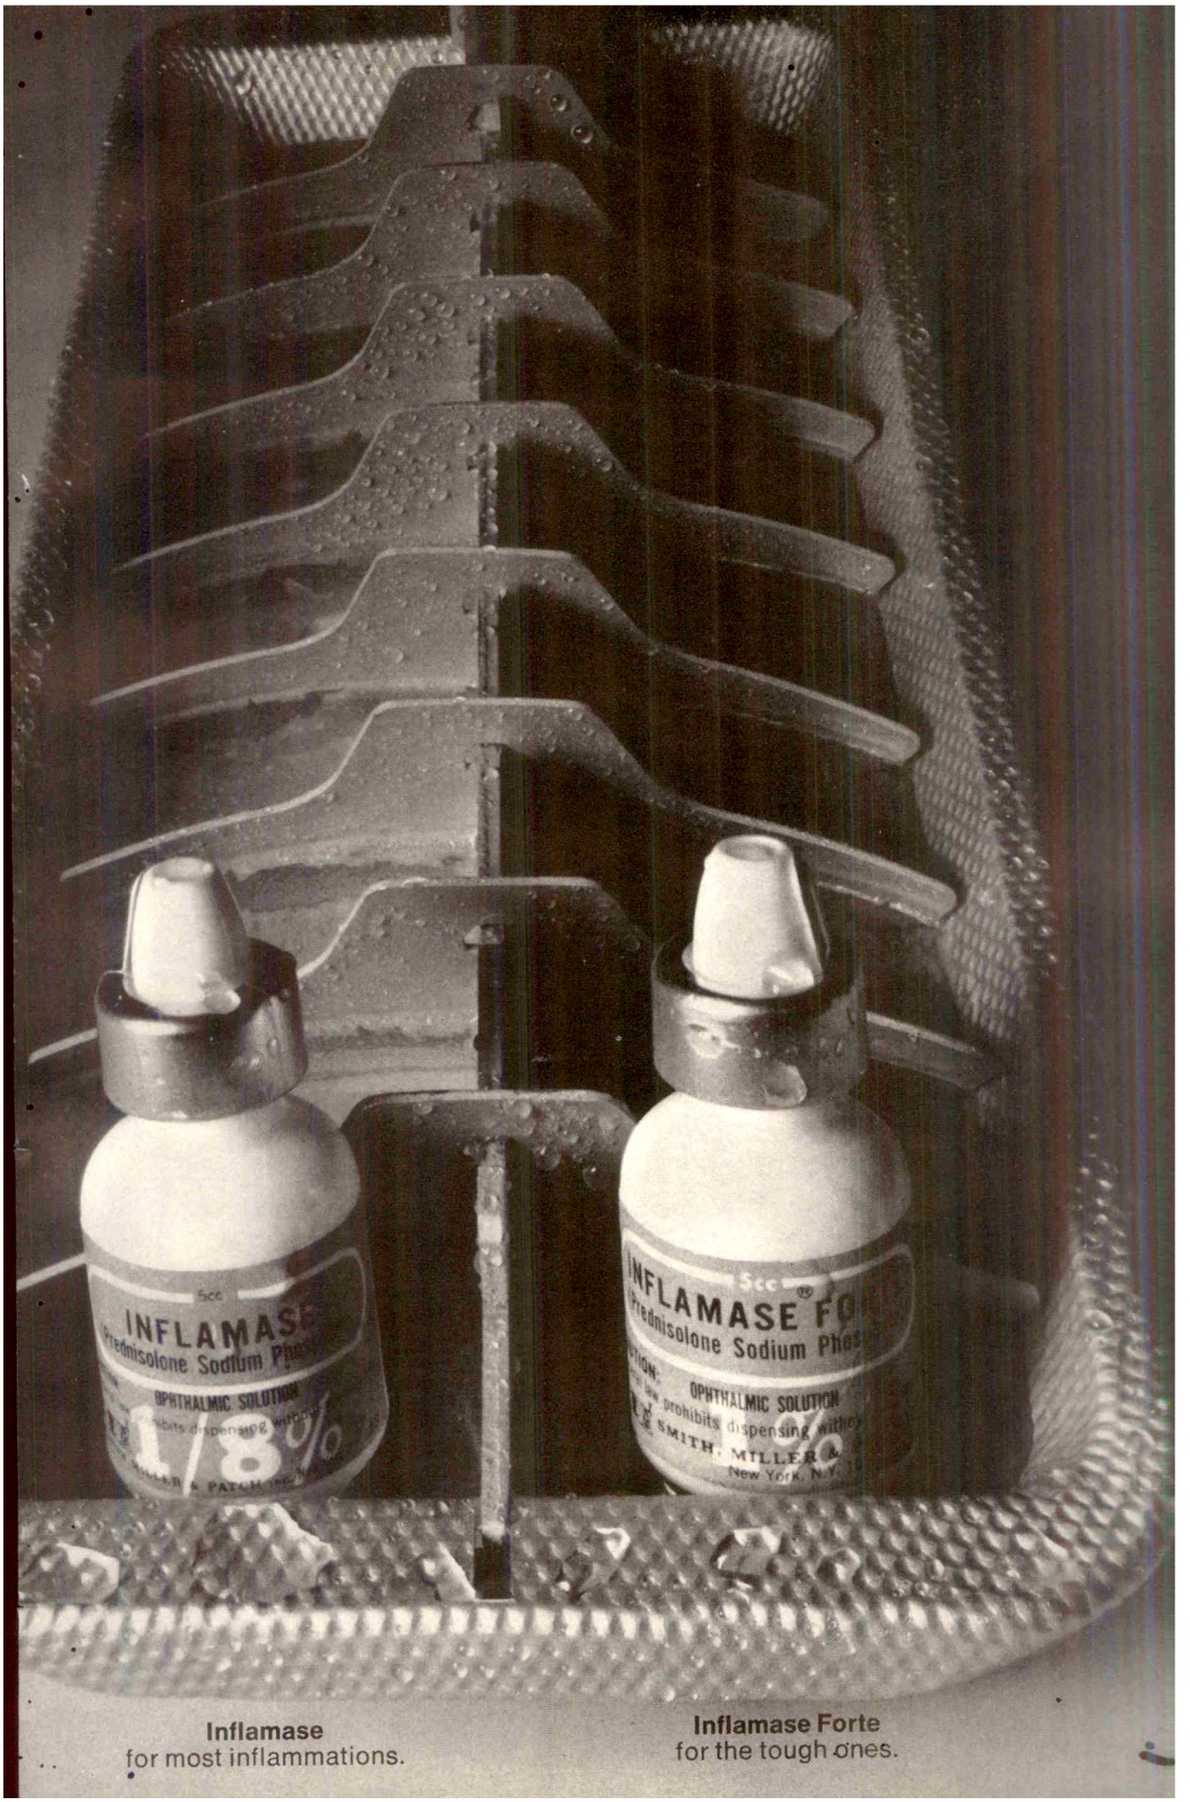
**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.



**Warning:** If irritation persists or develops, patient should be advised to discontinue use and consult prescribing physician.

**How Supplied:** 5 cc plastic squeeze bottle with dropper tip. These products are sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area, or other areas with the dropper tip of the bottle. Keep bottle tightly closed when not in use.

Store in cool place. Protect from light.



**Caution:** Federal law prohibits dispensing without prescription.

# Great for hot eyes

Both are true solutions of just Prednisolone Sodium Phosphate. Effective treatment for iritis, uveitis, ocular allergies and other inflammatory disorders. With Inflamase, reduction of possible steroid side effects. With Inflamase Forte, rapid control.

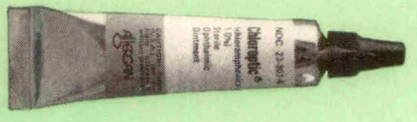
**Inflamase**
for most inflammations.

**Inflamase Forte**
for the tough ones.

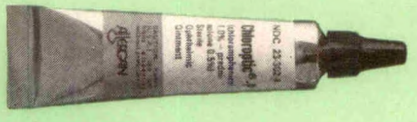
Sterile field
Sterile instruments
Sterile dressings
Sterile scrub suits
Sterile gloves
Sterile masks
But the ointment
may make a mockery
of it all

**"Iatrogenic infection must be seriously considered and eliminated by all concerned insofar as it may be prudently possible. [It] . . . may result in a break in sterile surgical technique . . . Those topical products for use in the environment of the hospital should be sterile. . . ."**
**—Evans, W. J.: FDA Papers, May 1970.**

**Vander Wyk and Granston[1] reported in 1958 that 71 out of 83 (85.5%) samples of ophthalmic ointments tested were unsterile. Other investigators, notably Bowman and Holdowsky[2], and Bowman[3] have also reported on ophthalmic ointment contamination using various testing methods.**



This plate was prepared from a commercially available ophthalmic ointment. The approximate number of microorganisms and the species (thereof per gram of ointment were:) Staphylococcus, 250; Achromobacter, 100; Nocardia, 50; Actinomyces, 50; Corynebacterium, 50; Bacillus, 200; Yeast, 50; Mold, 1900.



This plate shows the results obtained when one of a series of Allergan's new sterile ointments was tested using exactly the same procedure. No contamination could be detected.[4]

## Now, for the first time Allergan offers these New Sterile Ophthalmic Ointments.

### Chloroptic® (chloramphenicol) Sterile Ophthalmic Ointment

Contains: chloramphenicol . . . 1.0% (10mg/Gm) chlorobutanol (chloral deriv. as a preservative) . . . 0.5% with: white petrolatum, mineral oil.

### Chloroptic™-P Sterile Ophthalmic Ointment

(chloramphenicol-prednisolone)
Contains: chloramphenicol . . . 1.0% (10mg/Gm) prednisolone alcohol 0.5% (5mg/Gm) chlorobutanol (chloral deriv. as a preservative) . . . 0.5% with: white petrolatum, mineral oil.

### Atropine Sulfate 1.0% Sterile Ophthalmic Ointment

Contains: atropine sulfate . . . 1.0% with: chlorobutanol (chloral deriv. as a preservative) . . . 0.5% with: white petrolatum, mineral oil.

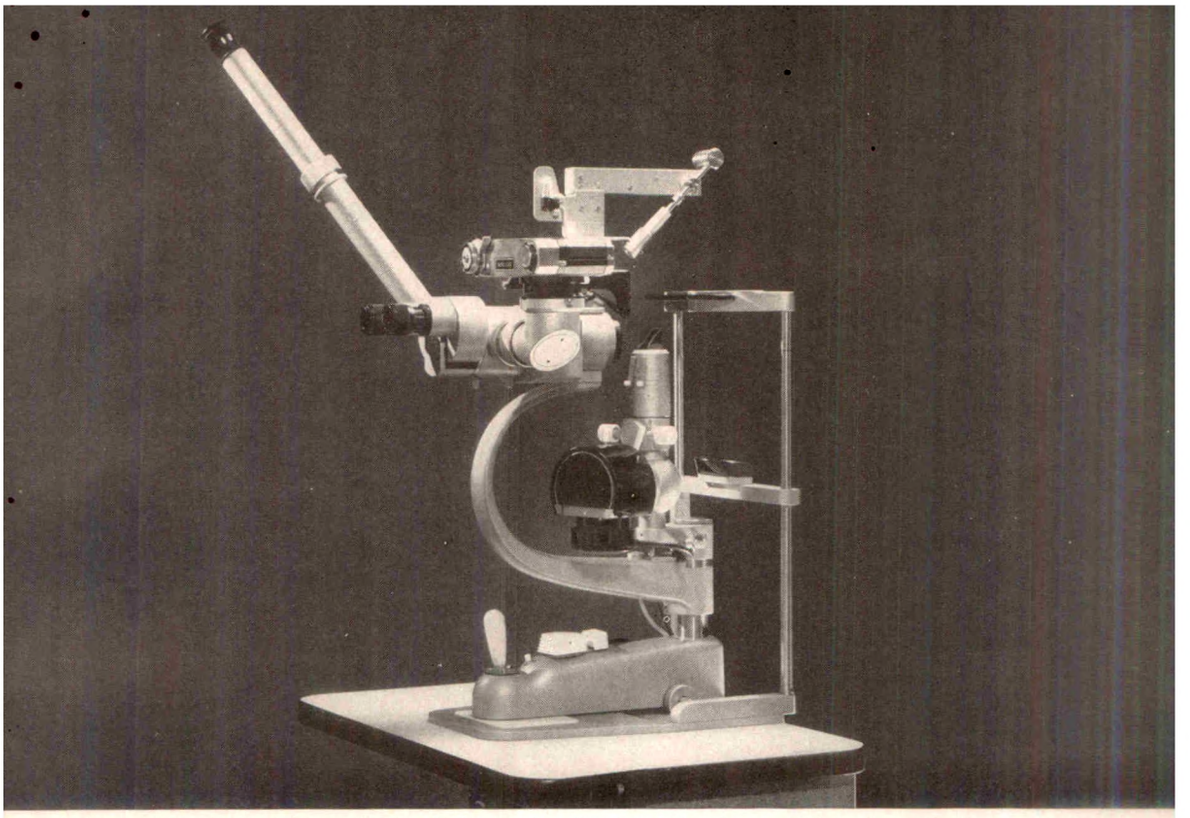
# The crystal drop assures stability



As you may be aware, the first sign of deterioration in a product containing epinephrine is a color change... reddish-brown or "yellowing." Each clear drop of PE* Ophthalmics is its own proof of stability...as also evidenced in clinical studies involving unrefrigerated shelf life, temperature changes and exposed-to-air studies simulating patient use. Proven shelf life, over 3 years (for maximum assurance, vials are date-coded on a 2 year basis). No change in clarity or potency was evidenced in any tests. The crystal clarity of every drop assures your patient full therapeutic effect, first drop to last.

PE* Ophthalmics provide simple *one-solution* treatment of open angle glaucoma... eliminating patient error, assuring the physician exact evaluation of therapy. Available in 5* strengths, in 15cc color-coded vials, nationwide and in Canada.

*Pilocarpine Hydrochloride 1%, 2%, 3%, 4%, 6% with Epinephrine Bitartrate 1% (½% Epinephrine Base).

**Contraindication:** Narrow angle glaucoma. **Precautions:** Use with caution in unverified glaucoma and hypertension. If irritation or sensitization occurs, discontinuance may be necessary.

Slit Lamp PE/E with Hruby lens, fixation device, applanation tonometer, beam-splitter, observation tube and camera.

# Why a Zeiss Slit Lamp?
# Because you get precisely what you pay for.

Precisely means the high resolution that has made Zeiss optics world-famous, and the precision operation that has made Zeiss engineering synonymous with craftsmanship. And, to make sure that the slit lamp you buy will be tailored precisely to you and your work, you can choose from a range of instruments and features unmatched by anyone. There's no reason all slit lamps should be alike (after all, all people aren't), so with Zeiss, even before you consider accessories, your choice is a wide one. For your convenience, we have:

**4 basic models**—manual and motorized, step-wise and zoom. The step-wise magnification system is from 6x to 40x (the widest range of any slit lamp from anyone), the zoom is 8x to 40x. They're called the SM/M, the PM/M, the PE/E, and, of course, the famous Photo-Slit Lamp, the ultimate in sophistication. Standard on the Photo-Slit Lamp, and available also on the other three models, is an extra-long working distance to facilitate surgical intervention.

**The unique Galilean observation system**—it allows the famous Zeiss beam-splitter (used on our Operation Microscopes) to be inserted, letting you attach observation tubes and still, cine, and television cameras—invaluable aids for consultation or teaching purposes—all operating directly through the optics of the microscope. And because it is telecentric, this system lets you work with eyes relaxed, focused on infinity, *sans* strain. It quite literally means fewer headaches.

**The unusual depth of observation**—a result of the combination of the great depth of focus of the biomicroscope and the unmatched depth of the slit image.

**High-eyepoint eyepieces**—for physicians who must wear corrective lenses, these eyepieces offer the same wide field of view enjoyed by non-eyeglass wearers.

**Ease-of-handling**—these light-in-weight instruments are easy to use on a refraction unit or a table, whether you're left- or right-handed, tall or short, or have any kind of special requirements.

For complete details write Carl Zeiss, Inc., 444 5th Avenue, N.Y., N.Y. 10018. (212) 736-6070.

Nationwide service.

*THE TISSUE-FRIENDLY*

# SUPRAMID EXTRA®

**SUTURE.** Polyfilament but neither braided nor twisted. New cable-type construction with several strands enclosed in a perfectly smooth cover of the same material, gives great pliability and superior strength. Strong as steel wire, handles as silk. No stitch irritation, no growth of tissue into suture. Sizes 10-0 to 8.

**SPECIAL NEEDLES:** Our CT needle for cataracts (wire size 0.30mm, length 9mm), CA needle for corneal work (wire size 0.30mm, length 6mm), and EX needle for special keratoplasties (wire size 0.2mm, length 5mm), a flattened reverse cutting needle to prevent "leaking wounds," equal to the smallest hand made eyed needles No. 82F, **and finally the smallest spatula needle on the market, length 5 millimeters, wire size 0.2mm, double armed with 10-0, 9-0 and 8-0 black Supramid Extra. Code Nos. 2SC-100, 2SC-90 and 2SC-80.**

**A NEW PRODUCT:** Implants—Sleeves (Tubes) for preventing adhesions in Eye Muscle Surgery. Method development by Edward A. Dunlap, M.D. Reference: Dunlap, Edward A.: Plastic Implants in Muscle Surgery, Archives of Ophthalmology, 80: 249-257, August 1968.

**TUBING.** *Fully inert because it is made of the same material as the suture;
* Thinnest walls of any surgical tubing, fully transparent and can be *repeatedly* autoclaved;
* Most economical. It is in your interest to compare prices and quality.

**FOIL.** Excellent results with our suture created the demand for Foil for plastic and reconstructive surgery in such cases as orbital fractures, lid reconstruction, etc. Foil is chemically identical with the sutures, thus just as inert when buried in the tissue.

Available in thickness from 0.05mm to 2.00mm, in sheets 15 x 20cm.

Can be steam-autoclaved, cut to size, and carved to shapes and forms.

# The new Zeiss Zoom OpMi 7... a true ophthalmological specialist.

The new OpMi 7 is truly special in every sense of the word. It's special in that it is designed only for ophthalmological microsurgery. And special too in price—its many outstanding design features are shared only with instruments costing considerably more.

**Wide field of view:** 55 mm at 3.6x — 95% more area than other instruments in its price range.

**Building block design:** it accepts all the valuable Zeiss accessories, including the Beam Splitter System for still and motion picture photography and TV, the unique high-eyepoint eyepieces for spectacle wearers, a fiber-optic "cool-light" illumination system, the assistant's stereo microscope with the same high quality optics as the surgeon's, and the 2x operating field magnifier.

**Choice of 3 stands:** including the new Ceiling Suspension System.

**Choice of 3 working distances:** 6", 7" or 8" to your specification.

That's only a start. For complete details, write or call Carl Zeiss, Inc., 444 5th Ave., New York, N. Y. 10018. (212) 736-6070.

# in post-operative retinal or cataract surgery

## Murocoll Phenylephrine, Scopolamine and Prednisolone (Murocoll Product #2c)

**FORMULA:** Sterile ophthalmic solution containing Phenylephrine Hydrochloride 10%, Scopolamine Hydrobromide 0.3% and Prednisolone 0.2%; preservatives chlorobutanol 0.5%; sodium bisulfite; polysorbate 20 and distilled water as inactive ingredients.

**CLINICAL INDICATIONS:** Used in intraocular inflammation such as uveitis and iritis, where it is desirable to maintain dilation, rest ciliary body as well as to decrease inflammation with post-operative retinal or cataract surgery.

**CONTRAINDICATIONS:** (a) Acute herpes simplex, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva. (b) Tuberculosis. (c) Fungal diseases. (d) Acute purulent untreated infections which, like other diseases caused by microorganisms, may be masked or enhanced by the presence of the steroid. (e) Purulent conjunctivitis and purulent blepharitis. Individuals with hypersensitivity to belladonna alkaloids.

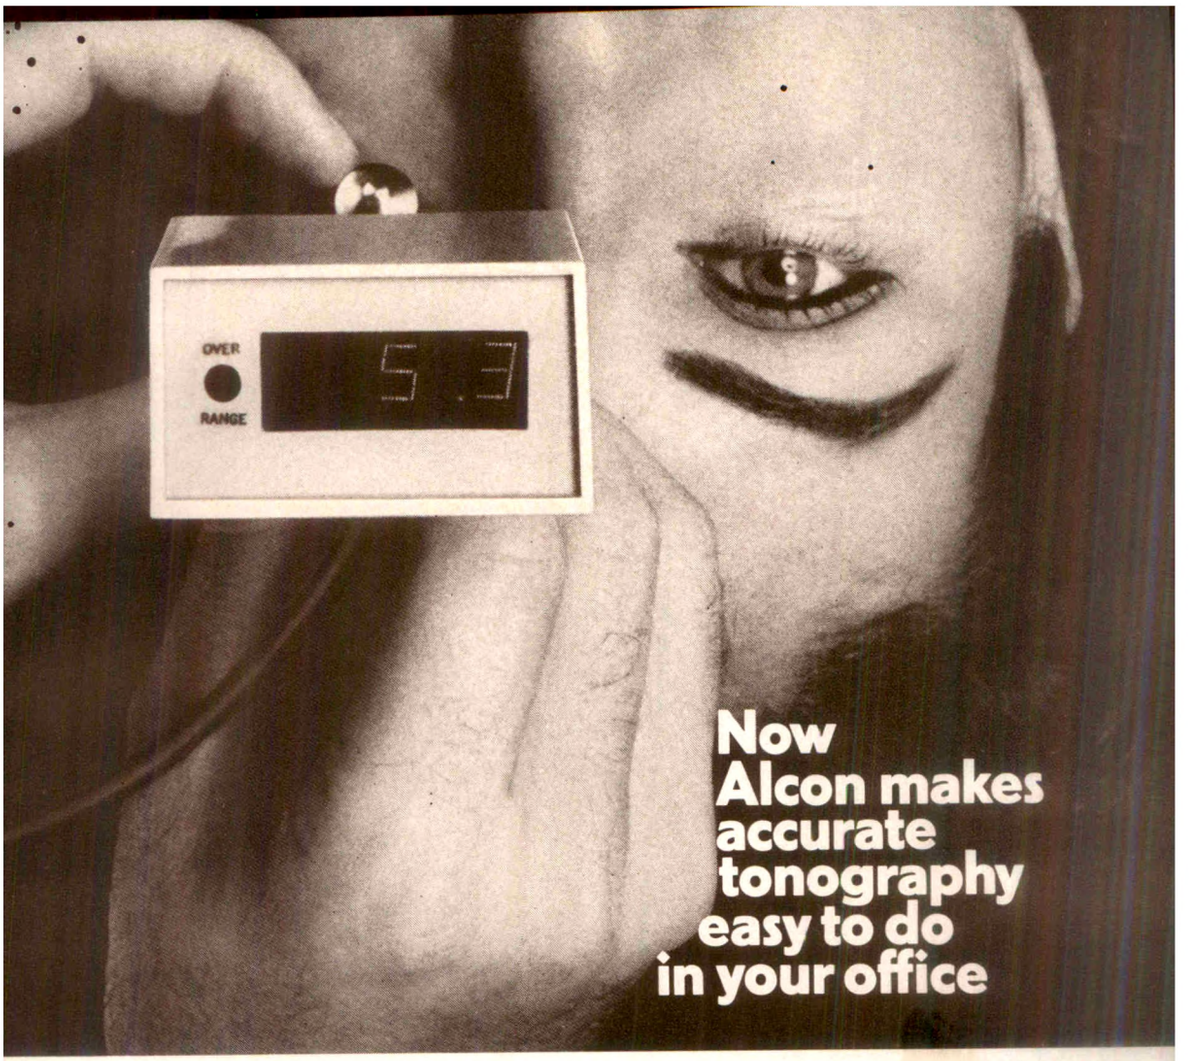
**PRECAUTIONS:** (a) Extended use of topical steriod therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. (b) In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids.

**CAUTION:** Should be used with caution in patients with narrow chamber angles.

**DOSAGE:** One or two drops in eye three or four times daily until all signs of intraocular inflammation are absent.

Use of this combination reduces the number of instillations that would be required if separate agents were prescribed, and materially reduces the cost of therapy.

**AVAILABLE:** 7.5 cc glass bottle with plastic dropper on prescription only.



**Complete ophthalmologic formulary available on request**

Muro preparations are available to all community pharmacists and hospitals through their drug service wholesaler.

# Now Alcon makes accurate tonography easy to do in your office

**ALCON introduces the EDT-103™—the first electronic digital tonograph and automated recorder. Only the EDT-103 provides accurate, simplified tonography for routine office use. And any member of your staff can be trained to use it in less than half an hour.**

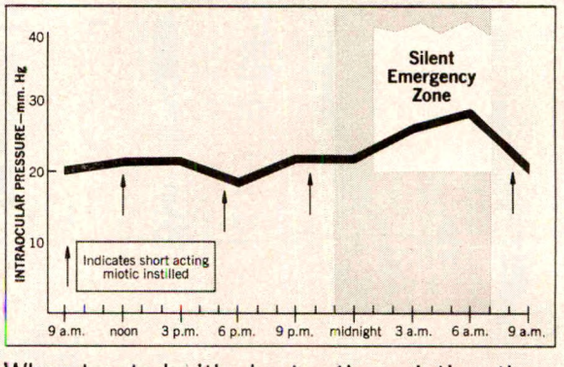
**easy to read:**
direct digital display of tonometric scale readings conveniently...at tonometer head

**easy to operate:**
self-activating recorder, automatically controlled and timed permanent patient record on "fan-fold" strip chart
automatic chart drive—maximum accessibility for easy loading

**easy to maintain:**
self contained tonography system is compact, lightweight, portable, in its own carrying case
all solid state circuitry
carries a one-year warranty, easily serviced
meets or exceeds all requirements of Specification 5

Write for additional information, or to have our representative arrange for a personal demonstration.

## EDT-103



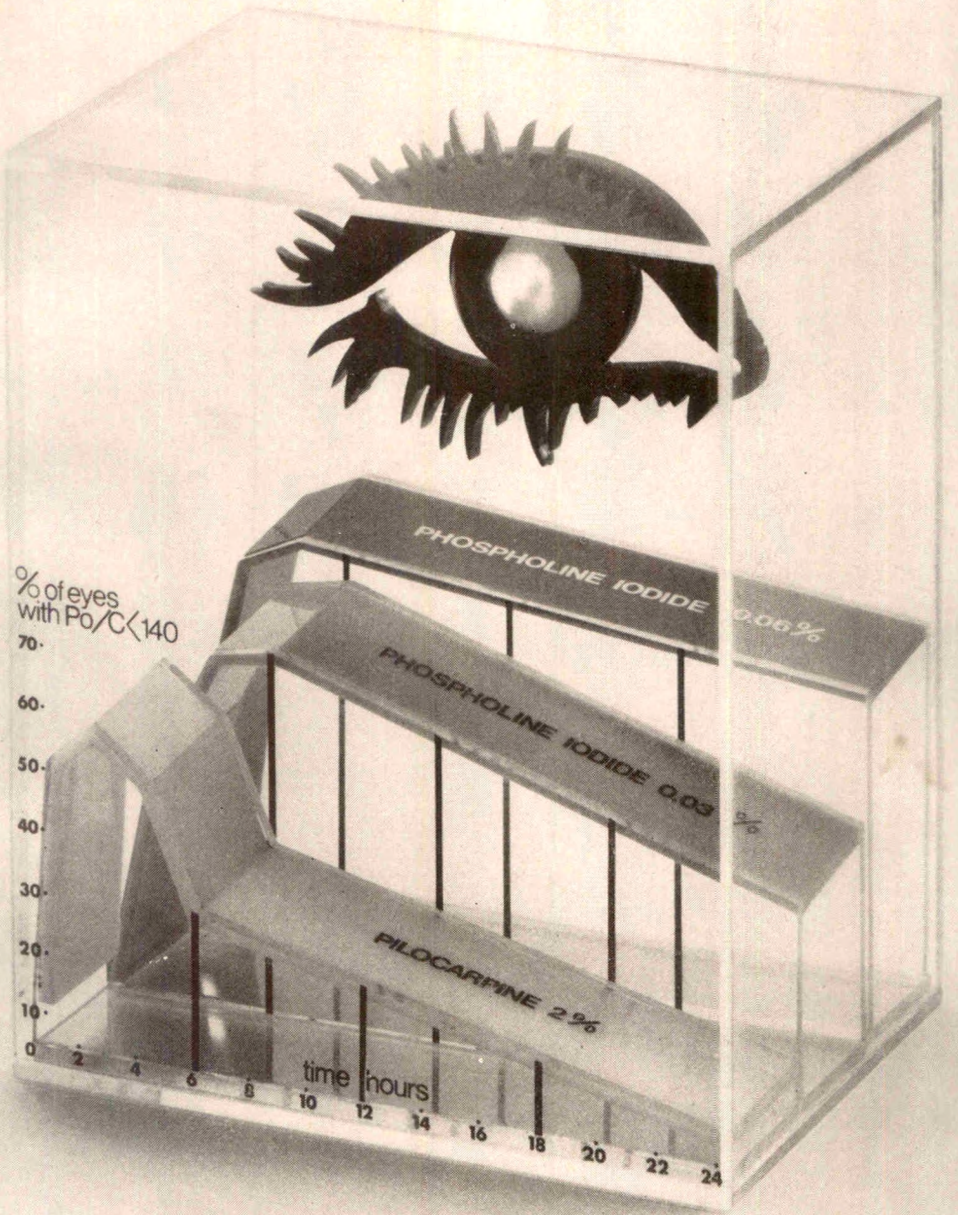
A new dimension in the detection and management of glaucoma—

Surgical Products Division, Alcon Laboratories, Inc./ P.O. Box 1959, Fort Worth, Texas 76101

# Not more potent, but longer acting...*

PHOSPHOLINE IODIDE 0.03% and 0.06% were compared with pilocarpine 2% in a study of the time course of changes in outflow facility and intraocular pressure after single dose administration in patients with open-angle glaucoma. While Phospholine Iodide 0.06% showed little diminution in effect on intraocular pressure after 24 hours, the effect of pilocarpine 2% declined markedly in the first few hours, and was almost completely dissipated after 24 hours. The action of Phospholine Iodide 0.03% was intermediate between that of pilocarpine 2% and Phospholine Iodide 0.06%.

## An important consideration in the management of glaucoma



When treated with short acting miotics, the patient with open-angle glaucoma runs the risk of an undetected intraocular pressure buildup during the night—a "silent emergency."

The longer acting Phospholine Iodide® (echothiophate iodide) may protect against this nightly insult. A single instillation of the 0.03% or 0.06% strength before retiring will act through the critical hours, and is especially recommended when you have found pilocarpine to be inadequate.

When initiating therapy... Phospholine Iodide 0.03% can often maintain 24 hour control of intraocular pressure with a single instillation at bedtime. It provides a smooth transition to the higher strengths—0.06%, 0.125%, 0.25%—when necessary. When indicated, epinephrine or carbonic anhydrase inhibitors may be prescribed with any strength of Phospholine Iodide.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide for ophthalmic solution)

Effect of Phospholine Iodide and pilocarpine on intraocular pressure control.

*Adapted from Barsam, P. C., Boston U. School of Med.: Time Curves of the Effect of Miotics on Intraocular Pressure and Outflow Facility, Scientific Exhibit, Annual Convention, American Academy of Ophthalmology and Otolaryngology, Las Vegas, Oct. 5-9, 1970.

See next page for Brief Summary of prescribing information.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide)

for 24 hour control in chronic simple (open-angle glaucoma and glaucoma secondary to aphakia

just 1 or 2 instillations a day
- for long lasting effect on ocular tension—
helps protect against a "silent emergency" at night
- may be substituted for the bedtime dose of a short acting miotic
that controls intraocular pressure by day, but
fails to provide adequate control during the night and early morning
- choice of four strengths for individualized therapy—
may be used alone or as a complementary agent

**BRIEF SUMMARY (for full prescribing information, consult package circular)**
**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE (echothiophate iodide) concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, browache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local)* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE (echothiophate iodide) therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic)* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

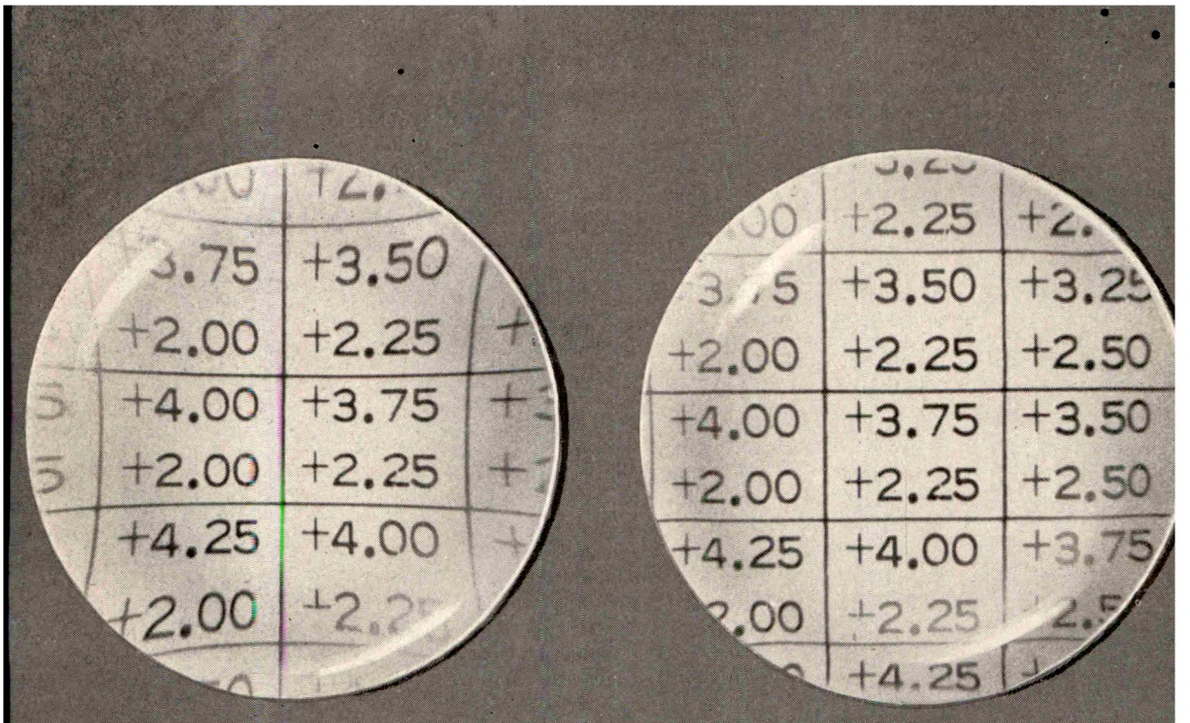
# There is still nothing like it.

The superb Donaldson* Stereo-Camera is still the standard of quality that all others try to match. None has yet.



And quality means more than precision construction. The Donaldson is simple to use — you concentrate on the subject, not on complicated controls. It is versatile — you can use it for close-up photography as you would an ordinary 35mm camera. It is a complete system — with an available drum viewer, strip viewer, and single slide viewer.

As for processing, we simplify that too — both developing and mounting if you wish. And last but not least, the Donaldson Stereo-System is now available without delay. Write today for a full description and ordering information. Mentor Division, Codman & Shurtleff, Inc., Randolph, Massachusetts 02368.

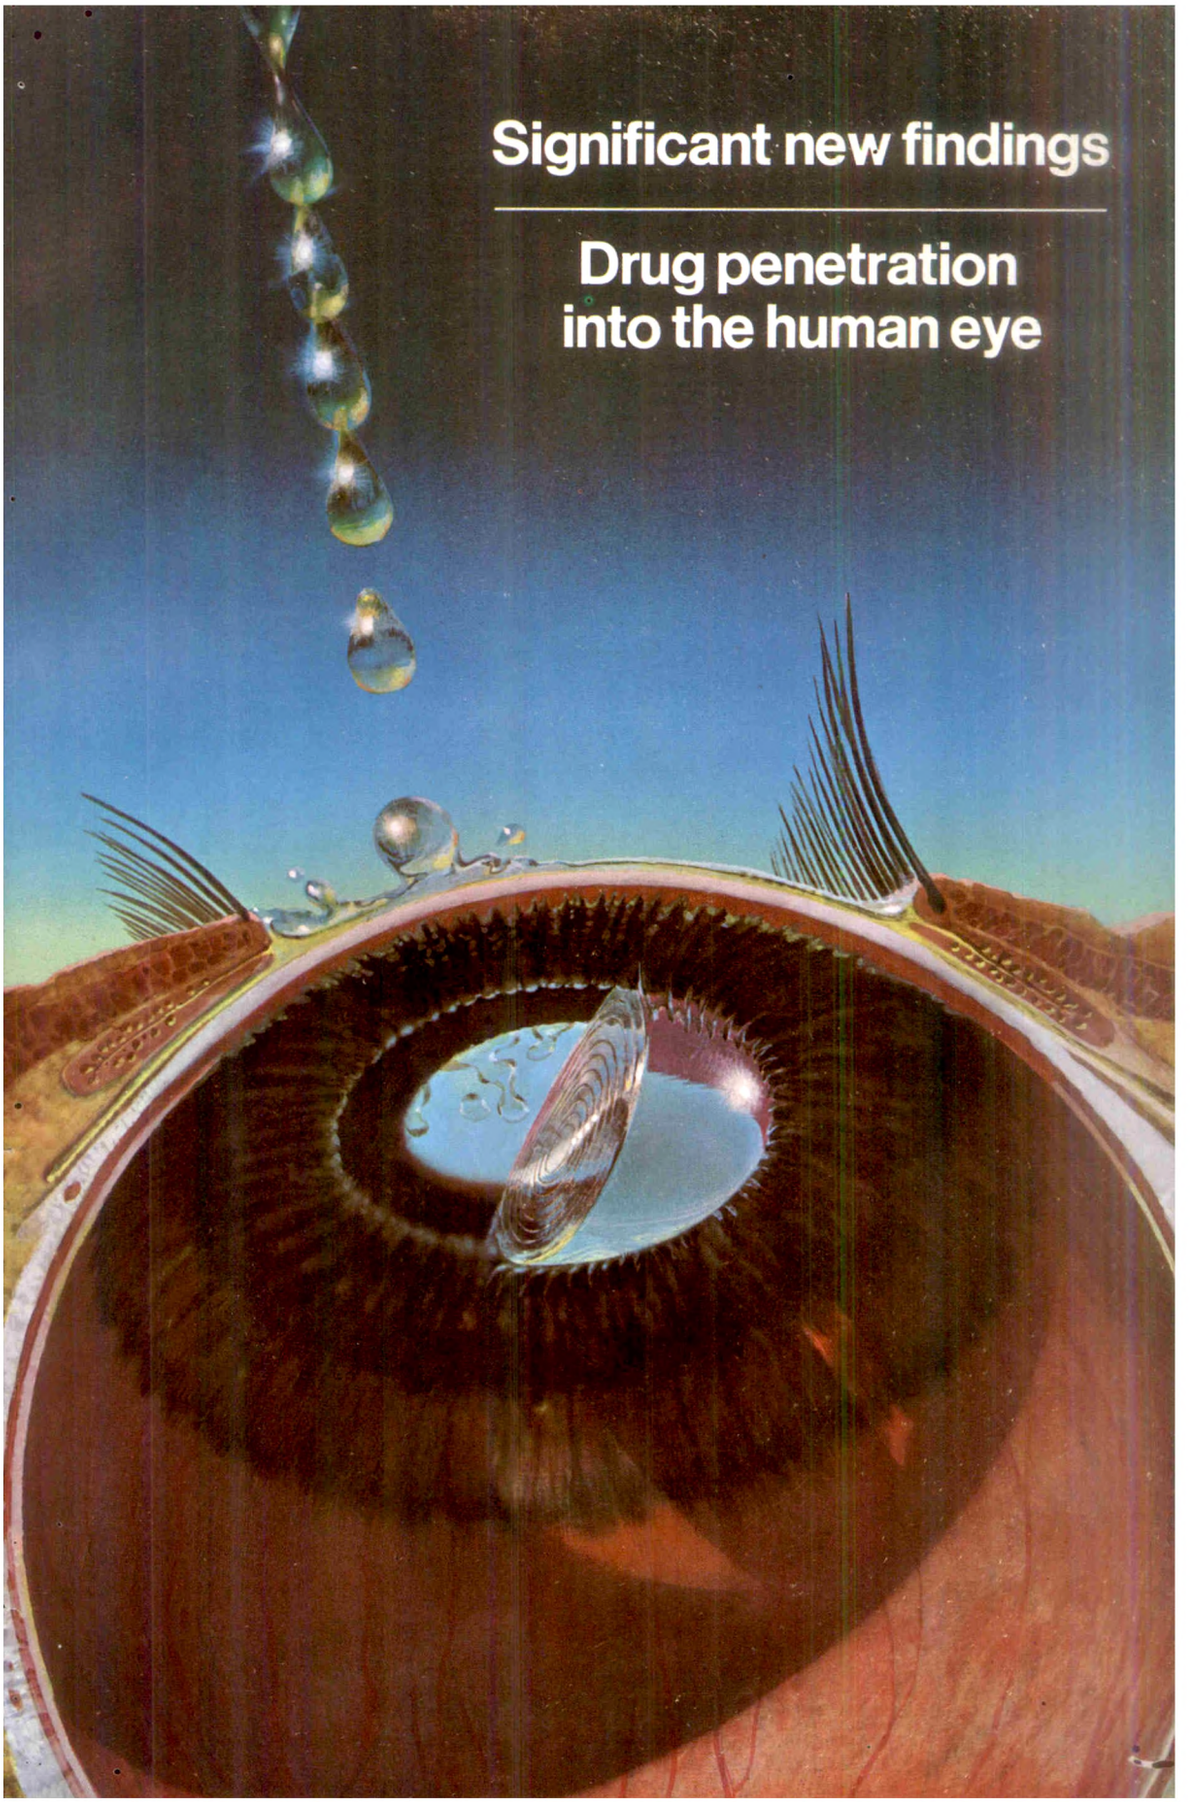
# BEFORE and AFTER

## YOUR PATIENT CHANGES TO ASPHERIC CRISTYL® LENSES BY TITMUS

Titmus Cataract Lenses combine advantages of aspheric curves, straight top or round segments, and featherlight Cristyl in full or lenticular field to benefit your patients *7 ways:*



1. WIDER FIELD OF UNDISTORTED VISION—Patient moves about with increased safety and confidence.
2. STRAIGHT TOP OR ROUND SEGMENTS—Optimum design/more comfortable seeing.
3. IMPACT-RESISTANT—Safeguards eyes/protects against lens breakage.
4. REDUCED WEIGHT—Fewer adjustments/daylong comfort.
5. GREATER CLARITY—Less surface reflection/more light/improved acuity.
6. ULTRA-VIOLET PROTECTION—Even clear Cristyl absorbs harmful rays.
7. UNIFORM DENSITY TINTS—Uniform transmission from center to edge.

Significant new findings
Drug penetration
into the human eye

# for the first time independent research relates ocular drug penetration in humans to your choice of ophthalmic vehicles

## Proof of penetration—new fluorophotometry concentration/duration study[1]

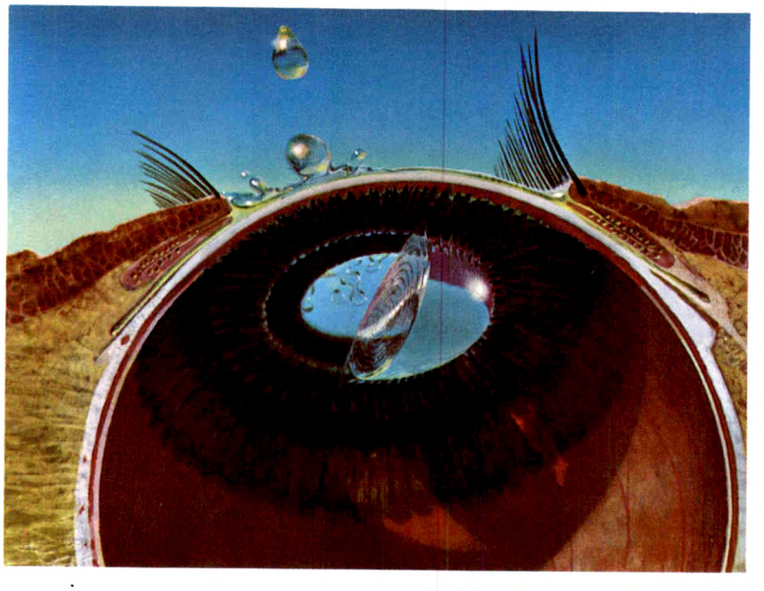
Using a slit lamp fluorophotometer, "the effects of ophthalmic vehicles on the intraocular penetration of topical fluorescein in man" were determined. "Quantitative data on ocular penetration of this drug, in man, in vivo, are presented."

### The study

Fluorescein combined with hydroxypropyl methylcellulose 0.5%, polyvinyl alcohol 1.4% and aqueous; each vehicle instilled in the eyes of 20 normal subjects; each subject served as his own control; hourly measurements of attained drug concentration were made quantitatively using a slit lamp fluorophotometer.

### The findings

CORNEA



Over a three hour period, hydroxypropyl methylcellulose produced corneal drug levels 85% higher than polyvinyl alcohol and 43% higher than the aqueous vehicles.‡

AQUEOUS HUMOR

Over a three hour period, hydroxypropyl methylcellulose produced aqueous humor drug levels 93% higher than polyvinyl alcohol and 42% higher than the aqueous vehicle.‡‡

### The authentication

The authors state that their findings may, or may not, be true for drugs other than fluorescein. However, the findings reported above were achieved "consistently and reproducibly"; data were analyzed and tested for significance on a computer.

# For greater therapeutic efficacy the most potent ocular steroid...

## Maxidex®

dexamethasone 0.1%

Dexamethasone has anti-inflammatory action thirty to fifty times that of cortisone (measured in activity by weight)[3] Dexamethasone is the most potent of the corticosteroids available for ophthalmic use.

**And MAXIDEX is dexamethasone.**

**More penetration[1]**
**More concentration in ocular tissue[1]**
**Most potent ocular steroid[4]**

*Description:* Sterile preparation containing: Active: Dexamethasone 0.1%; Vehicle: Sodium Chloride, Dried Sodium Phosphate, Hydroxypropyl Methylcellulose, Polysorbate 80, Disodium Edetate, Citric Acid (to adjust pH), Purified Water; Preservative: Benzalkonium Chloride equivalent to 0.01%.

*Contraindications:* Contraindicated in acute herpes simplex, vaccina, varicella, and most other viral diseases of the cornea and conjunctiva, tuberculosis; fungal disease; acute purulent untreated infections which, like other diseases caused by microorganisms, may be masked or enhanced by the presence of the steroid.

*Warnings:* Intensive or prolonged topical corticosteroid therapy is a possible factor in the formation of posterior subcapsular cataracts. Not recommended for long-term use in pregnant patients.

*Precautions:* Institute other therapy if inflammatory reaction does not respond within reasonable period. Discontinue use if sensitivity occurs. Extensive use of topical steroids may cause systemic side effects; ocular herpes simplex has occurred.

*Adverse Reactions:* Extended use may cause increased intraocular pressure which should be checked frequently. Perforation can occur in diseases causing thinning of the cornea.

Alcon

dedicated to advances in ophthalmic therapy

in deep-seated ocular inflammations

# MAXIDEX®

(dexamethasone 0.1%)

**Indications:** Relief and management of nonpurulent Blepharitis and Conjunctivitis.

**Dosage:** Initially, 1 or 2 drops placed in the conjunctival sac every hour until improvement occurs.

Thereafter, 1 or 2 drops 2 to 4 times daily.

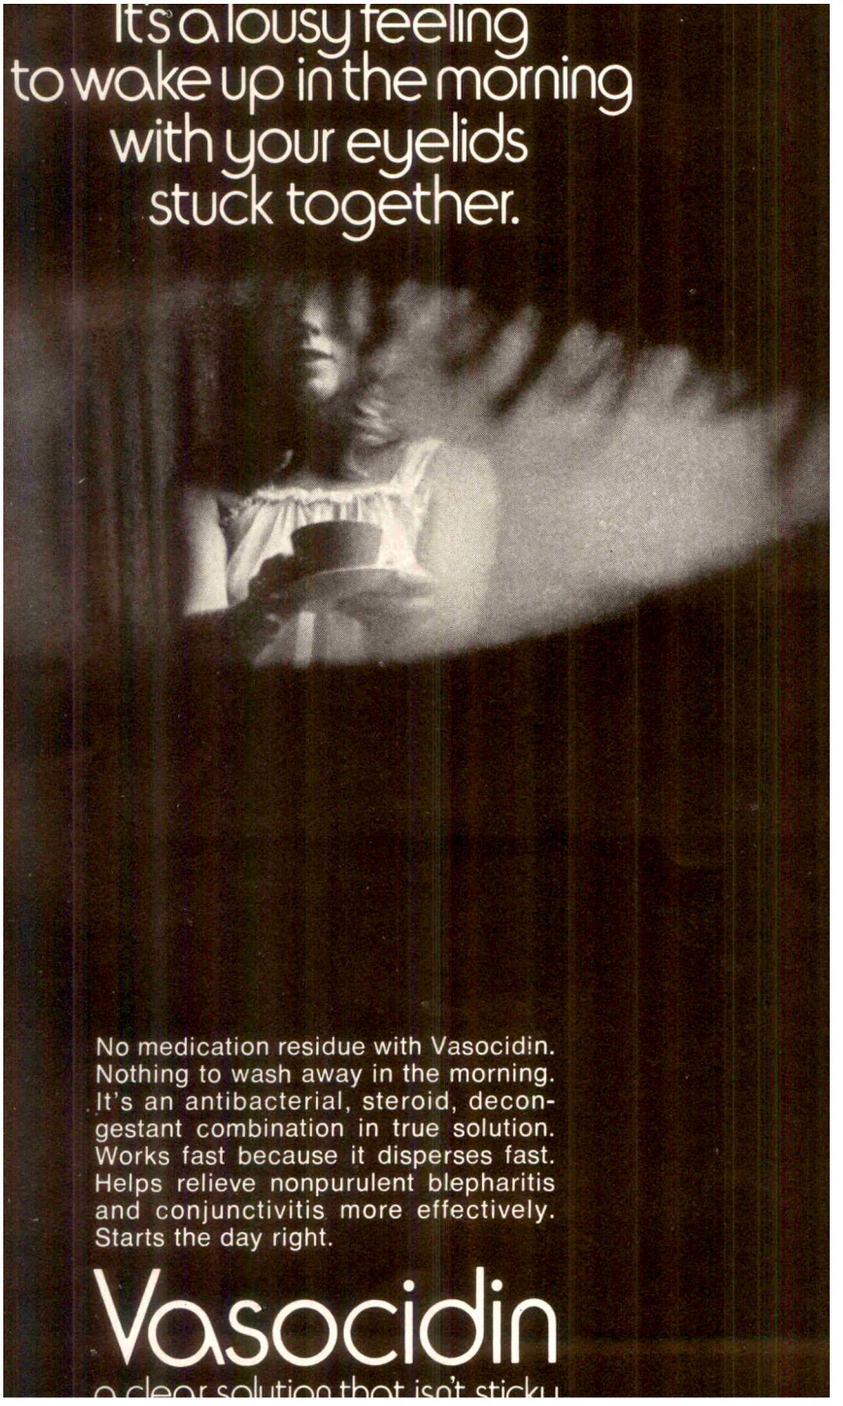
**Composition:**

Prednisolone-21-phosphate sodium .....0.25%
(Equivalent to Prednisolone 0.2%)
Sulfacetamide sodium ....10.0%
Phenylephrine HCl .....0.125%
Methylparaben .....0.02%
Propylparaben .....0.005%

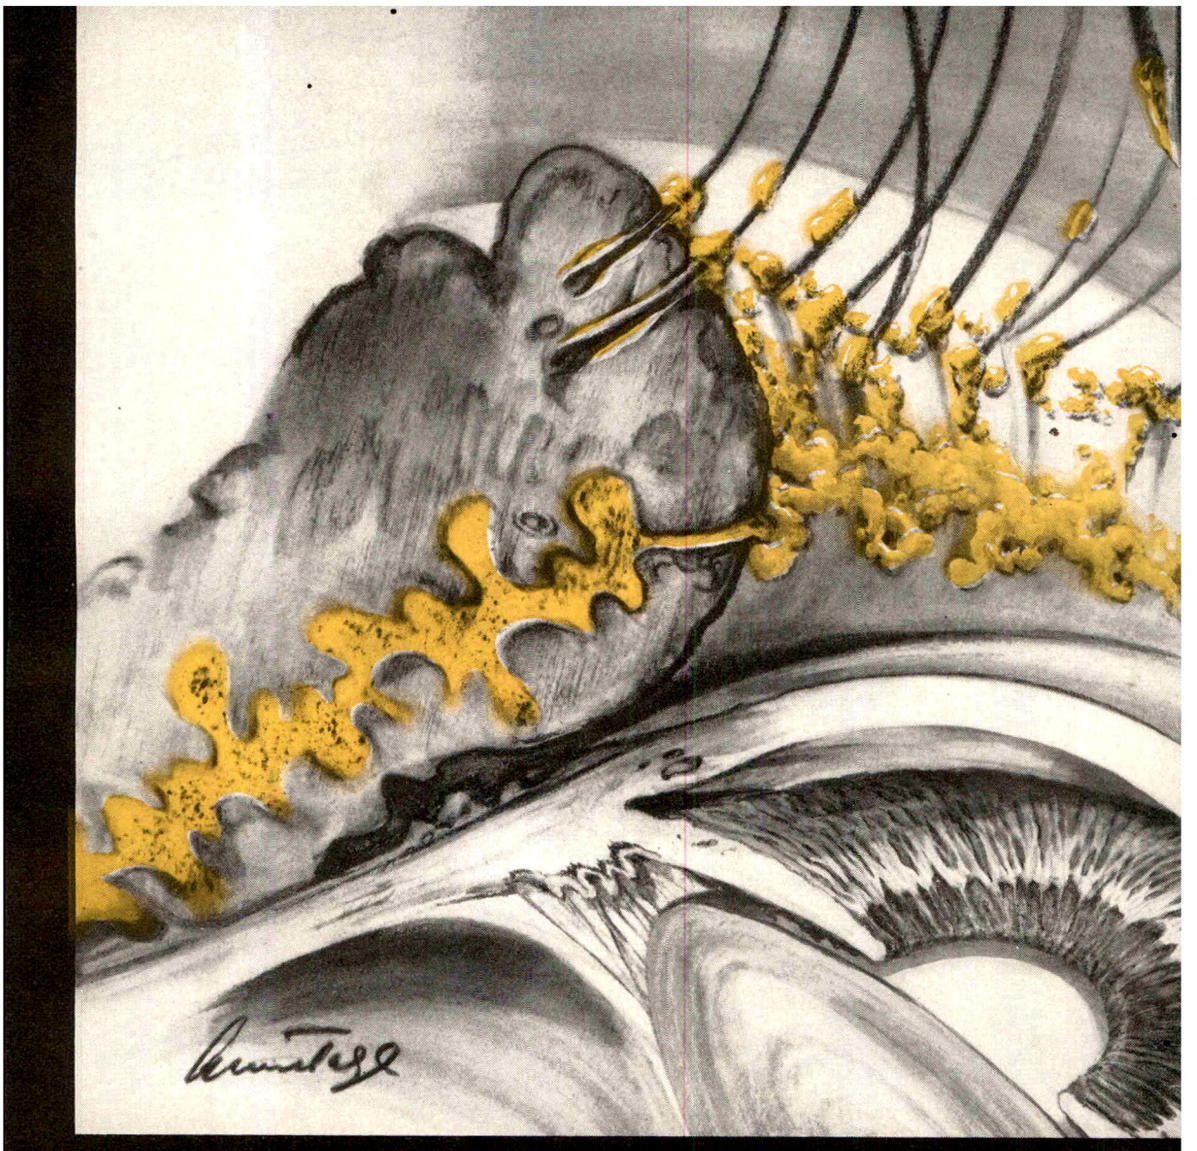
In a stabilized aqueous solution containing sodium thiosulfate and *SMP-68 (a combination of polyoxypropylene compound and polysorbate 80).

**Effectiveness:** The antibacterial spectrum of Vasocidin is particularly effective against the gram positive pyogenic cocci; E. coli, N. gonorrhoeae, Koch-Weeks bacillus and other bacteria susceptible to sulfacetamide. Because Vasocidin is a true solution, dosage is uniform and each drop is free of any irritating particles. The Vasocidin vehicle enhances the dispersion of active components. Sulfacetamide combats a wide range of pathogens; prednisolone reduces inflammatory reaction; phenylephrine relieves hyperemia. Local effects of active therapeutic agents appear to be prolonged by phenylephrine-induced vasoconstriction.

***Caution:*** *Federal law prohibits dispensing without prescription.*



**Contraindications:** Steroids are contraindicated in dendritic ulcers (herpes simplex), vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, as well as in fungal and tubercular ocular disease. Contraindicated in the treatment of purulent conjunctivitis or blepharitis. Should not be used by persons with narrow-angle glaucoma or those sensitive to sulfonamides. If irritation persists or increases, discontinue use and consult physician.



**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.

Vasocidin is sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area with the dropper tip of bottle. Keep container tightly closed.

**Supplied:** Plastic dropper-tipped vials, 5 cc.

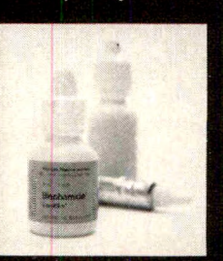
**Smith, Miller & Patch, Inc.**
401 Joyce Kilmer Avenue
New Brunswick, N.J. 08902

It's a lousy feeling
to wake up in the morning
with your eyelids
stuck together.
No medication residue with Vasocidin.
Nothing to wash away in the morning.
It's an antibacterial, steroid, decon-
gestant combination in true solution.
Works fast because it disperses fast.
Helps relieve nonpurulent blepharitis
and conjunctivitis more effectively.
Starts the day right.
Vasocidin
a clear solution that isn't sticky

# ONE RX CAN PROVIDE ROUND-THE-CLOCK THERAPY

## Blephamide® Liquifilm®

**OPHTHALMIC SUSPENSION**



Sodium sulfacetamide, 10.0%; prednisolone acetate 0.2%; phenylephrine HCl, 0.12%; Liquifilm (polyvinyl alcohol), 1.4%; and antipyrine, 0.1%.

Specifically designed to treat nonpurulent blepharitis. Patient-accepted for routine day and night use.

With Liquifilm®—the advantage, but not the disadvantage...of ointments—prolonged contact with lesions—no greasy appearance—ointments are not required to be sterile.

Dries quickly to a clear, invisible film on lids...so cosmetically acceptable, round-the-clock treatment virtually assured.

One-prescription economy.

**Why Use Two... When One Will Do!**

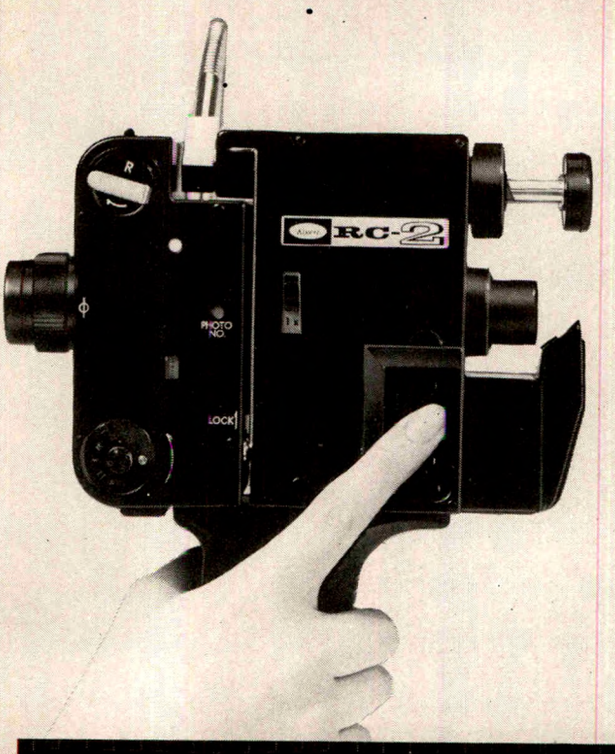
With BLEPHAMIDE LIQUIFILM, you provide antibacterial/anti-inflammatory/anti-allergy/anti-seborrheic activity—in a form that has the convenience of drops...the persistence of ointments. All of the advantages of both dosage forms...none of the disadvantages.

**Description:** Sodium sulfacetamide, 10.0%; prednisolone acetate, 0.2%; phenylephrine HCl, 0.12%; Liquifilm (polyvinyl alcohol), 1.4%; phenylmercuric nitrate, 0.004%; polysorbate 80, 0.1%; antipyrine, 0.1%; with: disodium edetate; sodium phosphate; dibasic anhydrous sodium phosphate; monobasic sodium thiosulfate; purified water; hydrochloric acid to adjust pH to 6.8.

**Indications:** Nonpurulent blepharitis and blepharoconjunctivitis (seborrheal, staphylococcal, and mixed); nonpurulent conjunctivitis (allergic and bacterial).

**Contraindications:** Acute herpes simplex (dendritic keratitis), purulent untreated infections, vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, ocular tuberculosis and fungal diseases of the eye.

**Warnings:**



1. In diseases due to microorganisms, infection may be masked, enhanced or activated by the steroid.
2. Extended use may cause increased intraocular pressure in susceptible individuals. It is advisable that the intraocular pressure be checked
3. In those diseases causing thinning of the cornea perforation has been known to have occurred with the use of topical steroids.
4. Use with caution in patients with known or suspected sensitivity to sulfonamides — if sensitivity or other untoward reactions occur, discontinue medication.
5. Should be used with caution in the presence of narrow angle glaucoma.
6. Reports in the literature indicate that posterior subcapsular lenticular opacities have been reported to occur after heavy or protracted use of topical ophthalmic steroids.

**Dosage and Administration:** 1 drop 2 to 4 times daily, depending on the severity of the condition.

**Supplied:** 5 cc. and 10 cc. plastic dropper bottles — on prescription only.

# Kowa RC-2

## fundus camera

*The simple approach to fundus and fluorescein photography.*

FLUORESCEIN FUNDUS PHOTOGRAPHY

To be fully meaningful to the medical profession, all instrumentation must function as an extension of the user's eyes, hands, and mind. The Kowa RC-2 fundus camera fully embodies this principle.

• *Fundus and External Photography* The basic RC-2 incorporates every conceivable advance in optics, mechanics, and electronics. Standard are built-in flash, 2X magnifying lens, automatic frame numbering for patient coding, and more. It will produce impeccable 35mm results even for inexperienced users.

• *Fluorescein Photography* By simply adding an auto-wind back, filters, and a quick-cycling power unit, the RC-2 becomes a flawless fluorescein photographic instrument.

• *Polaroid® Photography* An attachment gives you 60-second fundus photographs.

To see why the *total systems approach* has made Kowa's RC-2 the standard by which all others are measured, contact the representative in your area.

**STOXIL®**
**brand of IDOXURIDINE**

the only brand of IDU
available in two forms:
Solution—Ointment

Both now available in Canada

# The choice is yours

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.

**Description: 'Stoxil' Ophthalmic Solution** contains idoxuridine (5-iodo-2'-deoxyuridine) **0.1% (1 mg./cc.)** in distilled water. Preserved with thimerosal, 1:50,000. **'Stoxil' Ophthalmic Ointment** contains idoxuridine **0.5% (5 mg./Gm.)** in a petrolatum base. (White petrolatum and liquid petrolatum are inactive ingredients.)

**Contraindications:** Contraindicated in patients with known or suspected hypersensitivity to any of its components.

**Precautions:** Some strains of herpes simplex appear to be resistant. If there is no response in *epithelial infections* after 7 or 8 days of treatment, other forms of therapy should be considered.

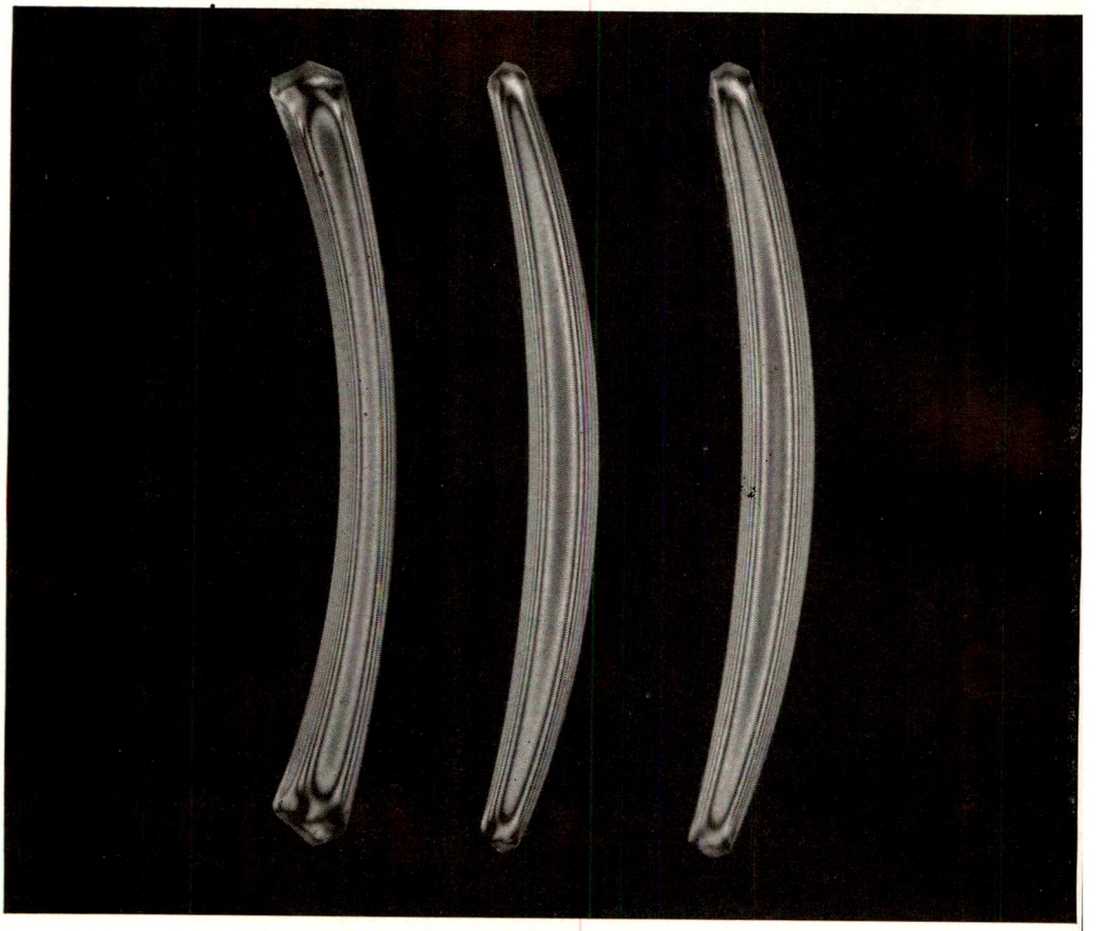
The recommended frequency and duration of administration should not be exceeded.

'Stoxil' is not effective in corneal inflammations in which the virus is not present.

Corticosteroids are usually contraindicated in herpes simplex keratitis.

Boric acid should not be used during the course of the therapy.

'Stoxil' Ophthalmic Solution should not be mixed with other medications.



**Adverse Reactions:** Occasionally, irritation, pain, pruritus, inflammation, edema of eye or lids and, rarely, allergic reactions have been reported. Photophobia has occurred. Occasionally corneal clouding, stippling and small punctate defects in the corneal epithelium have been observed. The punctate lesions may be a manifestation of the infection.

**How Supplied:** 0.1% Ophthalmic Solution (1 mg./cc.), in 15 cc. bottles with dropper; 0.5% Ophthalmic Ointment (5 mg./Gm.) in 4 Gm. tubes.

**Stability:** The Ophthalmic Solution should be stored in refrigerator until dispensed. 'Stoxil' Ophthalmic Ointment does not require refrigeration.

# locked-in confidence

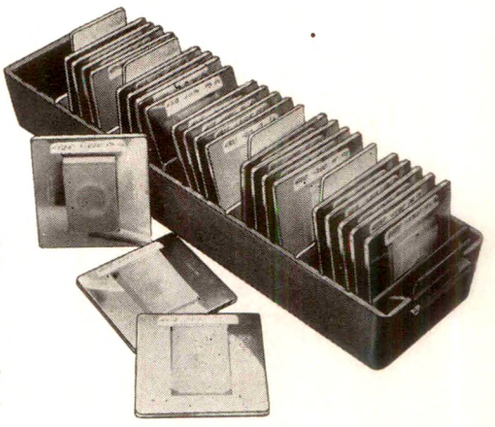
## A Closed Envelope of Compression Means Full Impact Resistance from Center to Bevel Crown

Legislation requiring impact-resistant lenses in all prescriptions is on the books in several states. A federal regulation requiring them is being considered. And with these acts comes the unsettling question of responsibility and liability for the protective lenses you dispense.

This unique and unretouched photograph shows in cross section three lenses heat-treated in a B&L Compact Heat-Treating Unit. Polarized light reveals the evenly balanced, compression-expansion stress structure that imparts so much extra strength. The continuous dark line marks the boundary between tension and compression layers. You can see that the compression layer is closed and uniformly thick; there are no openings for tension "leaks" or soft spots to give way under a tension shift.

B&L Compact Heat-Treating Unit gives you lenses with no tension "leaks."

This kind of structural uniformity is possible only with the even, low turbulence quenching of the exclusive B&L large-orifice, high air-volume process. A Compact Heat-Treating Unit produces lenses which have impact resistance far in excess of all legal or proposed standards.



Experience the confidence of dispensing the locked-in strength of lenses treated in a B&L Compact Unit. Ask your B&L Branch or B&L Distributor about this.

**Contact Lens Diagnostic Sets**

*(*As suggested in the text, Corneal Contact Lenses, Ed. by Girard, L. J., Sampson, W. G., Soper, J. W.— C. V. Mosby Co.)*

A set of optically perfect (Modern Arc inspected) diagnostic corneal lenses — each lens is finished in exacting reproducible detail.

Invaluable for:

1. Eliminating vertex distance errors.
2. Evaluating best visual acuities in cornea disease.
3. Predetermination of lens fit.
4. Analysis of patient reaction.
5. Analysis of visual acuities in subnormal vision.

# Who says Younger Lenses are only for women?

SOCIALLY PROMINENT RIVERSIDE, CONN. RESIDENT, GEORGE LOWTHER III

"When my eyes were examined recently, I was told that I needed bifocals. Maybe I did, but I didn't like the idea . . . why show that I'm getting older?

"I mentioned this and was told about Younger Seamless Lenses. It made good sense. As long as I can see well for reading and distance, it doesn't bother *me* that there are two different powers in my lenses, *as long as they don't show!*

"Call me vain if you will, but good vision and no change in appearance were all I asked and that's exactly what I've got with my Younger Lenses.

"I'm told women ask for them and I can understand why. After all, my wife now wears Youngers and it pleases me to know that *her* age doesn't show, either. But I can't understand why more men aren't wearing them, unless they aren't told about their advantages."

**Younger Lenses are available through most independent labs and all American Optical branches . . . in glass or hard resin.**

# HARD TIMES

Although U.S. academic institutions have been able to increase their spending for scientific research and education by an average of 8% per year in 1969 and 1970, the Federal Government accounted for only 2.4% of the increase both years. In 1970 about 40% of the total support for academic science was supplied by the Government. The difference between the 2.4% increase in Federal support and the average 8% increase in expenditures was made up by funds from a combination of sources: state governments, increases in student tuition and fees, foundation grants and private gifts. In terms of constant dollars the average increase of 8% per year in spending reduces to 5%. And when increases in college enrollments (13% in the two-year period) and operating costs are taken into account, the net effective support for academic science dropped at least 5% and more likely 10% between 1968 and 1970. These conclusions were reached by the National Science Foundation after it had sent questionnaires to 104 institutions granting doctoral degrees in science and had received replies from 662 science departments.

The hardest hit were large universities and private institutions, which were able to increase their science budgets by only 4% in the fiscal year 1970, compared with an average increase of 8.5% for all institutions and 10.9% for state universities. Overall the departments reporting the smallest increases in 1970 were physics and electrical engineering (1%), biological sciences and microbiology (4%), and biochemistry and sociology (6%). The departments with the largest increases were psychology (12%) and economics (16%). Nearly a third of the responding institutions said their life-science departments were most seriously hurt by the loss of Federal funds. Twenty-one percent said physics departments were most affected; 19% cited chemistry departments.

The number of teachers and postdoctoral fellows increased by only about 3.7% in 1970 as against 6.5% in 1969. The number of graduate students fell by somewhat less than 1% both years, except that the number supported by Federal funds dropped by 2.7% in 1969 and 5.1% in 1970. In the field of mathematics the number of graduate students supported by the Federal Government fell by 9.8% both years.

## NO MORE ACCIDENTAL ADHESIONS!

ONCE YOU GRASP THE LENS, AT NO TIME DOES THE IRIS OR ANY OTHER TISSUE ADHERE TO THE PROBE, EVEN WHEN THERE IS DIRECT CONTACT!. THIS EXCEPTIONAL ADVANTAGE IS DUE TO ITS SPECIALLY DESIGNED TIP.

OTHER IMPORTANT ADVANTAGES:

- Thin tip (2.75 mm.) with special shape for better visibility.
- Light weight (11 g.) Just like your ball pen.
- Heat - resistant, so it can be autoclaved repeatedly.
- Durable, it can be used a great number of times.
- Rechargeable, uses gas *"FREON" 12; commercially available.
- Low price.

# ALL CHLOROPTIC PRODUCTS ARE STERILE.. GUARANTEED STERILE.

## WHY ACCEPT LESS?

*The mark of guaranteed sterility.

In 1968, CHLOROPTIC® (chloramphenicol) brought ophthalmic chloramphenicol out of the dark ages with the introduction of the first ready-to-use solution. For the first time, physicians and patients were offered guaranteed sterility, laboratory-controlled potency, greater stability, and greater convenience. We didn't stop there...In 1970, Allergan introduced the first ophthalmic ointments guaranteed sterile with a tamperproof seal... CHLOROPTIC® (chloramphenicol) and CHLOROPTIC®-P (chloramphenicol-prednisolone). The potential risk of contaminated chloramphenicol ophthalmic ointments has been eliminated.

# *New. POLYSPECTRIN™ PRODUCTS ARE STERILE... GUARANTEED STERILE.

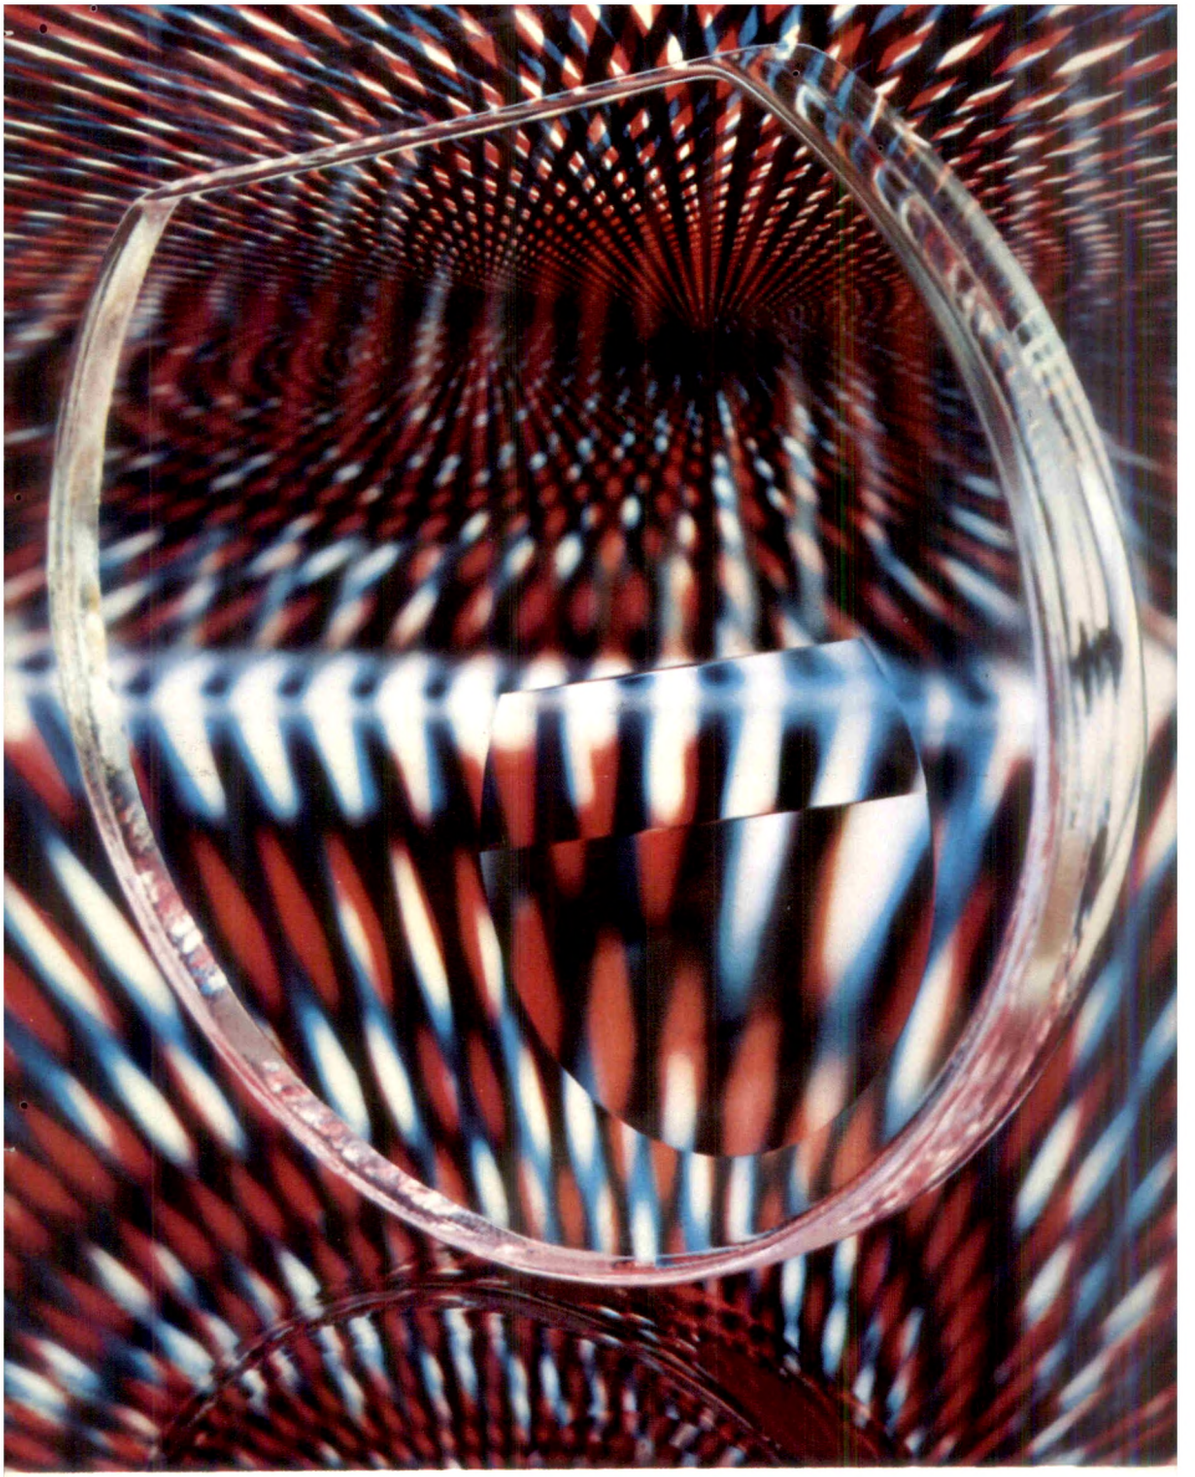
## WHY ACCEPT LESS?

*The mark of guaranteed sterility.

The first combination antibiotic regimen guaranteed sterile with a tamperproof seal.

ALLERGAN

Irvine, California / Montreal, Canada



Rapid de-frost is important. The surgeon needs that element of control in retinal detachment procedures and in cataract operations. Its importance increases with every additional "plus feature" that the Amoils system employs with it. The Amoils System is a complete system with due emphasis on safety, efficiency, economy, simplicity and performance. All the pencils are light and manoeuvrable but lose no strength or robustness because of it. They are all flash autoclavable. Accidental adhesions are eliminated because the pencils are applied warm to tissue before freezing starts. The Amoils Ophthalmic Cryo Unit is important because of its superiority, and it's superior because of the unique combination of individual features, like rapid de-frost.

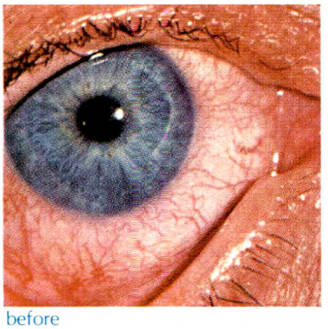
# A singular new antibiotic for the eye that works the way you think it should

## GARAMYCIN® brand of GENTAMICIN SULFATE OPHTHALMIC SOLUTION/OINTMENT

Each cc. or gram contains gentamicin sulfate equivalent to 3.0 mg. gentamicin.

## You think it should have a wide antibacterial spectrum

GARAMYCIN's wide range of antibacterial action is equal to the spectrum commonly prescribed in the combinations of neomycin, polymyxin and bacitracin or gramicidin in the treatment of external eye infections due to susceptible organisms. It has activity against a wide variety of both gram-positive and gram-negative organisms, including the "difficult" ones—*Pseudomonas aeruginosa* strains and Proteus.



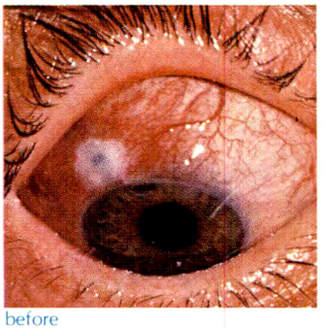
## You think it should be a single entity antibiotic

GARAMYCIN is a single entity antibiotic with a low incidence of sensitization or resistance*—can be used repeatedly with continued effectiveness, less concern about allergic potential (*Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.)

## You think it should be clinically effective

GARAMYCIN OPHTHALMIC has been described as appearing to be "...an antibiotic of choice for the initial treatment of external ocular infections."[1] It has "proved highly effective...for a wide variety of common bacterial eye infections..."[2] (due to susceptible organisms).
(1. Gordon, D.M.: Amer. J. Ophthal. 69:300 [Feb.] 1970. 2. Magnuson, R. H., and Suie, T.: JAMA 199:427 [Feb. 6] 1967.)

In acute catarrhal conjunctivitis and episcleritis† due to *Staphylococcus aureus* coagulase negative

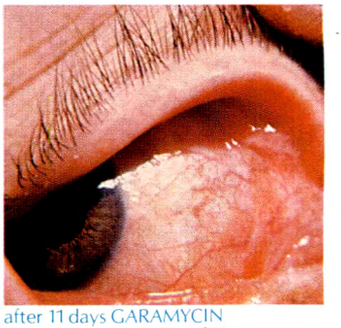


before

after 7 days GARAMYCIN OPHTHALMIC SOLUTION

In infected bleb (post-glaucoma surgery)† due to *Staphylococcus aureus* coagulase negative and *Streptococcus viridans*

before



after 9 days GARAMYCIN OPHTHALMIC SOLUTION

In acute conjunctivitis and dacryocystitis†† due to pneumococcus

after 7 days GARAMYCIN OPHTHALMIC SOLUTION

after 11 days GARAMYCIN OPHTHALMIC SOLUTION

# New GARAMYCIN® ophthalmic

brand of GENTAMICIN SULFATE SOLUTION/OINTMENT

†Photographs courtesy of D. Gordon, M.D., N.Y. ††Photographs courtesy of S. Fox, M.D., Baltimore, Md.

# You think it should have flexibility in dosage forms

GARAMYCIN OPHTHALMIC SOLUTION, sterile, isotonic, and buffered to pH of tears, does not blur vision, is well suited to daytime use—supplied in an unbreakable, easy-to-handle dispenser.

GARAMYCIN OPHTHALMIC OINTMENT provides gentle emollient action and keeps medication in contact with tissues for longer periods. It is particularly advantageous for nighttime use or in non-ambulatory patients—supplied in easy-to-use ophthalmic tube.

## Clinical Considerations

**Description:** GARAMYCIN is a bactericidal antibiotic of the aminoglycoside group active against a wide variety of pathogenic gram-negative and gram-positive bacteria.

GARAMYCIN Ophthalmic Solution is a sterile aqueous solution buffered to approximately pH 6.7 for use in the eye. Each cc. contains gentamicin sulfate (equivalent to 3.0 mg. gentamicin), disodium phosphate, monosodium phosphate, sodium chloride, and benzalkonium chloride as a preservative.

GARAMYCIN Ophthalmic Ointment contains, in each gram of ointment, gentamicin sulfate (equivalent to 3.0 mg. gentamicin), and methylparaben and propylparaben as preservatives in a bland base of clear petrolatum.

Although significant resistance in organisms isolated from patients treated with gentamicin has not occurred at the present time, this may occur in the future as resistance has been produced with difficulty *in vitro* by repeated exposures.

**Indications:** GARAMYCIN Ophthalmic Solution and Ointment are indicated in the topical treatment of infections of the external eye and its adnexa caused by susceptible bacteria. Such infections embrace conjunctivitis, keratitis and keratoconjunctivitis, corneal ulcers, blepharitis and blepharoconjunctivitis, acute meibomianitis, and dacryocystitis.

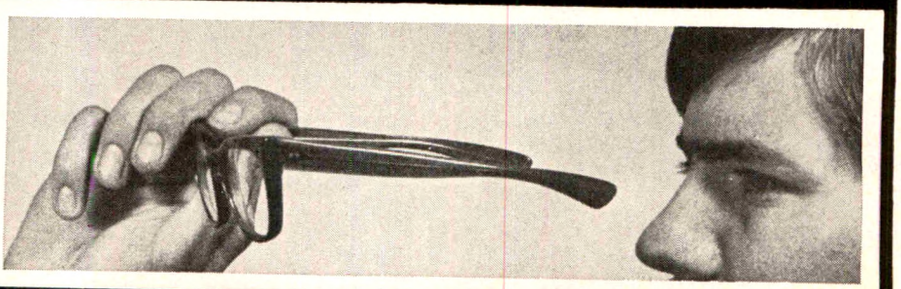
**Contraindications:** GARAMYCIN Ophthalmic Solution and Ointment are contraindicated in patients with known hypersensitivity to any of the components of these preparations.

**Precautions:** Prolonged use of topical antibiotics may give rise to overgrowth of nonsusceptible organisms such as fungi. Should this occur, or if irritation or hypersensitivity to any component of the drug develops, discontinue use of the preparation and institute appropriate therapy.

**Dosage and Administration:** GARAMYCIN Ophthalmic Solution: One or two drops every four hours. In severe infections, dosage may be increased to as much as two drops once hourly.

GARAMYCIN Ophthalmic Ointment: Apply a small amount to the affected eye two to three times daily.

**How Supplied:** GARAMYCIN Ophthalmic Solution, 5 cc. plastic dropper bottle, sterile, box of 1. GARAMYCIN Ophthalmic Ointment, 1/8 ounce tube, box of 1.



Note: Store away from heat.

Schering

SCHERING CORPORATION, UNION, NEW JERSEY 07083

# SHIELD OR HAZARD...?

ARMORLITE, INC. - IMPACT RESISTANT LENSES FOR EVERYONE

# Control cost as well as pressure

Patients will welcome the economy of Pilocar Twin Pack. An especially important consideration for the glaucoma patient who must use pilocarpine month after month. You'll welcome the therapeutic flexibility afforded by the wide range of available potencies. Good reasons to prescribe Pilocar Twin Pack when initiating pilocarpine therapy or changing potency.

**COMPOSITION:** Pilocar Twin Pack Ophthalmic Solutions are buffered, isotonic, stabilized solutions of Pilocarpine Hydrochloride and Hydroxypropyl Methylcellulose. The solutions are available in concentrations of ½%, 1%, 2%, 3%, 4% and 6% Pilocarpine Hydrochloride. All the concentrations, in addition to the respective amount of the Pilocarpine, contain:

Hydroxypropyl Methylcellulose .....0.33%
Benzalkonium Chloride .....0.01%
Disodium Ethylenediamine Tetraacetate ..0.01%

In an aqueous isotonic, buffered, stabilized solution containing potassium chloride, boric acid and sodium carbonate.

**INDICATIONS:** As a miotic in the treatment of Glaucoma, more specifically, the chronic simple Glaucoma of the open angle type. While the closed angle Glaucoma differs completely from the open angle Glaucoma, Pilocar Ophthalmic may be used to relieve the tension in patients seen early, during hospital diagnostic tests and prior to surgery.

The most prevalent clinical application for Pilocar is in the treatment of Glaucoma Simplex (open angle or chronic Glaucoma). Pilocar acts as a miotic to contract the pupil and reduce the intraocular pressure, thereby attaining the desired relief.

In acute Glaucoma, the objective aims at opening the anterior chamber to lower intraocular pressure by medical means, i.e., Pilocar, for at least 12 hours prior to emergency surgery.

**DOSAGE AND ADMINISTRATION:** The initial dose is one or two drops. This is repeated up to six times daily depending on individual response. During acute phases, the miotic must also be instilled into the unaffected eye, as it may be subject to an attack of angle closure Glaucoma.

The frequency of instillation and the concentration of the Pilocar depends on the severity of the Glaucoma and response of the patient. The Ophthalmologist must ascertain just how much miotic is necessary for each individual patient, in much the same way that the Physician determines how much insulin is necessary to stabilize a patient's diabetes. The most widely used concentrations are the 1% and 2%.

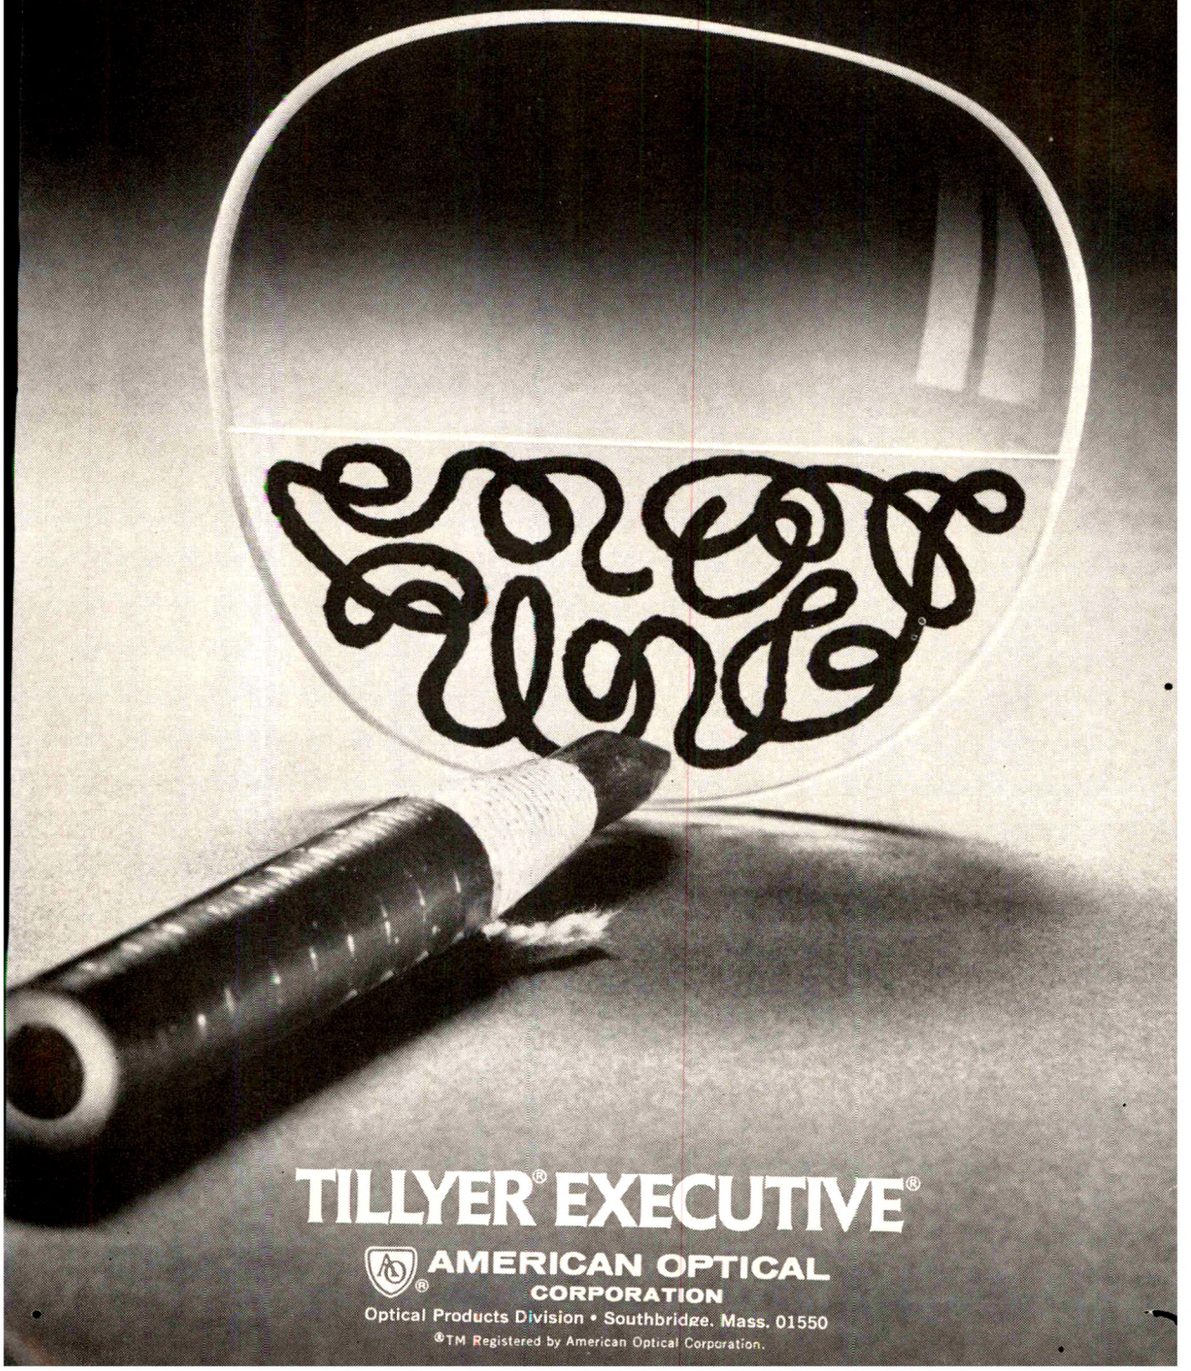
**CRITERIA OF EFFECTIVENESS:** Treatment is continued as long as the intraocular pressure is controlled and there is no visual deterioration as indicated by changes in the visual fields. If the pressure tends to be on the high side or normal and there is no change in the visual fields, patients may be maintained on the miotic therapy indefinitely. No patient should use more of the miotic drug than is necessary to satisfactorily control the pressure.

**CAUTION:** Federal law prohibits dispensing without prescription.

**FOR TOPICAL OPHTHALMIC USE ONLY:** If irritation persists or increases, patients should be advised to discontinue use and consult a physician.

Pilocar Ophthalmic Solutions are sterile when packaged. To prevent contaminating dropper tip and solution, care should be taken not to touch the eyelids or surrounding area, or other areas with the dropper tip of the bottle. Keep bottle tightly covered when not in use.

**HOW SUPPLIED:** Two 15 cc. polyethylene dropper-tip bottles—½%, 1%, 2%, 3%, 4% and 6% concentrations.



**Smith, Miller & Patch, Inc.**
401 Joyce Kilmer Ave., New Brunswick, N.J. 08902

If irritation persists or increases, discontinue use. *Dosage and Administration:* one to two drops instilled in each eye every three to four hours or less frequently, as required to relieve symptoms. *How supplied:* Albalon™ is available in 15 cc. plastic dropper bottles on prescription only.

*from an independent study conducted on a controlled population; data on file, Allergan Research Department.

# LAST YEAR W TOLD YOU ABOUT THE "PRESSURE-SPARING" EFFECT OF HMS...

(medrysone)

# ...APPARENTLY YOU WANT TO KNOW MORE.

# SO TAKE THIS NEW LOOK AT HMS.

Drawing on nearly seven years of extensive clinical research experience, let's consider those questions you have asked most frequently.

### "Is HMS too mild to benefit my patients with inflammatory conditions?"

In the past five years, numerous independent studies on HMS (medrysone) have been published including those by Becker, and Thygeson.[1-4] Virtually all have reached the same conclusions: HMS is an effective treatment for superficial ocular inflammations.

Additionally, in a recent survey, 76% of the ophthalmologists interviewed who had tried HMS, found it effective when used for the recommended conditions.[5]

### "What therapeutic possibilities are now open to me, with HMS, that were not available with other mild steroids?"

First, over 30% of the population is likely to respond to steroids with an intermediate to high increase in intraocular pressure; steroid use with these patients must therefore be selective and cautious.[6] With HMS, most of these patients now can safely receive long-term steroid treatment.

Secondly, there are those glaucoma patients who must be treated specifically with epinephrine but are nevertheless sensitive to this drug. With HMS as concomitant therapy, Becker and Kolker reported that there was "sufficient improvement in glaucoma control so as to avoid surgery" by allowing continuation of epinephrine therapy.[7]

### "I haven't seen a rise in IOP with mild steroids. Isn't the real concern with the more potent steroids?"

There is ample evidence that .1% dexamethasone produces significant increases in IOP[1,4,8], and even .12% prednisolone, the mildest of the commercially available ophthalmic steroids, has the potential to increase IOP. Conversely, Doctors Becker and Kolker found in their investigational study that "medrysone (HMS) can be administered to patients four times a day for periods of several months with essentially no elevation of intraocular pressure even in individuals highly susceptible to such elevation."[7]

### "Can I treat uveitis and iritis with HMS?"

It is *not* indicated for these conditions. Its merits should only be judged in those conditions where indicated: allergic and vernal conjunctivitis, episcleritis, and epinephrine sensitivity.

### "Is HMS uncomfortable for the patient to use?"

Results of a recent patient study showed that 96% of those tested found HMS completely comfortable in the eye.[9] Though early batches of the product did cause some minor irritation to the eyes of a few patients, this has not been a recurring problem.

HMS® (medrysone)
LIQUIFILM® OPHTHALMIC SUSPENSION

ALLERGAN

Please see next page for Prescribing Information.

## Prescribing Information for

# HMS®(medrysone)

LIQUIFILM® OPHTHALMIC SUSPENSION

DESCRIPTION: Contains:
medrysone.....1.0%
Liquifilm® (polyvinyl alcohol).....1.4%
with: benzalkonium chloride, disodium edetate, sodium chloride, potassium chloride, sodium phosphate monobasic monohydrate, sodium phosphate dibasic anhydrous, methylcellulose, purified water, and sodium hydroxide or hydrochloric acid if needed to adjust pH. HMS (medrysone) is related structurally more to progesterone than to other available corticosteroids.

INDICATIONS: HMS (medrysone) is effective in the treatment of allergic conjunctivitis, vernal conjunctivitis, episcleritis and epinephrine sensitivity. HMS (medrysone) is not indicated in iritis or uveitis as its therapeutic effectiveness has not been demonstrated.

CONTRAINDICATIONS:
HMS (medrysone) is contraindicated in the following conditions:

1. Acute untreated purulent ocular infections.
2. Acute herpes simplex (dendritic) keratitis.
3. Viral diseases of the conjunctiva and cornea.
4. Ocular tuberculosis.
5. Fungal diseases of the eye.
6. Hypersensitivity to any of the components of the drug.

WARNINGS:

1. Infectious diseases of the eye may be masked, enhanced or activated by steroids.
2. Corneal or scleral perforation occasionally has been reported with prolonged use of topical steroids. In high dosage they have been associated with corneal thinning.
3. Prolonged use of topical steroids may increase intraocular pressure although data from 2 uncontrolled studies[4,7] indicate that in patients with increased intraocular pressure and in those susceptible to a rise in intraocular pressure upon application of topical steroids, there is less effect on pressure with HMS than with dexamethasone or betamethasone.
4. Prolonged use of topical corticosteroids may rarely be associated with development of posterior subcapsular cataracts.
5. Systemic absorption and systemic side effects may result with the use of topical steroids.

PRECAUTIONS:

1. HMS (medrysone) is not recommended for use in iritis and uveitis as its therapeutic effectiveness has not been demonstrated in these conditions.
2. With prolonged use of HMS (medrysone) the intraocular pressure and lens should be examined periodically.
3. In persistent corneal ulceration where a steroid has been used, or is in use, fungal infection should be suspected.
4. The use of topical steroids in pregnancy should be limited to conditions serious enough to warrant such treatment, so that possible risk to the fetus may be justified by the expected benefit to the mother.

ADVERSE REACTIONS: Occasional transient stinging and burning may occur on instillation.

DOSAGE AND ADMINISTRATION: One drop instilled in the conjunctival sac up to every four hours.

SUPPLY:
As a 5 cc. sterile suspension in plastic dropper bottles on prescription only.

NOTE: Bottles filled to one-half capacity for proper drop control. Do not freeze.

# JAVAL-SCHIOTZ OPHTHALMOMETER —HAAG-STREIT

The Javal-Schiotz Ophthalmometer is in great demand for the fitting of contact lenses. It provides quick and accurate measurements of the corneal radius of curvature, the refractive power, and the direction of the principle meridians. Its range extends from 5.5 to 11 mm., or from 30 to 60 diopters. Two readings—the radius of curvature in millimeters and the refractive power in diopters — can be made on the two graduated scales of the arc. The use of complementary colors, which when superimposed on each other produce white light, enables the observer to focus very accurately. If desired, color glasses can be removed for work with white images.

Unusual luminous fixation point can be easily seen even by patients with poor vision. New dual-purpose "joystick" focusing control simplifies and speeds up positioning of the instrument in all directions.

**H5500-950** — Javal-Schiotz Ophthalmometer on spring-balanced table #1000, with head and chin rest, transformer, 7.5 mm. testing ball, chin rest papers, 10 bulbs 6V, breath shield and cover. . . . . $940.00

**H5500-951** — Javal-Schiotz Ophthalmometer, Unit Model. . . . . $705.00

# LENSOMETER® lens measuring instrument

The Lensometer is a meter or instrument designed to measure the power of a lens when light enters the lens in parallel rays. It gives the power in dioptric values. The basic optical design of Lensometer instruments is almost fifty years old. But the function and limitations are still often misunderstood.

The Lensometer instrument is very accurate in checking the power of a single-vision lens or the distance portion of a multi-focal lens. However, when checking the power of a bifocal addition, it is important to understand the limitations of the Lensometer instrument.

When you refract, you first determine the patient's requirements for comfortable distance vision. You then add to his correction the amount of plus power required for comfortable near vision. This requirement is for vision at 13″ to 16″—*and the rays of light as they come from this near image to the eye are divergent.*

Your prescription, as it is written, indicates that you have given your patient a certain amount of power for distance. And then added a plus lens for near vision. When the prescription has been made up, it should be checked on the Lensometer instrument to make sure the Rx is what you ordered for your patient.

Therefore, you check the Rx with the convex side of the lens toward you. The Lensometer instrument will give a true and accurate reading for the distance portion. But if you check the power through the segment—without reversing the lens in the instrument—the difference between the distance power and the power through the segment will not always equal the power you prescribed as an addition.

This is because the segment of the lens is being measured for use at infinity. Whereas you prescribed the addition for use at near, with rays divergent rather than parallel.

To make sure you get what you prescribe, you must check the addition by reversing the prescription in the Lensometer instrument and checking the power of the lens through the segment as compared with the power of the lens at an equal distance above the optical center. This will enable you to determine if the plus lens you prescribed for an addition is duplicated in the Rx.

When improperly checked, the power of the addition can vary anywhere from .09D to .37D from what your Rx called for (depending upon the power and thickness of the distance lens).

It's inconvenient to reverse the lens to determine the power of the addition. But it's the only way to determine the true value of the Rx. And it's the *only* way to make sure that your patient gets the quality lens that you prescribed.

# 18 new ways to treat patients: 18 new Press-On™ Lenses

These eighteen new lens powers dramatically extend the treatment capabilities with Press-On Optics by OSG. The 1mm-thin membranes now range in power from +1D through +20D, including popular fractional diopters. All are lightweight, apply in minutes, are cosmetically attractive and optically outstanding.

With the new powers, Press-On Lenses can now provide help:

**For Post-Operative Cataract Patients . . .**
by permitting immediate post-op wearing of an aphakic correction in their own familiar spectacles . . . by providing aspheric correction with the widest panoramic field of view available

**For Low Vision Patients . . .**
by applying needed power to the ocular surface of even large diameter high fashion frames . . . by providing a large diameter bifocal field not previously available above +3.5D . . . by using as regular bifocal segments up to +6D while providing sufficient decentration to obtain binocular fusion

**For Patients with Vocational Demands . . .**
by meeting unique gaze requirements of librarians, dentists, carpenters, etc. with specially located power segments . . . by providing extra magnification for fine work of jewelers, machinists, inspectors and others . . . by supplying an added safety "laminate" to the ocular surface of a regular spectacle lens . . . by making hyperopic spherical corrections to the inside surface of welders' or machine operators' goggles . . . by adding immediate spherical power to industrial safety glasses for faster on-the-job utilization of new personnel.

**For Patients with Special Hobbies . . .**
by providing out-of-the-way or high-power segments for hobbyists and sportsmen, such as golfers, bowlers, stamp collectors, model builders, fly tyers, etc. . . . by making hyperopic spherical correction to the inside surface of skiers' or skin divers' goggles

**For Bifocal Patients . . .**
by allowing use of higher power segment in various sizes, shapes and positions not previously possible . . . by helping beginning presbyopes establish acceptance of bifocal correction on existing single vision spectacles . . . by creating an intermediate range over existing bifocals for new trifocal wearers before grinding in glass or plastic . . . by converting single-vision sunglasses, including Polaroid and Photochromic, to bifocals . . . by providing segments usable on large size fashion frames

New Press-On Lens plus powers—1D through 8D and 14D through 20D—supplement the 9D through 13D lenses originally introduced by OSG. All are available from an ophthalmic distributor near you. For more information about the Press-On Lens System contact your local distributor or write, Optical Sciences Group, Inc., 24 Tiburon Street, San Rafael, California 94901.

*with a contact lens insurance program that has been thoroughly tested for 10 years...*

# RLI insures "soft" contact lenses

RLI began preparations for the new soft contact lens years ago. Yes, that's right! RLI's regular contact lens protection program has been years ahead of its time. Our program and its systems have been thoroughly and successfully tested by the ophthalmic profession for ten years. This is your assurance of simplicity, reliability and integrity for you and your contact lens patients. Its many easy operating features, low premium cost, the highly effective recall system are immediately adaptable to the new soft contact lens situation.

We have made one significant change for soft contact lens wearers. RLI has strengthened the automatic recall system by adding a **six month recall** regardless of the term of the patient's policy. This means that your soft contact lens patients will receive a reminder to have their eyes examined and/or lens inspected **every six months.**

This six month recall for soft contact lens wearers will be available through both our regular, and the Rx 6/12 laboratory programs.

For further information about RLI's regular and soft contact lens insurance program, contact RLI today!

# Who's Out of Date?

Doctors are increasingly being blamed for not bringing to their patients enough of the benefits of recent medical progress. Overwork, isolation and frank lack of motivation are cited as contributing toward an inability to keep up to date. Rarely is it suggested that a substantial amount of the trouble might be due to our system of medical education.

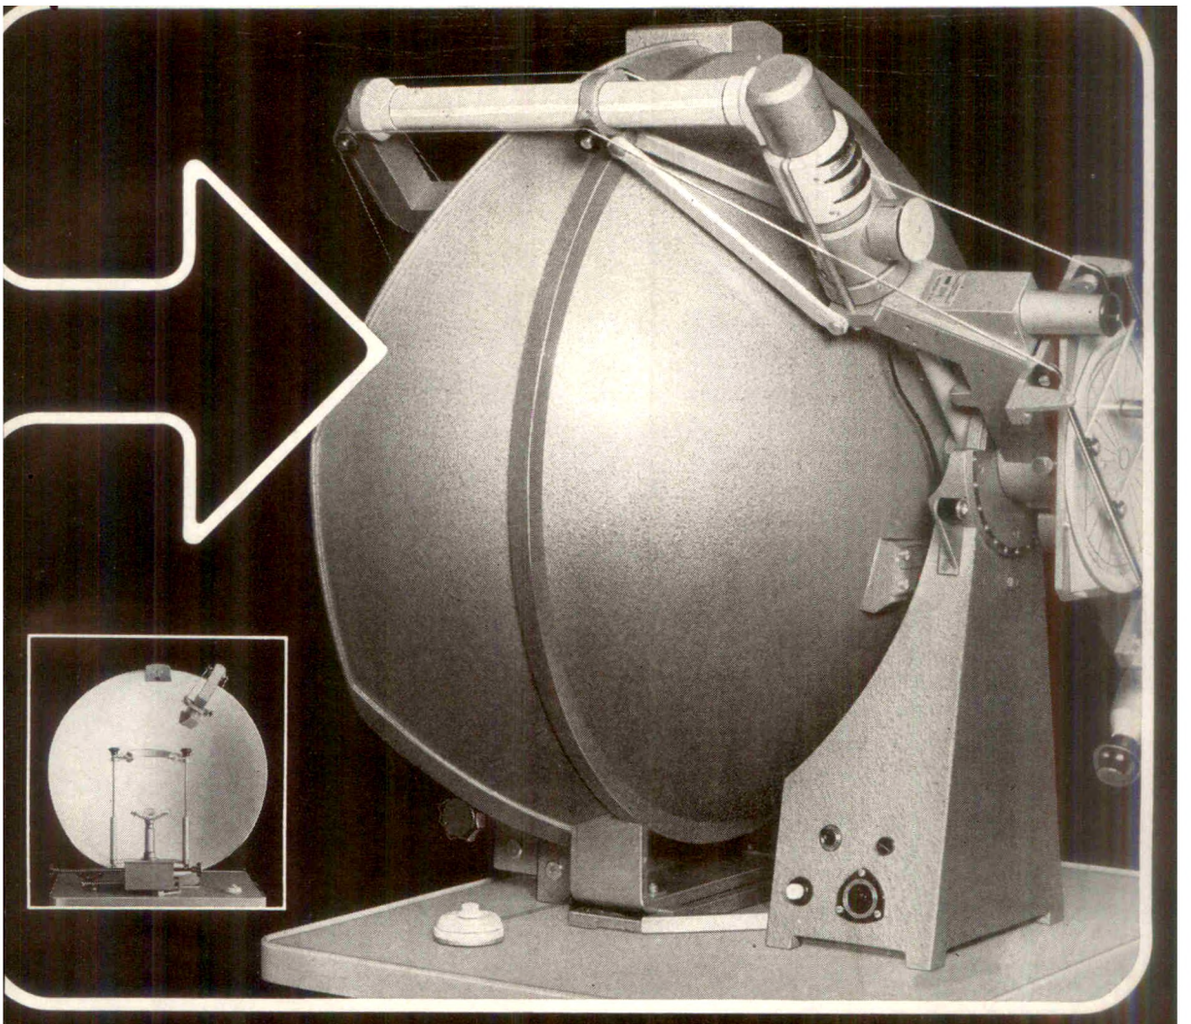
The fact is, however, that the accelerating accumulation of scientific knowledge has made our style of medical education as out of date as its oldest products, and with less awareness in the universities than in the remotest doctor's office. The amount of information now both available and necessary for proper patient care has grown far beyond the ability of any person to carry in his head. Despite any disclaimers to the contrary, the vast apparatus of American medical education has not accepted that fact and continues with what it perceives as its mission of programming its graduates with sufficient information for a lifetime of practice in some specialty. The chief instrument for enforcing this self-defeating demand for memorization on students and house officers (and the chief evidence of that demand) is our elaborate hierarchal test complex. As presently constituted, the tests given by the National Board of Medical Examiners and all the major specialty boards limit the information a candidate may use to what he carries into the hall in his head. Most medical-school tests do the same thing.

After eight years of such tests it is small wonder that the average graduate adopts a style of practice in which all the information he uses is what he can remember. Yet, as unconscious of what they are doing as the most mindless of L.M.D.'s, medical educators persist in writing the same prescription over and over, ordering bigger and bigger doses of the same medicine, despite the obvious signs that it is not working and the patient has had far too much already.

What are some of the effects of clinging to this outmoded concept of medical education?

The first is on the student. The requirement to commit facts to memory has long been recognized as taking much of the fun out of medical school and to a degree out of residency. Worse than that, it severely limits the scope of what is taught. For example, the amount of factual data that can be memorized for the first part of the National Boards seems not to represent the best possible scientific preparation for a career that will be at its peak in the year 2000. On the wards, patient care and the development of clinical skills and judgment suffer while attending professors deliver extemporaneous board-oriented lectures.

The second effect is on the doctor. Many of our best men pay a terrible personal price in a fore-doomed struggle to "keep up." There are many doctors' wives who will testify that, next to the telephone, it is the stack of unread journals on their husbands' desks that most intrudes on what should be evenings spent in a happy domestic relation. The journals are either being read or worried about, in either case casting a discouraging spell on the evening. Journal reading becomes a joyless exercise, with the reader racing for speed and retention and wondering if he should take a course in speed reading, if only he could find the time for it.



Finally, and most importantly, is the effect on the problem patient and his chances of getting the best possible care. An enlightening study* of a doctor's day clocked the minute-by-minute activities of 20 internists and general practitioners. There was not a single notation suggesting that any one of the 20 stopped to look up anything pertaining to any one of the patients he saw during an entire week. Clearly, some patients were being shortchanged.

If we are to train doctors who will do better than this, we must shift our emphasis toward the skillful obtaining of information rather than on its retention. The whole fabric of medical education must be altered to emphasize that different orientation. One of the first things to be changed must obviously be the tests. Most written tests, including those of the specialty boards, could well be taken to the library before being returned. The passing grade might be moved close to 100 per cent, and candidates given two or three chances to pass. Oral examinations could be similarly modified to allow the candidate an appropriate search for information. Instruction should be at more basic levels than at present and designed to help promote a critical understanding of specific articles. There should be further emphasis on training the student to develop judgment in when to turn to the library for help, skill in using available sources of information and retrieval, and a discriminatory critical taste in reading the medical literature.

Graduates of such a system should do much better than present ones in making effective use of the information that will come to be available at an increasing rate over their lifetimes.

Now Alcon introduces...

all the advantages in extraocular use that BSS™ provides in intraocular surgical use

# Eye-Stream™

balanced salt irrigating solution

**physiologically balanced**—unlike other external irrigating solutions EYE-STREAM is a balanced salt solution (cytophilic), containing the seven principal ionic species found in the fluid that bathes internal ocular tissues.
**and it is ready-to-use**—anytime and anywhere: office, clinic, emergency room, home. Just twist the cap, squeeze the plastic dispenser bottle (one hand will do it), and EYE-STREAM goes to work.
**assured sterility and stability**—the EYE-STREAM solution as contained in the bottle is sterile; preservative protects against contamination after the bottle has been opened.

this versatile ophthalmic irrigating solution
**washes out** foreign bodies, mucus secretions, fluorescein, chemicals
**cleans up** after goniometry, tonometry, office surgery, contact lens fitting and all without irritating delicate ocular tissue

*and for all intraocular surgical use...*
*BSS™ (Balanced Salt Solution, Alcon®)*

**Available:** 1 fluid ounce and 4 fluid ounce sterile plastic dispenser bottles. **Ingredients:** Sodium chloride, potassium chloride, calcium chloride, magnesium chloride, sodium citrate, sodium acetate, purified water. **Preservative:** Benzalkonium chloride 0.01%. **Directions:** Flush eye(s) as needed, controlling flow rate by pressure on bottle. **Warning:** Keep container tightly closed. Do not touch dispensing tip to any surface since this may contaminate solution. **Not for injection**

# THE STRUCTURE AND FUNCTION OF EXTRAOCULAR MUSCLE— AN APPRAISAL OF THE DUALITY CONCEPT

THE GIFFORD MEMORIAL LECTURE*

GOODWIN M. BREININ, M.D.

*New York, New York*

Ophthalmic physiologists have long been intrigued by the observation that the different types of eye movement have characteristically different time courses ranging from the extremely rapid to the very slow.[1] Fast saccadic, or version (phasic) movements may reach a speed of 400-600 degrees per second, requiring only milliseconds for completion, while slow vergence (tonic) movements in the order of 10-20 degrees per second may require up to a second for completion. This duality of function has led to the postulation of an underlying dual anatomic and physiologic mechanism described in a landmark paper by Hess and Pilar,[2] 1963. Considerable evidence has been adduced from anatomic, pharmacologic, and physiologic studies to support this concept. Rapidly proliferating experimental data, however, now indicate a vastly more complex organization than was initially thought to be the case. The suggestion that a system involving both somatic and autonomic elements accounts for the rapid and the slow movements respectively (Alpern and Wolter,[1] 1956) has not been substantiated.

From the Department of Ophthalmology, New York University School of Medicine. This study was supported in part by Grants EY00191-13 and EY00309-05 from the National Eye Institute.

* Presented before the Chicago Ophthalmological Society on May 22, 1970.

Reprint requests to Goodwin M. Breinin, M.D., Department of Ophthalmology, New York University School of Medicine, 550 First Avenue, New York, New York 10016.

## ANATOMY

Extraocular muscle of man and most animals contains both extrafusal (motor) fibers and intrafusal (spindle) fibers. The latter have not been seen in extraocular muscle of rabbit, cat, and dog but do occur in primates.

The organization of extraocular muscle into small-diameter and large-diameter extrafusal muscle fibers has long been known (Kato,[3] 1938). On the basis of fiber histology the former have been called "felderstruktur," and the latter "fibrillenstruktur" in the terminology of Kruger,[4] 1949, and Kruger and Gunther,[5] 1955. Felderstruktur refers to the fieldlike appearance of the small fiber in cross section with poor, irregular demarcation and separation of the myofibrils by the very scanty sarcoplasmic reticulum. The fiber is considered to be slow or tonic. Fibrillenstruktur refers to the fibrillar appearance of the large fiber in cross section with well-demarcated myofibrils surrounded by an abundant sleeve of sarcoplasmic reticulum. This is the typical twitch or fast fiber. The slow fiber has been most extensively studied in the frog "tonus bundle." Kruger's terminology has proved popular although with increasing information (Zenker and Anzenbacher,[6] 1964), the distinction between the two types begins to blur.

The earliest physiologic studies of the two fiber types were also carried out in amphibia —by Tasaki & Mizutani,[7] 1944, in the toad, and by Kuffler and Vaughan Williams,[8,9]

1953, in frog iliofibularis. The twitch fiber of extraocular muscle closely resembles the twitch fiber of skeletal muscle. It receives innervation from large diameter motor nerves (alpha range) and exhibits one or two motor end plates resembling the "en plaque" ending with many post-junctional folds. The tonic fiber of extraocular muscle has no counterpart in the peripheral skeletal musculature of mammals although it is also present in the stapedius and tensor tympani muscles of the middle ear. It bears resemblance to the tonic fiber of the frog. It receives innervation from small-diameter motor nerves (gamma spectrum) and exhibits nerve endings distributed along its length resembling the multiple "en grappe" endings. These lie in apposition to the sarcolemma with few or no post-junctional folds. There is good evidence that muscle fibers with distributed innervation receive nerve fibers from more than one nerve cell (polyneuronal), a quite unique situation giving rise to the possibility of a variety of methods of control and response. The exact locations and relations within the ocular motor nuclei of the cell bodies of nerves supplying twitch and slow (tonic) fibers are not yet known.

The typical twitch muscle fiber has a well delineated transverse tubular system which in association with two terminal cysterns of the longitudinal sarcoplasmic reticulum forms characteristic triads. These triads are located at the junction of the A and I bands of the sarcomere in mammals. The transverse tubule is in continuity with the surface membrane (sarcolemma) and provides a conductive pathway for the nerve action current from the fiber surface into its interior. In this way, depolarization activates the rapid excitation-contraction coupling mechanism with calcium release from the sarcoplasmic reticulum to the myofibril and its recapture by the sarcoplasmic reticulum during the repolarization phase. The actual contraction of the fiber presumably occurs by the sliding of the thin actin past the thick myosin filaments within the sarcomeres through the formation of reversible chemical bonds or bridges (sliding filament theory).

The tonic muscle fiber has few or no triads and only a rudimentary transverse tubular system. The excitation-contraction mechanism, therefore, lacks the physical basis for rapid muscle contraction. The distributed innervation is necessary for contraction of the whole fiber which occurs slowly and segmentally rather than in the rapid, all or none manner of the twitch fiber. The most recent studies of extraocular muscle suggest that between the typical twitch and slow fibers occur three other fiber types intermediate in structure, enzyme profiles and presumably function (Peachey,[10] 1969).

## Ultrastructure

Reports on the ultrastructure of extraocular muscle are in close agreement concerning some fibers but at striking variance with respect to others. In a recent conference, Peachey,[10] 1969, reviewed the literature and attempted a synthesis of these conflicting and confusing findings.

He criticized the concept that the muscle fibers run the whole length of the muscle. If they do not, then transverse sections of the muscle could show marked differences depending on the level of section (vide infra). It is also clear that there is a considerable species variation so that the fiber characteristics of rabbit, cat, dog or monkey do not correspond precisely with each other or with man. In addition, there is variability among the extraocular muscles themselves. Thus the ultrastructure of superior oblique differs from rectus and even inferior oblique. It has been noted that the levator and retractor bulbi appear to contain only twitch fibers.

It is generally agreed that a layer of small fibers invests the orbital surface of the muscle. The small fibers, however, also occur throughout the thickness of the muscle. Kern,[11] 1965, recorded in vitro acetylcholine contracture of the orbital surface layer of tonic fibers which could be readily separated in the rabbit. Miller,[12] in 1967, found the sur-

face layer to correspond with red muscle by histochemistry and its heavy content of mitochondria. He defined the central muscle mass by these criteria as white. His assumption that the surface layer is responsible for vergence and fixation while the center is used for following and saccadic movement, while intriguing, cannot be accepted as fact for reasons which will be presented later.

The structural definitions of twitch and slow fiber have been steadily changing. The large fibers which show abundant sarcoplasmic reticulum discretely separating the myofibrils; with regular, regimented Z lines; with clear-cut triads at the A-I interface of the sacromere; with well-delineated M lines, singly innervated with only one or two en plaque type endings showing numerous post-junctional folds, are accepted as twitch, fast, fibrillenstruktur fibers. The small fibers exhibiting scant sarcoplasmic reticulum with coalescent, poorly separated myofibrils; with wavy, irregular, poorly registered Z lines; with few or no triads; with absent M lines; with multiply innervated en grappe type endings showing few or no post-junctional folds are accepted as slow, tonic, felderstruktur fibers. The typical slow fiber may have heavy accumulations of mitochondria and demonstrate abundant succinic dehydrogenase enzyme activity indicating an extensive oxidative metabolism characteristic of slowly contracting muscle. The typical twitch fiber has a scanty mitochondrial concentration and an enzyme profile indicating a glycolytic metabolism characteristic of rapidly contracting muscle. Nevertheless, marked variations of morphology, mitochondrial and enzyme distribution have been reported in the extraocular muscle fibers.

After reviewing the literature, Peachey[10] has delineated five fiber types—two on the orbital surface of the muscle and three in the interior. These vary from the typical twitch and slow to markedly atypical fibers. He cautions against the easy acceptance of such terms as fast and slow; fibrillenstruktur and felderstruktur, en plaque and en grappe. That the extraocular slow fiber is indeed analogous to the frog slow fiber is in question as well as the entire present correlation of structure and function. The presence or absence of M lines may turn out to be related to fixation technique; innervation pattern (single or multiple) may also prove an unreliable criterion; fiber size is also unreliable since some fibrillen-type fibers are smaller than some felder-type fibers. Nevertheless, until more precise information and analysis is available we may be forgiven for persisting in the use of these terms for heuristic and practical reasons.

In our laboratories, Davidowitz has recently devised a method for correlating the fine structure of longitudinal and transverse sections of given extraocular muscle fibers. Specific cells may be preselected for this purpose from serial cross-sections of the entire muscle, thus making it possible to repeatedly examine the same fiber along its length.

Preliminary findings indicate that the detection of all fiber types within an extraocular muscle may require that one sample that muscle thoroughly along its length, insofar as the distribution of fiber types and their layering apparently varies considerably from origin to insertion. Even the orbital surface layer of small-diameter cells may be seen to subdivide into two layers of different fiber diameter at some portions of the muscle, while elsewhere along the surface only one or neither of these populations may appear.

If these observations are sustained it will help explain the varying reports in the literature. Of interest is a recent report by Floyd,[13] in 1970, of a previously undescribed cholinesterase-staining muscle-fiber-muscle-fiber junction in cat extraocular muscle. This adds to the complexity of fiber relationships and raises many questions of fiber function.

## Pharmacology and physiology

The pharmacologic responses of extraocular muscle have long been of great interest. Frequently cited is the unusual sensitiv-

ity of this muscle to acetylcholine, choline, and nicotine (Duke-Elder and Duke-Elder,[14] 1930, Brown and Harvey,[15] 1941). It has been shown by Breinin and Perryman,[16] 1964, that the enhanced chemical sensitivity of extraocular muscle over peripheral skeletal muscle does not hold up with the exception of the phenomenon of contracture—the sustained contraction of the muscle fiber in the absence of muscle action potentials. Drug-induced contracture constitutes a major distinction between these muscle types and has been stated to depend upon the slow, multiply innervated fibers (Kern[11] 1965) which tend to be concentrated in the outermost (orbital) surface of the extraocular muscle. The phenomenon is best seen after the use of succinylcholine, which depolarizes the muscle fibers, presumably engendering a flaccid paralysis of the twitch fiber and a contracture of the slow fiber. Contracture may produce up to one-third of the maximal tetanic tension (Bach-y-Rita and Ito,[17] 1966, Eakins and Katz,[18] 1966). Lacking the slow fiber, peripheral skeletal muscle does not show contracture to a comparable drug concentration.

It has been reported that the extraocular muscles contract with epinephrine (Eakins and Katz,[18,19] 1966-7, Sanghvi,[20] 1967). This is a debatable point, conflicting with other reports (Breinin and Perryman,[16] 1964). Neither stimulation nor paralysis of the cervical sympathetic neural chain induced or altered the response of the extraocular muscle (Brecher and Mitchell[21] 1957, Van Allen and Blodi,[22] 1960). It seems doubtful that epinephrine is a physiologic stimulant of extraocular muscle, although it may exert indirect effects producing weak contraction. The responses of extraocular muscle to cholinomimetics have been reported recently by Sanghvi and Smith,[23] 1969. They believe that the drug-induced activation of mixed muscle systems (twitch and slow) may be due to direct depolarization and contracture plus propagated membrane depolarization consequent to a drug-induced effect post- or presynaptically. The contribution of each of these routes of activation is a function of dose of the stimulant. They also found, surprisingly, that the eye muscles are less sensitive to tubocurarine than limb muscles and suggest that the slow fibers are more sensitive than the twitch fibers. These observations, however, are at variance with clinical experience in man. The authors point out morphologic, physiologic, and pharmacologic similarities of the slow muscle fiber and the slow intrafusal spindle fibers of cat.

The ability of extraocular muscle to contract very quickly reflects its organization into small innervation ratio units resulting in a very brief twitch and a high tetanus fusion frequency. The twitch time of 5-8 msec (Cooper and Eccles,[24] 1930) and the high fusion frequency (400-600°) appear based on the fast twitch fiber. The classic slow fiber has a much longer rise time (20-27 msec) and a long decay (up to 200 msec) (Bach-y-Rita and Ito,[17] 1966). It produces prolonged segmental, graded contractions rather than twitches and has a very low fusion frequency (15-25). The controversial "slow, multiply innervated twitch fiber" presumably produces an intermediate speed contraction.

The existence of a fast and slow response system in extraocular muscle of the cat was most convincingly shown by Hess and Pilar[2] in 1963. They patterned their experiments on the studies in frog by Kuffler and Vaughn Williams,[8,9] 1953, which conclusively demonstrated the existence of slow and fast nerve and muscle fibers. Tasaki and Mizutani,[7] 1944, had previously demonstrated the dual response in the toad. The fast fiber in the frog corresponds with the usual twitch skeletal muscle fiber. The slow fiber is unique and is found in muscles subserving amplexus, the prolonged grasping of male and female frogs during mating. The fibers differ in membrane potential, end-plate, and miniature end-plate potentials and particularly

in the existence of typical all-or-none, propagated action potentials (spikes) in the twitch fiber whereas only multiple, non-propagated, small junctional potentials occur in the slow fiber. The twitch fiber shows the usual non-graded contraction, whereas the slow fiber exhibits graded contractions. Hess and Pilar,[2] in 1963, used intracellular microelectrode techniques to characterize the electrophysiologic properties of the two fiber types in cat extraocular muscle. They also determined the innervation pattern and histology by both light and electron microscopy.

They found that one fiber group (twitch) had propagated action potentials averaging 80 mv. These cells had resting potentials averaging 65 mv. The end-plate potential had a rise time of 2-3 msec. A second fiber group (slow) had complex non-propagated potentials of much smaller amplitude (12-14 mv) arising from multiple sites within the fiber and exhibiting a polyneuronal origin. The membrane potential of these cells averaged 45 mv.

Miniature junctional potentials were recorded from both groups of fibers and showed a longer duration and higher amplitude in the slow fiber.

Bach-y-Rita and Ito,[17] 1966, carried out a similar study on the cat. The principal difference lay in their report that slow fibers were also able to produce propagated action currents (spikes) when suitably stimulated. In fact, the authors stress the existence of the "slow, multiply innervated twitch fiber." This has become a central point of controversy since it indicates loss of distinction between the two groups. The fiber groups, however, were differentiable by impulse conduction velocities, range of membrane potentials, amplitudes and frequencies of miniature end-plate potentials, responses to succinylcholine, frequency of stimulation required for tetanus, and by velocities of conduction of the nerve fibers innervating each of the muscle fiber types.

The existence of tonic and phasic fibers in extraocular muscle of rabbit was actually first shown by Matyushkin,[25] 1961. He clearly recorded typical fast action potentials by stimulation of phasic fibers and the slow, non-propagated potentials occurring spontaneously in tonic fibers. Similar findings in rabbit were obtained by Ozawa,[26] in 1964. Both described the occurrence of spontaneous potentials only in slow fibers, an observation of paramount interest. This correlates with reports that only small nerve fibers and related central cell bodies show spontaneous activity, whereas large-diameter nerve fibers and their central connections are silent until eye movement is called for. This has led to the inference that the constant tonic activity characteristic of the electromyogram (EMG) of extraocular muscle is a product of the slow motor system exclusively. It has also been proposed that saccadic movement is a property solely of the fast motor system whereas vergences, fixation, and pursuit movements are attributable to the slow system. The importance of these concepts to clinical ophthalmology is self-evident, but they are far too simplistic and do not fully accord with the facts.

A precise interpretation of the normal EMG of extraocular muscle still eludes us. The motor unit activity of tonic firing clearly consists of propagated spikes. These could not arise from non-propagated junctional potentials and could not be a product of the slow system unless we accept Bach-y-Rita and Ito's postulation of the slow, multi-innervated twitch fibers; hence the importance of establishing the existence and role of such spike producing slow fibers. Studies of ocular kinesiology have not shown an exclusive role for either twitch or slow fibers—in fact, both systems appear implicated in all movements but may differ in the degree to which they are involved. It seems reasonable to suppose that the fast system plays the predominant role in saccades, whereas the slow system is primarily involved in vergence, fixation, and perhaps pursuit, providing the

sustained and steadying features of such movements. The seductive charm of this reasoning, however, must not lead us to premature conclusions. Nothing is yet established in fact. These considerations have led to more rigorous efforts to establish the electrophysiologic characteristics of the slow fiber system. Pilar,[27] 1967, analyzed electrical and mechanical responses of the cat superior oblique slow fiber. He convincingly demonstrated that under a variety of conditions the slow fibers respond with graded contractions and without propagated overshoot potentials. He pointed out sources of error in Bach-y-Rita and Ito's arguments for the slow, multiply innervated twitch fiber. The classic slow and fast systems are given strong support by his paper. Ozawa, Cheng, Davidowitz, and Breinin,[28] 1969, reported a combined physiologic and morphologic study of potentials and fiber type in extraocular muscle. EMG potentials were recorded simultaneously with spontaneous intracellular multifocus slow potentials, using computer and optical techniques. EMG potentials clearly synchronous with the spontaneous intracellular potentials were found to be monophasic and at least 4 msec in duration—clearly different than spike potentials. After recording such potentials the same fibers were intracellularly stained with the dye-fast green injected through the recording micro-electrode; the marked fibers were then stained for innervation type by cholinesterase stain. A positive correlation of slow potential with the multiply innervated fiber was obtained. The recorded potentials closely resembled those obtained by Matyushkin,[29] 1964, and Nemet and Miller,[30] 1968, and interpreted by them as arising in slow fibers. A similar correlation has been obtained in spike-producing, singly innervated fibers.

In a series of experiments[28] determining membrane potential, the occurrence of spontaneous potentials, the ability to produce overshoot spikes by stimulation, and the correlation with fiber type through fiber marking with fast green and cholinesterase stain for innervation pattern, it was found that an overshoot spike potential was obtained in two "silent" fibers of multiply innervated type. Of 53 fibers producing spontaneous, slow, multifocus potentials, none could be stimulated to produce action potentials. An additional 23 "silent" fibers in which spike potentials could be evoked were found to be singly innervated.

In reviewing electromyograms of extraocular muscle, many traces have been obtained showing long duration, monophasic waves. These were originally misinterpreted as "envelopes" owing to the remoteness of the electrode from active muscle fibers. On further probing of the muscle, areas of spiking activity were usually obtained. In some muscles no spiking activity at all was encountered. Under general anesthesia spike activity is rare whereas traces of slow monophasic activity are frequently obtained. These appear reasonably to be of slow fiber origin. In decerebrate cat experiments the extracellular electrode was applied to the extraocular muscle surface by means of a manipulator. Frequently, one obtained pure slow activity consisting of long-duration monophasic waves. With gradual penetration, layer by layer, the activity shifted to spikes. On reversal of direction, the surface slow activity was again encountered. This suggests that it is entirely possible to record classic slow activity in the extracellular EMG electrode (Breinin, unpublished observations.)

The question still remains unanswered whether spike activity may also reflect the slow motor system. Until this point is resolved it will be difficult to ascribe a given movement to a specific fiber type or system.

It is tempting to speculate but premature to aver the existence of a differential pathology involving the fiber systems. Is strabismus attributable to a derangement of one or the other systems or to an imbalance between them? Are neuromotility disorders related to

specific defects in fiber mechanisms? Is there a differential susceptibility of fast and slow fibers to various pathologic agents and conditions? If such fiber-specific pathology does exist, it may lead to a differential therapy and hence to a more rational etiologic and therapeutic approach to extraocular muscle disorders.

### Bio-engineering

The increasing application of engineering principles to the oculomotor system has been most productive. The dynamics of extraocular muscle have been extensively investigated by Robinson[31-33] 1964-69, employing the classic approaches of muscle force–velocity and length–tension plots and by study of the nature of orbital resistance. From these studies it is possible to formulate muscle models and to speculate on the servo-systems which govern eye movement. Although still in their infancy, these investigations have led to valuable insights in both normal and abnormal oculomotor physiology.

Robinson has analyzed the mechanics of ocular saccadic, smooth pursuit, and vergence movement in man. His findings are summarized as follows along with some comments and criticisms.

1. The eye is impulsively driven in a saccade by a brief burst of force much larger than that needed to hold the eye in its new position.

2. The mass of the eyeball plays a negligible role in determining the time course of the saccade.

3. There is no active checking. The eyeball is decelerated by the highly viscous nature of the orbital supporting structures.

The last conclusion is evident in EMG traces of saccadic movement which show an abrupt inhibition of the agonist at the termination of a saccade without any preceding checking action by the antagonist. The saccade is thus ballistiform in nature. It is extraordinary that the viscous orbital resistance, including that of the muscles themselves, is sufficient to stop high-velocity saccades with minimal overshoot—almost as though the globe hits a stone wall.

4. Larger saccades are achieved by increasing the duration of the excess force applied since the intensity of the force, although large, is limited. In engineering parlance this is termed frequency compensation (or neural pre-emphasis).

5. Smooth pursuit movements are markedly different than saccadic and exhibit quite different mechanical parameters.

This evidence is adduced for separate and independent control systems. There is no basis, however, for assuming that separate fiber types are involved. Typical spike EMG traces correlate closely with a given movement. There is no evidence of classic slow fiber activity unless we accept Bach-y-Rita and Ito's postulation of slow, multi-innervated twitch fibers.

6. Vergence movements, on the other hand, show a slow rise of tension compared with other movements. The time course of vergence movements suggests a very different neuromuscular control mechanism and leads to the implication of the slow fiber system.

The evidence of tension (Robinson[34]) and EMG (Miller,[35] 1958) studies indicate that the peak of tension may outlast the peak of recorded electrical activity. This lack of correlation is the basis of the suggestion that a fiber system not recorded in the EMG is active—presumably of slow motor type. There are many sources for error in this suggestion. The EMG electrode may not have been placed suitably with respect to the active units and hence did not record them, as Robinson notes. The fact that some units may have a specific field of action and thus not be commensurate with tension; has also been known for many years. But the fact that classic slow fibers can be recorded in the EMG is of fundamental importance and these have not yet been demonstrated in vergence studies. That the slow, multi-inner-

vated twitch fibers postulated by Bach-y-Rita and Ito are responsible for the slow time course of vergence awaits demonstration. It appears reasonable that both slow and twitch fibers operate in vergence but to differing extents.

## Conclusion

The attempt to correlate specific fiber types and function is at present bogged down in uncertainty. We do not know how many different fiber types actually exist. The early exposition of two fiber types, fast and slow, is being discarded in favor of three, five or more fiber types. Indeed, there may be a whole spectrum or continuum of fibers ranging from slow to intermediate to fast. The histologic criteria of separateness are beginning to break down so that we do not know what exactly constitutes a slow fiber. Still less can we ascribe a specific function to a specific fiber type. It is clear that motor systems of very different organization participate to differing extents in the various eye movements. Attempts to unravel the puzzle will require much more work at both the functional and structural levels, including the central nervous system and the peripheral effector mechanism. Despite its oversimplification, we must pay tribute to the dual-fiber concept which has led to the most astonishing worldwide development of interest in the oculomotor system by physiologists, anatomists, and ophthalmologists. From burgeoning laboratory and clinical studies we are gaining a fascinating understanding and appreciation of the complexity, diversity, and utility of the visuomotor mechanism. It is reasonable to hope that these studies will lead to significant clinical advances in strabismus and neuromotility disorders.

We also see in the slow motor mechanism a possible link between amplexus in the frog and vergence in man—another example of nature eternally adapting structure to function, preserving in the more complex organisms those modifications which serve the purpose and have withstood the test of time.

## Summary

The structure and function of extraocular muscle is analyzed in terms of the duality concept, which defines a slow and a fast motor system based upon slow and fast muscle fibers. The anatomical characteristics of the slow and fast motor system, including muscle and nerve, are reviewed with respect to light and electron microscopic structure. The pharmacology and physiology of extraocular muscle are reviewed with respect to the special properties of the slow and fast muscle fibers and their innervation. After consideration of the role of the slow and fast motor system in the electromyelogram, and finally, bio-engineering aspects of ocular movement in terms of the slow and fast motor systems, it is concluded that there is insufficient evidence to ascribe specific functions to specific muscle fibers. It is probable that eye movements are based upon coordinated and integrated action of both slow and fast motor systems. The consideration of oculomotor function as manifestation of either a slow or a fast motor system is an oversimplification, but this concept is proving helpful in stimulating research in normal and abnormal eye movement.

# LIMITATIONS OF COVER TEST IN DETECTING STRABISMUS

PAUL E. ROMANO, M.D.
*Chicago, Illinois*

AND

GUNTER K. VON NOORDEN, M.D.
*Baltimore, Maryland*

The cover test—the placing of a cover before one eye and observing the fellow eye for a refixation movement—is of fundamental value in the diagnosis of manifest strabismus. Recently, several ultra-small-angle types of strabismus have been described.[1-3] In these conditions, the cover test is essential to both definition and diagnosis. Also, the absence of a shift on the cover test has been said to indicate the absence of strabismus,[4] the presence of binocular single vision,[5,6] and bifoveal fixation.[7,8]

The smallest shift detectable with the cover test has been estimated to be from one to four diopters.[9-11] Ludvigh[12] concluded that excursions of less than 1 to 2 prism diopters could not be reliably perceived by the unaided eye. He arrived at this conclusion by having several examiners individually observe the eyes of one subject who performed voluntary fixation movements of known amplitude after a signal by the examiner.

In view of the scarcity of comparable experimental data and the renewed emphasis being placed on the cover test, we have undertaken the present study in order to define the limits of this test.

## METHOD

Ten experienced examiners with normal vision were tested for their ability to detect small saccadic refixation eye movements as elicited by the cover test. They included four orthoptists, two senior ophthalmology residents, two post-residency ophthalmology fellows, and the authors.

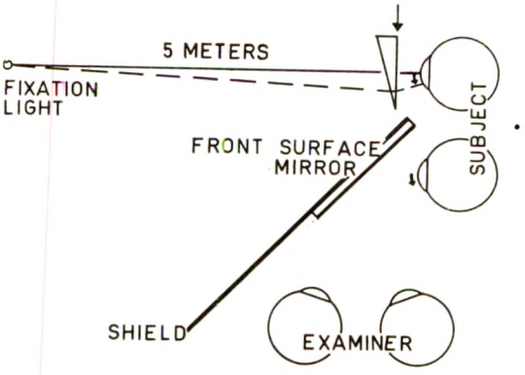

Fig. 1 (Romano and von Noorden). Experimental method. Simulation of cover test in clinical use. A small reflex refixation eye movement is induced by a prism while the examiner attempts to detect and describe it.

Each individual served as an examiner, and then as the subject for a subsequent examiner. The experimental arrangement is illustrated in Figure 1. The subject's right eye fixated a light at five meters. Prisms were placed, base-out or base-in, one at a time, before the right eye. This induced a small conjugate refixation movement. The examiner observed the left eye of the subject through a front surface mirror. The front surface mirror and shield prevented any fusional movements of the subject's eyes. It also prevented the examiner from observing the time or method of induction of eye movements.

The examiner was requested to indicate when the eye had moved and also the direction of the movement. Prisms of four, three, two, one, and one-half prism diopter's power were presented singly in a statistically deter-

From the Wilmer Institute, Johns Hopkins University School of Medicine, Baltimore, Maryland. This study was supported in part by Research Grants NB-1896-02 and EY-00274 from the National Eye Institute, Bethesda, Maryland. TABLE 1

RESULTS IN AN EVALUATON OF THE COVER TEST—NUMBER OF ERRORS IN 20 TRIALS AT EACH MAGNITUDE OF EYE MOVEMENT

| Eye Movement | Examiner | | | | | | | | | | Average Errors |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | |
| Four ΔD | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| Three ΔD | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| Two ΔD | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| One ΔD | 0 | 0 | 3 | 5 | 0 | 4 | 0 | 14 | 6 | 4 | 3.6 |
| One-half ΔD | 4 | 7 | 5 | 20 | 9 | 13 | 4 | 18 | 6 | 16 | 10.2 |

mined random order. For a control, a rectangular piece of glass without prismatic power was inserted before the subject's eye at random intervals. With 20 trials of each of the five prism sizes, a total of 100 possible eye movements was presented to each examiner.

## RESULTS

The results are shown in Table 1. All 10 examiners made no error in detecting movements of two prism diopters or more. For movements of one prism diopter, the average was 3.6 errors in 20 trials; for movements of one-half prism diopter, the average was over 10 errors in 20 trials.

At the 95% probability level, our experienced examiners were, individually and as a group, unreliable in detecting movements of one-half prism diopter. For movements of one prism diopter, the group was still not reliable at that probability level, although several individual examiners were. All examiners were, with no exception, reliable in the detection of movements of two prism diopters or more. The best scores (examiners 1 and 7) were achieved by an orthoptist in training and by an ophthalmology resident.

## DISCUSSION

In spite of differences in experimental technique, our results agree closely with those obtained by Ludvigh.[12] Of the 11 examiners in his series, Ludvigh found none reliable at one-half prism diopter, eight reliable at one prism diopter, and three at two prism diopters. As a group, his examiners, like ours, were reliable only in detecting movements of two prism diopters or more.

Therefore, we concur with Ludvigh and recommend that two prism diopters be considered the smallest deviation routinely detectable by the cover test. A more conservative limit may be appropriate considering ordinary examining conditions.

We wish to emphasize that the absence of a detectable shift on the cover test means only that a deviation, if present, is probably less than two prism diopters. A negative result on the cover test does not necessarily rule out strabismus, nor does it imply that normal binocular single vision or bifoveal fixation is present. For instance, the cover test will be negative in cases of microstrabismus with parafoveal fixation and identity between the degree of eccentricity of fixation under monocular, and the angle of anomaly under binocular conditions.[3]

What, then, should be done to close this gap in our clinical testing abilities? We find ourselves in agreement with Ludvigh's[12] conclusions of over 20 years ago in this regard: "... either a subjective test should be employed or the examiner should use magnification." The latter should improve the level at which reliable results could be obtained. It would not, however, aid in detection of those forms of microstrabismus in which no movement of the deviated eye occurs on covering the fixating eye.

Of better value in such situations are tests that indicate the degree of binocular cooper-

ation. For this purpose, we recommend the four-diopter prism test[13-14] and tests for stereoacuity.[15]

## Summary

Ten experienced examiners attempted to detect small monocular refixation eye movements, simulating the ordinary clinical use of the cover test. Reflex refixation movements were induced in the observed eye by placing prisms ranging from one-half to four prism diopters before the opposite fixating eye. A shield prevented fusion and the observation of movement induction by the examiner. Although several individual examiners were better, the group as a whole could detect only movements of two prism diopters or more with statistical reliability at the 95% level. The cover test, therefore, is considered unreliable for detecting deviations of less than two prism diopters. The absence of a detectable shift on the cover test does not rule out strabismus or establish the presence of normal binocular single vision or bifoveal fixation.

# THE PATHOGENESIS OF RETINAL DYSPLASIA

ARTHUR M. SILVERSTEIN, PH.D., BENNIE I. OSBURN, D.V.M.,
AND ROBERT A. PRENDERGAST, M.D.
*Baltimore, Maryland*

The term retinal dysplasia has been employed with two connotations in the ophthalmic literature. Its early use[1,2] was the more general, referring to abnormalities in the histogenesis of the developing retina. The term was used more restrictively by Reese and Blodi[3] and Reese and Straatsma[4] to designate a specific syndrome consisting of multiple congenital anomalies, including bilateral ocular abnormalities, presenting a more or less typical histopathologic picture. The widespread application of karyologic analysis during the past decade has made it clear that most of the cases of this syndrome described by Reese and coworkers[3,4] were probably related to a trisomy in the D group of chromosomes (13-15 trisomy).[5-9]

In their description of unilateral retinal dysplasia cases, Hunter and Zimmerman[10] objected to use of the term retinal dysplasia to describe the clinical syndrome, and preferred to restrict its use to the designation of a retinal lesion. They point out that dysplastic retina may be found in a number of different types of eye abnormalities, with or without systemic anomalies, and either unilaterally or bilaterally. They, and other authors, agree that dysplastic development of the retina may result from a wide variety of non-hereditary causes, and more recently Ricci[8] has extended the list of genetic contributions to this pathologic condition.

There are generally, however, only a limited number of pathogenetic mechanisms whereby a specific tissue change within the body may be effected. A review of the retinal dysplasia cases at the Armed Forces Institute of Pathology and at The Johns Hopkins Hospital suggests that all of the cases may conveniently be subdivided into four categories. The first three are as follows: (1) those resulting from hyperplastic extension of the retina into "abnormal" sites away from its pigment epithelium, (2) those secondary to detachment of the retina from the pigment epithelium, and (3) those occurring in an otherwise normal location over areas devoid of pigment epithelium such as occur in colobomas. It will be obvious that the underlying feature in each of these dysplastic processes is the suggested importance of the retinal pigment epithelium as the organizing factor primarily responsible for the normal histogenesis of the retina during development.[10] But another category exists also: (4) an in situ dysplastic process which may involve the entire retina or only a small portion thereof, and in which there is no evidence that the dysplastic retina has ever been separated from its underlying pigment epithelium.

It is the purpose of this paper to illustrate these four types of retinal dysplasia and to discuss their pathogenetic implications.

## MATERIALS AND METHODS

Our survey included an examination of all cases diagnosed as retinal dysplasia in the files of the Eye Pathology Laboratory of The Johns Hopkins Hospital as well as a reexamination of all similarly diagnosed AFIP cases, including those reviewed by Reese and coworkers[3,4] and by Hunter and Zimmerman.[10] No effort was made to review ex-

haustively all other forms of congenital ocular anomalies, although some types of retinal dysplasia have been illustrated by cases bearing other primary diagnoses.

The histopathologic characteristics of the retinal alterations described by Reese and associates and by Hunter and Zimmerman were applied to the present study. These include an aberrantly organized retina with typical irregular round or oval rosettes usually formed of immature rod and cone processes, with an external limiting membrane and outer nuclear layer and occasionally a plexiform layer and inner nuclear layer in addition. In other places there may be disorganization of the normal cellular pattern, with immature cells, and often increased amounts of glial tissue. As will be apparent, an abnormal relationship of the retina to the vitreous is frequently but not invariably encountered.

## Results

### Dysplasia secondary to proliferative outgrowth of the retina

It is occasionally observed that the retina, in response to some unknown stimulus, grows out beyond the boundaries of its normal anatomic position. This situation is often encountered in the presence of other ocular anomalies such as those which accompany 13-15 trisomy. It may also be seen in instances of failure of closure of the fetal fissure with cyst formation. In some cases of bilateral or occasionally of unilateral retinal dysplasia, the major portion of the retina may be normal in structure and position, but retina will be found to have extended past the optic disk and up the persisting hyaloid stalk toward the persisting and usually hyperplastic primary vitreous (Fig. 1). In such situations, the hyperplastic retina is found to be dysplastic and may show more or less typical rosette formation, starting at the point of its departure from the subjacent pigment epithelium. In other cases, the posterior retina around the optic disk is found to be normal, but the peripheral retina, perhaps initially detached by the organizing retrolental mass, becomes hyperplastic and grows inward in a disorganized and dysplastic fashion (Fig. 2). Where there is incomplete closure of the fetal fissure, a hyperplastic retina can occasionally be found growing in ectopic locations, sometimes even outside of the globe (Fig. 3). Under these conditions, the retina is almost invariably dysplastic.

Two points are worthy of note in connection with this type of retinal dysplasia. First, it is significant that large portions of the retinas of these affected eyes (i.e., those segments lying in normal apposition to their pigment epithelium) are found to be normal. Of perhaps greater significance, however, is the observation that occasionally the proliferative outgrowth of retina may be accompanied for part of the way by an analogous proliferative outgrowth of epithelium. When

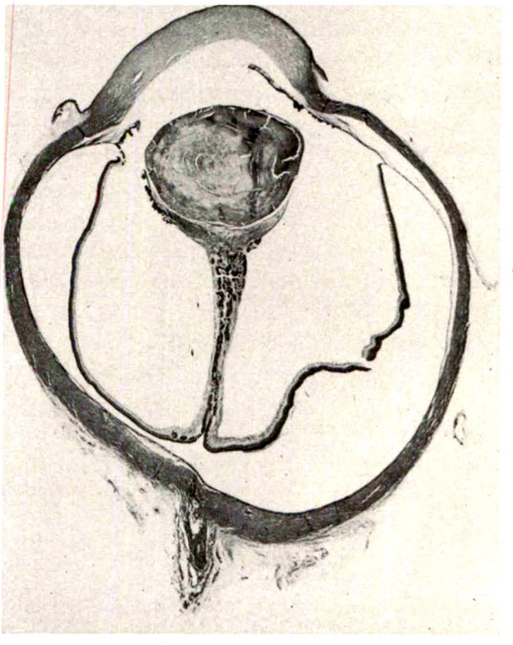

Fig. 1 (Silverstein and associates). Normal retina is present throughout most of the eye. At the optic nerve it has grown up along the persisting hyaloid stalk, and is dysplastic in this ectopic location (AFIP Case 1305972, hematoxylin and eosin, ×7).

retinal dysplasia described above, there is no evidence in these instances that the retina has ever been separated from its underlying pigment epithelium, although a small transient detachment during a critical stage of retinal maturation cannot be excluded.

There is, however, at least one form of retinal dysplasia in which it is known with certainty that the dysplastic process has occurred while the retina was in its normal position adjacent to the pigment epithelium. This form of retinopathy has been produced experimentally by infection of the fetal lamb with the attenuated bluetongue virus vaccine. This interesting biological story is described more fully in another paper.[12] Briefly, the organism employed, while modified to be nonpathogenic in the adult sheep, proves to be highly pathogenic in the young fetal lamb and produces hydranencephaly and generally a bilateral retinopathy. When the fetus is infected early in the second trimester of gestation, a progressive retinal lesion ensues, with a marked cytopathogenic effect on all cell layers of the retina. Within the first two weeks, the resulting disorganization of retinal architecture is accompanied by the formation of rosette-like structures (Fig. 9). Where destruction of the cellular elements of the retina has been extensive, the process resolves to leave an attenuated, almost acellular membrane in some areas, while in other areas a more typical picture of retinal dys-

plasia with rosettes and gliosis is seen (Fig. 10). It bears emphasis that at no time during the course of this retinitis can retinal detachment from the pigment epithelium be seen.

## Discussion

Retinal dysplasia appears commonly to be associated with the 13-15 trisomy syndrome, in which bilateral retinal and other ocular defects are generally associated with a variety of congenital anomalies elsewhere in the body.[3-9] It was on the basis of this concurrence of findings that Reese and coworkers[3,4] applied the term retinal dysplasia to designate the entire syndrome, at a time prior to the advent of karyologic analysis, when the genetic basis for this disease was unknown. This usage was questioned by Hunter and Zimmerman,[10] who pointed out that retinal dysplasia could be found unilaterally in a significant number of cases where other congenital anomalies were absent, and indeed in other obviously unrelated disease processes as well. These authors suggested that use of the term be restricted to the designation of a histopathologic abnormality of the retina, by virtue of the nonspecific nature of its development and the wide variety of its causes. The limited survey which we present in this paper strongly supports this view, since retinal dysplasia has been found to accompany not only 13-15 trisomy, but also congenital retinal folds,[2] sex-linked recessive Norrie's disease,[8,13-16] certain colobomas and cysts,[2,11,17] cyclopia,[18] idiopathic focal dysplasia of the retina,[10] and finally an experimental retinopathy associated with hydranencephaly produced by viral infection of the fetal lamb in utero.[12]

Those cases of retinal dysplasia which we have examined and reported herein appear to fall into four distinct categories, some of which may, however, be seen together within the same eye. Three of these categories appear to be based upon a common pathogenetic mechanism. In the first of these, dysplasia of the retina is associated with its proliferative outgrowth away from the pigment epithelium, either from the nerve head along a persisting hyaloid stalk, from the peripheral retina toward a persisting retrolental mass of hyperplastic primary vitreous, or even outside the globe in a colobomatous cyst. The second type of retinal dysplasia accompanies detachment of the developing retina from its normal apposition to the pig-

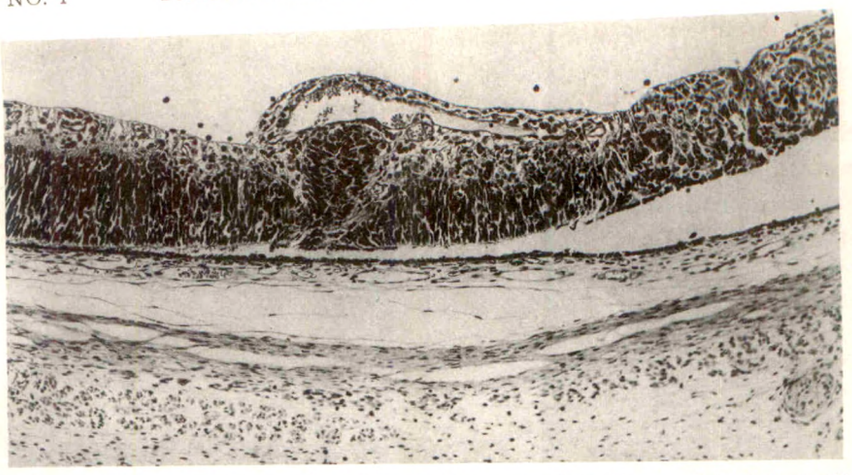

Fig. 9 (Silverstein and associates). Experimental bluetongue virus disease of fetal lamb. The animal was infected at the beginning of the second trimester of gestation and sacrificed 12 days later. Note inflammatory infiltrate, destruction of retinal cells, and immature rosette formation (hematoxylin and eosin, ×85).

ment epithelium, or perhaps may follow a failure of coaptation of the primitive layers. The third type is encountered when the retina suffers disorganized development due to a congenital absence of the pigment epithelium layer, such as may occur at the site of a coloboma. These observations appear to support the contention that the principal organizing factor in the normal histogenesis of the retina is the pigment epithelium, and that when this layer is lacking, disorganization and dysplasia may ensue. This is reinforced by the finding that even in the vitreous or behind the lens, retinal organization may be almost normal when juxtaposed to pigmented epithelium. It is of interest that the retinal pigment epithelium is also held to be responsible for the normal development of the choriocapillaris.[2]

A number of observations support the notion that it is only during a critical stage of its development that the retina is dependent upon an adjacent organizer to preserve its normal anatomic relationships. On the one hand are observations on the production of retinal hyperplasia and dysplasia with rosette formation induced by photocoagulating the retina of chick embryos,[19] following in vitro culture of retina or in vivo trephining of the eye of developing rats,[20] and x-irradiation of the human fetus in utero.[21] On the other hand, it is well known that detachment of the

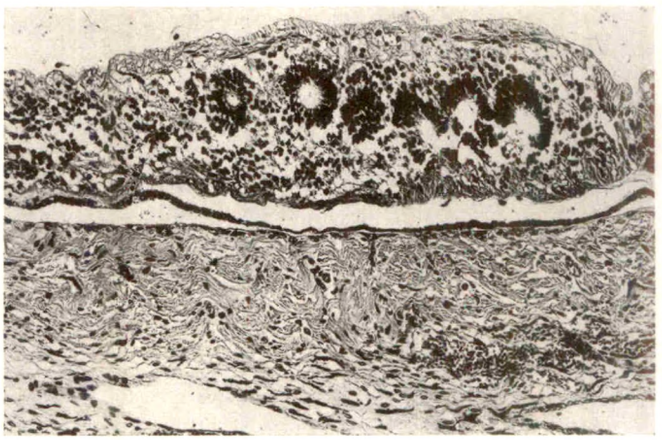

Fig. 10 (Silverstein and associates). Experimental bluetongue virus disease of the fetal lamb. At birth (105 days after infection) the inflammatory reaction has subsided, and a highly disorganized retina with gliosis and rosettes remains (Masson, ×135).

mature retina from its pigment epithelium leads to degeneration without the typical signs of dysplasia. The only instance of dysplastic changes in a mature retina which we have seen is that of a 55-year-old man described in the files of the Armed Forces Institute of Pathology (Case no. 697461), one of whose eyes showed focal retinal detachments with rosette formation. The only significant item in this patient's history was the report of a penetrating wound of the same eye some 20 years earlier. Pusey,[22] however, suggested that dysplastic rosettes might result from inflammatory processes in the adult eye.

It is obvious that retinal dysplasia is not the specific accompaniment of a single disease entity, but rather is a nonspecific response of the retina at certain stages of its development, presumably inducible by a variety of etiologic factors. Whereas the three types of retinal dysplasia described above are all associated with separation of the developing retina from its pigment epithelium, a fourth type of dysplasia appears to occur in a retina in continuous contact with pigment epithelium. Certain of these cases are characterized by a small and discrete area of dysplastic retina. While it cannot be ruled out with certainty that the developing retina had suffered a minor detachment, undergone dysplastic changes, and then reattached, no evidence survives in these cases to indicate that this indeed took place. We can be sure, however, in our studies of experimental bluetongue virus infection of the fetal lamb in utero, that the retina remained firmly attached to its pigment epithelium during the course of the disease process. It is possible, of course, that the pigment epithelium has undergone an alteration by the virus which so extensively effaced the retina, but morphologic signs of such an alteration cannot be found. It would appear rather that the extensive cytopathogenic effects of the virus and the accompanying inflammation lead directly to depopulation and disorganization of the developing retina, and that the rosettes which form represent an abortive attempt by the remaining cellular elements to effect some sort of reorganization. Once again, the change is most likely possible only at a critical stage of retinal development, since the extensive retinopathies associated with other inflammatory reactions in the more mature retina are unaccompanied by rosette formation. Although the rosette of retinoblastoma differs from that found in retinal dysplasia, it is of some interest that in this instance also the rosette represents an attempt to achieve some form of cellular organization in the less anaplastic forms of this tumor,[11] with more highly differentiated cells forming more extensive receptor processes in the form of fleurettes.[23]

The retinal dysplasia seen in this experimental model would appear to be more a component of degeneration followed by repair in the immature retina than an original dysgenesis. Whether the rosette invariably accompanies hyperplastic infolding of the retina[2,17,24] is presently unclear. Our own observations lead us to believe that rosettes may also form by the condensation of receptor cells around organizing foci of cells such as are often seen within the rosette lumen.

## Summary

Retinal dysplasia may be found in association with a variety of congenital abnormalities of the eye, some genetically transmitted and others due to exogenous influences. The dysplasias due to retinal hyperplasia, to retinal detachment or failure of coaptation, or to congenital absence of pigment epithelium suggest that orderly retinal morphogenesis may depend upon the organizing influence of an adjacent pigment epithelium. Dysplasia may also result from a necrotizing inflammatory response of the retina to infection, resulting in disorganization and abortive repair rather than true dysgenesis.

# AN EXPERIMENTAL, VIRUS-INDUCED RETINAL DYSPLASIA IN THE FETAL LAMB

ARTHUR M. SILVERSTEIN, PH.D., CHARLES J. PARSHALL, JR., D.V.M., BENNIE I. OSBURN, D.V.M., AND ROBERT A. PRENDERGAST, M.D.
*Baltimore, Maryland*

Influenced by the publications of Reese and coworkers,[1,2] the term retinal dysplasia has most commonly been employed in the ophthalmic literature to denote a syndrome consisting of bilateral retinopathy and a variety of other ocular and extraocular congenital anomalies. More recent advances in our understanding of genetic disease have suggested that the cases described by these authors are most probably due to a trisomy involving the 13-15 ($D_1$) group of chromosomes.[3] Hunter and Zimmerman[4] have described a series of cases of unilateral retinal dysplasia generally lacking the accompanying multiple anomalies so typical of the 13-15 trisomy syndrome, and the lesion has also been reported in the dog as a bilateral condition, again without systemic malformations.[5,6] Hunter and Zimmerman suggested that the term retinal dysplasia should thus be used to designate a histopathologic retinal lesion rather than an entire clinical syndrome. We have strongly supported this suggestion,[7] pointing out that the development of retinal dysplasia may be based upon a number of pathogenetic possibilities and probably a wide variety of etiologic agents. This paper describes the experimental production of one such type of retinal dysplasia, which follows quickly on the heels of a cytopathogenic attack upon fetal retinal cells by a viral agent.

The virus used in these studies is the bluetongue virus of sheep. Apart from the demonstration that a viral agent is capable of producing a necrotizing retinopathy with retinal dysplasia (as well as a variety of central nervous system lesions), several other fascinating points emerge from this study. First, the viral agent employed to produce the fetal disease is an attenuated, live-virus vaccine which is nonpathogenic in the adult animal. Second, the virus is only able to produce retinopathy and encephalopathy in the fetal lamb during the first half of gestation, after which the agent appears to lose its pathogenicity for the fetus, presumably in response to some maturational event in the host. Finally, whereas the wild virus appears predominantly to affect the vascular system in the adult animal and to spare the central nervous system, the principal target of the attenuated virus in the susceptible fetal host is found to be the brain, the spinal cord, and the retina. We shall describe in a later paper[8] the results of our study on the central nervous system changes accompanying this viral infection; the present paper will be devoted to a description of the ocular changes.

## MATERIALS AND METHODS

*Pregnant sheep*—The ewes employed in this study were of random mixed breed, from three to six years old. Through the courtesy of the Sheep and Fur Animal Research Branch, Animal Husbandry Research Division, Beltsville, Maryland, servicing by the ram was done under controlled conditions, and the date of conception could be established within one to two days. The gesta-

From The Wilmer Institute, The Johns Hopkins University School of Medicine. tion period of the ovine is 150 days.

*The virus*—Bluetongue virus vaccine (Blucine) was obtained through the courtesy of Cutter Laboratories Berkeley, California. This is a vacuum-dried preparation of live virus modified by repeated serial passage through chick embryo. The vaccine was reconstituted immediately prior to use with the standard diluent provided with the vaccine, and always used on the day of reconstitution.

*Surgical procedure for intrafetal infection*—The surgical procedures employed have been described elsewhere.[9] The only technical modifications have been a discontinuance of the use of anticoagulant, and substitution of halothane-oxygen anesthesia in place of the ether-oxygen employed in earlier studies. At the desired stage of gestation, the fetus was exteriorized and injected intramuscularly in one of its extremities with 0.05 to 0.1 ml of the reconstituted bluetongue vaccine. The fetus was then returned to the uterus and a standard closure effected.

*Delivery of fetal animals and collection of specimens*—At the desired interval after intrafetal infection, the fetus (and when present, its twin, whether inoculated or not) was delivered by hysterotomy, following essentially the same procedure outlined above for the initial laparotomy. Following exposure of the fetus through the incised fetal membranes and uterus, a blood sample was withdrawn from the umbilical cord. The cord was then cut and the fetus removed for autopsy. Both eyes, the brain and spinal cord, and a representative selection of other tissues were fixed in a solution containing 20% ethanol in 10% neutral formalin for later histopathologic workup. Microscopic sections were stained with hematoxylin and eosin, and others with methyl green-pyronin.

## Results

### The normal development of the eye in the fetal lamb

In order to put into perspective some of the histopathologic changes described below, it is appropriate to review briefly some of the normal histologic stages of development of the fetal lamb's eye during the period of interest in this study, with emphasis on the development of the retina.

In many respects, after 55 days of gestation the normal eyes of fetal lambs grossly resemble those of the adult animal. Histologically, the eyes of fetal lambs taken between 55 and 86 days of gestation reveal muscular fibers external to a rudimentary fibrous sclera. The choroid appears as a delicate vascular complex in a loosely arranged stroma, with a discrete choriocapillaris already apparent in some areas. Evidence of a tenuous basement membrane similar to Bruch's membrane is seen beneath a well-ordered and continuous retinal pigment epithelium whose cells contain moderate numbers of pigment granules in the region of the ora serrata, and a decreasing degree of pigmentation as one progresses from the equator to the optic disk. Little or no pigmentation is evident in the region that will later become the tapetum lucidum. A discrete outer limiting membrane lies immediately adjacent to the pigment epithelium, with only an occasional strand of eosinophilic material visible to forecast the future rod and cone layer. At this stage the outer and inner nuclear layers are fused, and there is no evidence of an outer plexiform layer. There is a distinct inner plexiform layer, a highly cellular ganglion cell layer with but few neurons present, and a very well-vascularized nerve fiber layer covered by a fairly distinct internal limiting membrane. The most conspicuous processes in the nerve fiber layer are the vertical Müller's fibers and vessels; very few horizontal nerve fibers are observed. A primitive ciliary body and iris are present. A fine web of capillaries appears almost to surround the entire extent of the lens.

As gestation continues, the sclera and choroid become more mature and thicker. Pigmentation of the pigment epithelium becomes more pronounced and extends further backward toward the optic disk. At about 85 days of gestation, there is a beginning differ-

entiation of the cells of the still-fused inner and outer nuclear layers, with the outer nuclei becoming more elongated and the inner ones more rounded. By 96 days of gestation, the inner and outer nuclear layers are separated by a discrete outer plexiform layer. At this time also, there is an increase in the numbers of ganglion cells in the ganglion cell layer, and horizontal nerve fibers become more apparent. Whereas there is little evidence of a rod and cone layer at 90 days' gestation, some three to four weeks later this layer is present and offers a fairly mature appearance.

### Ocular pathology of lambs infected at 50 to 58 days' gestation

Twelve fetal lambs were infected with the bluetongue virus vaccine near the start of the second trimester of gestation, and they and two twins that were not injected were sacrificed at intervals thereafter. The degree of pathology in the uninjected twin was similar to that of its sibling in each instance.

*Six days postinoculation*—As soon as six days after infection of the fetus at a distant site, early changes could be seen in the retina, most prominently involving the nerve fiber layer (Fig. 1). For the most part, the lesions appeared to center on the retinal vasculature, whose endothelial nuclei were rounded and somewhat vesicular. There was a scattered perivascular accumulation of mononuclear inflammatory cells. The internal limiting membrane was irregular, and the Müller's fibers were conspicuous. Focal areas of necrosis were characterized by pyknotic and fragmented nuclei, and pink globular material appeared in place of the vertical fibers. In the nuclear layer associated with these areas, there were clear foci apparently resulting from a loss of cells. Some nuclei of glial cells in the inner plexiform layer were pyknotic. An occasional mononuclear inflammatory cell was found in the stroma of the choroid. The endothelial cells of the choroidal vessels appeared swollen.

*Nine days postinoculation*—In one animal

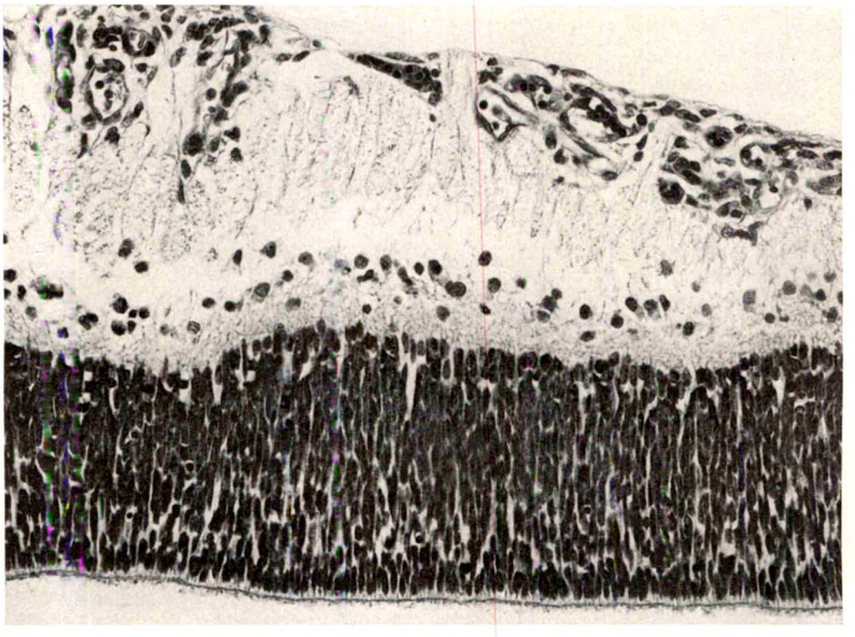

Fig. 1 (Silverstein and associates). Six days after infection of a fetal lamb at 54 days gestation, the earliest changes are centered upon the retinal vessels. Endothelial cells are rounded and prominent, and there is a scattered perivascular accumulation of mononuclear inflammatory cells. Pyknotic nuclei may be seen in the fused layers (hematoxylin and eosin, ×270).

minimal involvement of intraocular structures, consisting of a scattering of inflammatory cells in the internal layers of the retina, persisting evidence of a diffuse loss of cells in the fused inner and outer nuclear layers, and a mild diffuse choroiditis. The most conspicuous inflammatory infiltrate involved a mixed mononuclear-polymorphonuclear inflammation of the lacrimal gland and duct.

A second animal examined at this time (the twin of the one described above) was much more severely involved. The retinal changes in the eyes of this animal were analogous to those observed in the 12-day fetuses, but the degree of inflammatory infiltrate and retinal degeneration was much more extensive. There was a more widespread degeneration of the inner layers of the retina and loss of cellular elements in the nuclear layers, with monocytic infiltrates more diffuse and more prominent in the retina (Fig. 5) and choroid. There was a mild diffuse mononuclear infiltrate of the iris and ciliary body, with the retrolental vessels apparently serving as the source of a predominantly monocytic exudate. Mild, predominantly perivascular infiltrates of lymphocytes, plasma cells, and histiocytes were found in the still-fused eyelids.

*Twenty-one days postinoculation*—The inflammatory response was markedly diminished in the eyes of these animals. A few mononuclear cells persisted in the vitreous. Focal areas of necrosis involving all the areas of the retina were located in randomly scattered areas, occasionally appearing to be secondary to a severe focal choroiditis (Fig. 6). In some regions there was a persistence of folds in the retina where the nuclear layers nearly approximated the internal limiting membrane. The most prominent evidence of the earlier reaction was the presence of glial nodules in the nerve fiber and inner plexiform layers. In some areas pigment-laden cells were found in the nuclear layer, presumably a migration from the occasionally disturbed pigment epithelium layer. The lesions in the choroid were fairly well localized, and for the most part consisted of nodules of macrophages.

Fig. 4 (Silverstein and associates). Same eye as shown in Figures 2 and 3. A focal area of choroiditis is associated with a retinal fold and an increased degree of retinal necrosis (hematoxylin and eosin, ×100).

*One hundred and five days postinoculation*—In the three animals examined at this time, all signs of active inflammatory disease had disappeared. In two of the animals, the principal changes involved the retina and choroid. The atrophic retina appeared to consist of an internal and external limiting membrane enclosing in the main a glial stroma. There were a few areas where an attenuated outer nuclear layer with its rods and cones approximated the pigment epithelium, and other regions where rosettes were located, consisting of an external limiting membrane separating abortive rod and cone processes and a layer of receptor cells (Fig. 7). The pigment epithelium was incomplete in some areas and fibrous stroma and vessels from the choroid appeared to invade the retina, while glial elements from the retina appeared

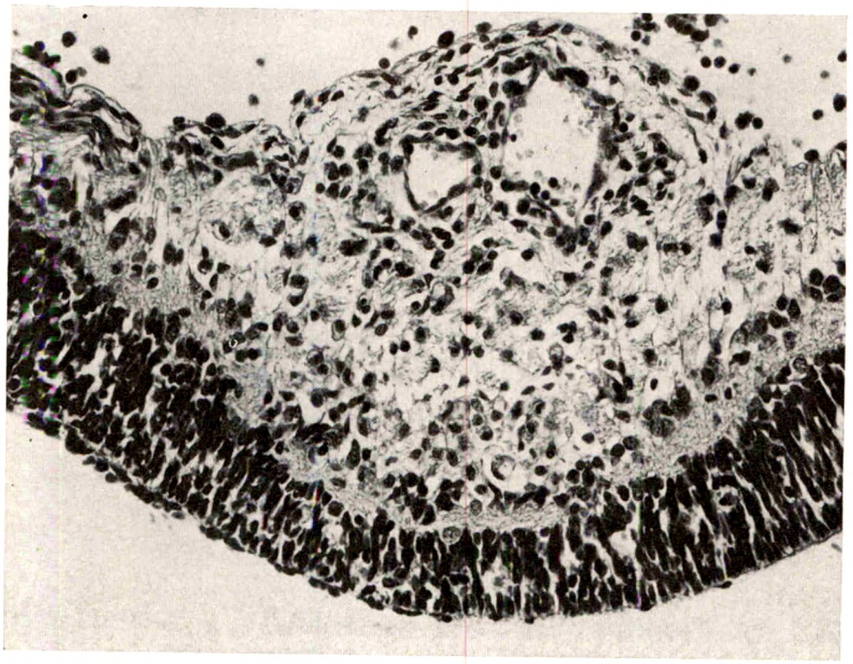

Fig. 5 (Silverstein and associates). Fifteen days after infection, there is more widespread degeneration of the inner layers of the retina in some locations, accompanied by a greater loss in the nuclear layers (hematoxylin and eosin, ×230).

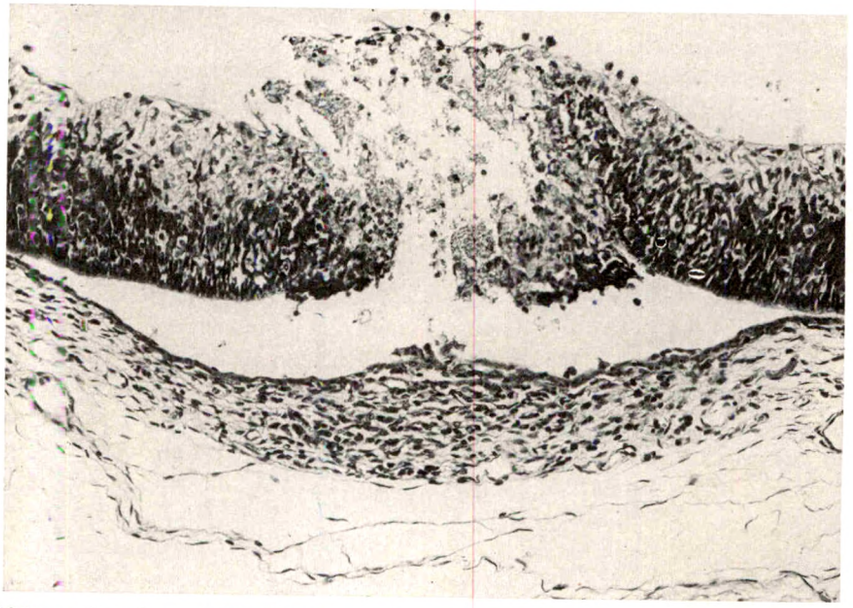

Fig. 6 (Silverstein and associates). Twenty-one days after infection, inflammatory response has markedly diminished. In this eye, less involved generally than several others, cell loss and degeneration can be seen in the nuclear layers of the retina. At the site of a focal choroiditis, the adjacent retina is completely necrotic (hematoxylin and eosin, ×140).

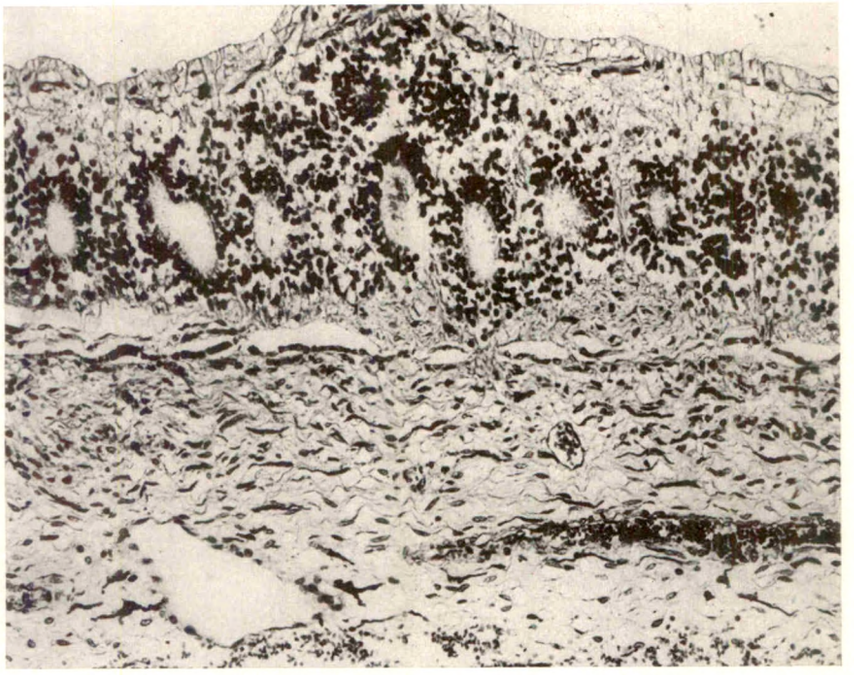

Fig. 7 (Silverstein and associates). One hundred and five days after infection, the inflammatory reaction has completely subsided. In some areas oval rosettes are present, consisting of a more or less well formed outer nuclear layer, an external limiting membrane, and abortive receptor cell processes. Note the interruptions in the pigment epithelium, through some of which fibrous tissue and vessels from the choroid appear to invade the retina, while through others glial elements from the retina penetrate to the choroid (Masson, ×140).

to invade the choroid through dehiscences in Bruch's membrane (Fig. 7). The remainder of the retina consisted of glial cells, many of which assumed a fibrillar appearance. In other areas, hyperplasia of pigment epithelium had occurred, as well as migration of these cells into the atrophic retina (Fig. 8). In yet other sites, the stroma and retina were fused, and a distinct pigment epithelium could not be observed. In some regions, the choriocapillaris was replaced by a fibrous stroma. The iris and ciliary body of these eyes appeared normal.

In one animal examined at this time, the retinal involvement was far less pronounced. There was some attenuation of the nuclear layers, and in some areas cystic changes in the nerve fiber layer. Surprisingly, the most prominent changes seen in this animal were signs of an earlier interstitial keratitis with extensive residual vascularization and scarring of the middle layers of the stroma with a degree of thinning of the central cornea.

### Ocular pathology of fetuses infected at midgestation

Six animals were infected at 70 to 75 days' gestation, and sacrificed at intervals thereafter. In contrast to the animals infected at the beginning of the second trimester of gestation, the animals infected at midgestation showed a significantly lesser degree of retinal involvement, and especially a marked diminution in the extent of mononuclear inflammatory infiltrates in the retina.

*Ten days postinoculation*—There was a moderate involvement of the vessels of the inner layers of the retina, especially at its periphery, with prominent endothelial cells and a very mild mononuclear cuffing of inflammatory cells. Occasional glial nodules were found, involving the nerve fiber layer, the in-

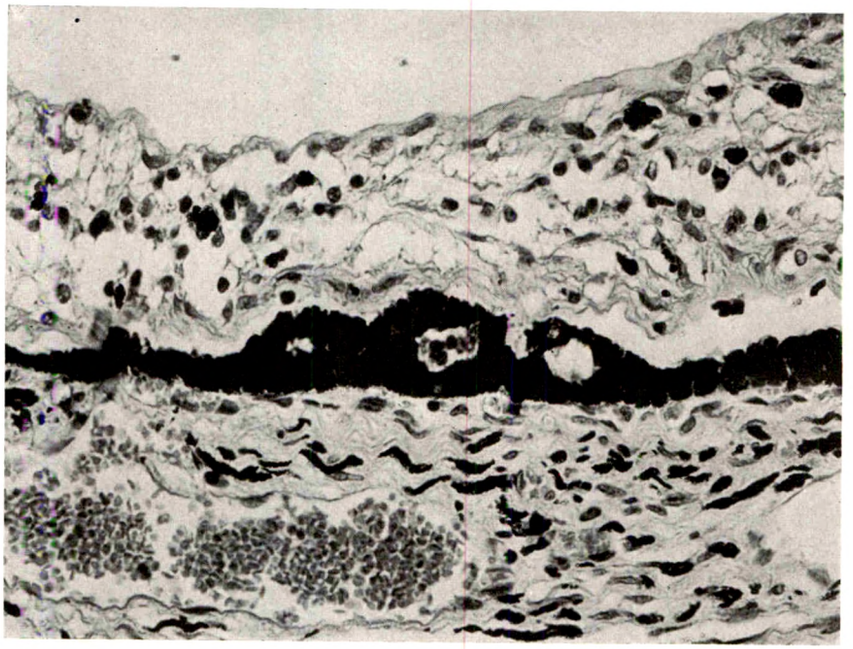

Fig. 8 (Silverstein and associates). Another area from the same eye as Figure 7. Here, destruction of the retina has been more extensive. There is hyperplasia of the pigment epithelium as well as migration of these cells into the atrophic retina (hematoxylin and eosin, ×350).

ner plexiform layer, and the inner nuclear layer. A single small focus of retinal necrosis was observed, involving all layers of the retina, apparently associated with a subjacent chorioiditis.

The most severe changes were found in the choroid. Endothelial cell nuclei were often large and vesicular, and there was a diffuse mononuclear inflammatory infiltrate extending through much of the choroid, with a scattering of neutrophils and eosinophils. A few plasma cells were present in some areas. In one eye a scattering of neutrophils was present immediately beneath the corneal epithelium. On the surface of the cornea in this area were clusters of neutrophils and necrotic debris.

*Twenty days postinoculation*—There was a persistence of the mild diffuse choroiditis at this time, involving both mononuclear and polymorphonuclear leukocytes. Throughout the retina, however, and in the almost complete absence of inflammatory cell infiltrates, there was evidence of a scattered loss of cells in the now-separated inner nuclear layer. Numerous vacuoles were seen along the entire extent of this layer, along with occasional pyknotic nuclei and nuclear fragments. Only rarely was a similar involvement of the outer nuclear layer observed. In places the inner layers of the retina appeared somewhat attenuated, and an occasional glial nodule appeared in the nerve fiber and ganglion cell layers. The rest of the eye was unremarkable.

*Sixty-three to seventy-six days postinoculation*—Only an occasional residual inflammatory cell could be found in the otherwise normal choroid at this time. The retinas also appeared fairly normal, except for areas here and there where the inner nuclear layer appeared to be somewhat thinner and less cellular than the normal control.

### Ocular pathology of fetuses infected during the last trimester

Three animals were inoculated with the live-virus vaccine at 100 to 125 days' gesta-

tion, and in general they showed little or no pathologic consequences. In one animal infected at 100 days' gestation and sacrificed three weeks later, the only lesion observed throughout the fetal eye consisted of a single glial nodule which involved the inner nuclear, inner plexiform, and nerve fiber layers. In an animal infected at 120 days' gestation and examined 10 days later, no lesions of any kind were observed. A third fetus was infected after a gestation of 125 days, with gestation then allowed to continue to normal term. This lamb was sacrificed at slightly over a month of age, or 63 days after inoculation. Only the residue of an old, apparently mild iritis was seen in one eye of this animal.

## Discussion

We have used the term retinal dysplasia in this paper to denote a certain type of histopathologic lesion, rather than a syndrome involving both ocular and extraocular pathology, in line with the suggestion of Hunter and Zimmerman.[4] It was pointed out in another paper[7] that congenital retinopathy of this type could be found not only in 13-15 trisomy, but also in Norrie's disease, in association with colobomata and cyclopia, and secondary to retinal detachment of unknown etiology. The underlying cause of these types of dysplasia appears to be the absence of the organizing function of the pigment epithelium at a critical stage of development during which it is required for orderly histogenesis. While little evidence could be adduced from the human material suggesting that inflammatory disease might also lead to retinal dysplasia, it appeared quite reasonable to assume this possibility. This might result in inflammatory detachment of the retina with consequent dysplasia, or else dysplasia in situ secondary to retinitis.

Data are presented in this paper demonstrating that a severe retinopathy with many of the features of retinal dysplasia can be produced in the fetal lamb following systemic infection by a viral agent, the bluetongue virus of the sheep. In addition to a severe encephalopathy (which will be described in detail elsewhere[8]), this virus produces in the young fetal lamb an acute retinitis characterized by a mononuclear inflammatory infiltrate and severe necrosis of the cellular elements of the developing retina. In areas where the retina is not completely obliterated, the picture of a disorganized and dysplastic retina with rosette formation is seen.

The earliest signs of retinal disease are apparent within six days after infection of the fetus, after which the disease runs a very tempestuous course and quiets down almost completely within the succeeding two weeks. At no time during the disease has the fetal retina been observed to become detached from its underlying pigment epithelium. The dysplasia encountered in this situation thus represents not a dysplastic growth of the primitive anlage deprived of the organizing influence of pigment epithelium, but an abortive effort on the part of the remaining cells of the retina to regroup and repair. While some alteration of pigment epithelial function by the virus cannot be ruled out, the absence of any morphologic signs of such a process coupled with the obvious cytopathogenic activity of the virus in the superjacent retina would seem to argue strongly against this possibility.

These data lend further support to the theory that retinal dysplasia is not a specific process, but rather an alteration which may be caused by a number of apparently unrelated mechanisms. As suggested in another paper,[7] dissociation of the immature retina from its presumed necessary juxtaposition to the pigment epithelium either by detachment, proliferative outgrowth away from the pigment epithelium, or congenital absence of pigment epithelium leads to its further abnormal (dysplastic) development. In the present situation, retinal development has progressed normally up to the point where virus-induced destruction of the various retinal elements leads to a disorganization and

attempt at repair closely resembling the dysplastic process. Of great importance to both of these mechanisms, however, is the immaturity of the retina. After a certain stage of development, the retina is presumably too highly differentiated to be able to support typical dysplastic changes. It is probably for this reason that we do not see dysplasia of the more mature retina following detachment or necrosis secondary to retinitis or chorioretinitis.

Several other points deserve more than passing mention in connection with the present studies. The first concerns the critical nature of host factors in determining the pathogenicity and virulence of a given organism. More and more we are becoming aware that the use of attenuated live-virus vaccines, although rendered nonpathogenic for the adult, may not always be used with impunity in a pregnant recipient, by virtue of some special susceptibility of the immature fetus. Indeed, the first hint that this was the case with the bluetongue vaccine was provided by observations in the field,[10] and later experimentally,[11,12] of so-called "dummy" (hydranencephalic) lambs born to ewes that had been immunized with the vaccine during pregnancy. This danger presupposes, of course, that the agent in question is able to cross the placenta, a condition which may not obtain in all instances. The bluetongue viral vaccine obviously does cross the placenta, as is witnessed by fetal infection when either the mother or, in several instances in this study, a twin is inoculated.

It is of further interest that the altered status of the host may affect profoundly the nature of the disease process produced by a given pathogen. In the adult sheep, the wild strain of the bluetongue virus produces a pathology centered on vascular changes with accompanying subcutaneous and fascial edema, erosion and ulceration of oral mucous membranes, and necrosis of skeletal and cardiac muscle.[13] There is no evidence that the adult suffers any central nervous system or ocular pathology during the course of its disease. When the egg-passed attenuated virus is introduced to the fetus either by maternal immunization or directly, as in the present study, a completely different disease is produced in the fetal host. This consists, early in gestation, of massive necrosis of neural and retinal tissues, resulting in hydranencephaly and retinal degeneration and dysplasia with few if any of the hallmarks of the natural adult disease.

Finally, the changing nature of the fetal disease with increasing age of the fetal host presents a most fascinating biological problem. Infection of the fetus at the beginning of the second trimester of gestation (50-58 days) is almost invariably accompanied by massive destruction of neural and retinal cells. The inflammatory infiltrates which accompany this disease are predominantly monocytic and histiocytic, with few lymphocytes and even fewer plasma cells in evidence. At about midgestation (75-100 days), the nature of the disease changes markedly. Now there is little evidence of cytopathogenicity and necrosis in either the brain or the retina, but instead only widely scattered glial nodules in the retina and a change of venue of the inflammatory reaction to the choroid. The inflammatory infiltrate at this stage is more highly lymphocytic, with plasma cells now in evidence. By 100 to 125 days gestation, infection of the fetus fails to produce any retinal pathology at all, and those mild inflammatory infiltrates formed elsewhere possess large numbers of both lymphocytes and plasma cells.

There exist at least two reasonable although not mutually exclusive explanations for the changing nature of this fetal disease and the difference between fetal and adult susceptibility to this attenuated live virus. It is possible that the immature neural and retinal cells of the developing fetus are peculiarly susceptible to the cytopathogenic effects of this viral agent. With increasing maturation, it might be supposed that some biochemical or physiologic change in these cells renders them impervious or otherwise

unsusceptible to viral attack. On the other hand, there is some indirect evidence to suggest that the maturational event which protects the older fetus and adult from the more destructive disease may be immunologic in nature.[12,14] It is known that the mammalian fetus may develop immunologic competence to a given antigen at a very distinct time in its development.[15] If the fetal lamb were to achieve immunologic competence to the bluetongue virus at about midgestation then it would be able to participate in its own defense against the viral infection, sufficiently perhaps to prevent infection and destruction of neural and retinal cells. This possibility finds some support in the changing cytologic picture of this disease as described above, and in some preliminary evidence which we have obtained that neutralizing antibody to the bluetongue virus can be found in the infected fetus only after some 75-100 days' gestation.

Finally, the interrelationship of retinopathy with hydranencephaly such as is described in this paper draws our attention to possible retinal involvement in other forms of encephalopathy. Urman and Grace[16] have published a pathologic description of a congenital, autosomal recessive encephalomyopathy of calves. In addition to a primary disturbance in myogenesis and internal hydrocephalus, an invariable finding was complete retinal detachment with dysplastic retinal tissue in the stalk connecting the optic disk to the posterior surface of the lens. Hydranencephaly with congenital blindness has also been reported in calves,[17] but here the blindness is apparently cortical, since the eyes were reported to be ophthalmoscopically and microscopically normal. Hill and coworkers reviewed the ocular signs associated with human hydranencephaly.[18] Although a variety of ocular signs have been noted in association with hydranencephaly, the single case on which they present histopathologic findings shows extensive retinal degeneration and gliosis, although without typical dysplasia. These authors emphasize the multiplicity of pathogenetic mechanisms that may lead to hydranencephaly, a point which we have emphasized in our discussion of retinal dysplasia.

## Summary

Retinal dysplasia, accompanying extensive destructive retinopathy and hydranencephaly, has been produced in the fetal lamb with the attenuated bluetongue virus, a live-virus vaccine nonpathogenic in adult sheep. With increasing maturity, the nature of the ocular disease changes in the fetus, until late in gestation it demonstrates a typical adult resistance to the viral agent. Some of the host factors which may modulate the apparent pathogenicity of infectious agents have been discussed, along with some of the maturational events which may account for the increased resistance of the older fetus and adult to this viral agent.

# ANTERIOR SEGMENT ISCHEMIA FOLLOWING SCLERAL BUCKLING IN SICKLE CELL HEMOGLOBINOPATHY

STEPHEN J. RYAN, M.D.
*Baltimore, Maryland*

AND

MORTON F. GOLDBERG, M.D.
*Chicago, Illinois*

The "anterior segment ischemia syndrome" comprises a set of severe complications of retinal detachment surgery. This syndrome may frequently nullify an otherwise successful scleral buckling procedure,[1-4] due to the development of postoperative keratopathy, intraocular inflammation, hypotony, and cataract. Its pathogenesis has been attributed to several different factors at the time of surgery, including (1) interruption of the anterior ciliary arteries,[5,6] (2) damage to the long posterior ciliary arteries,[1,7] and (3) placement of an encircling element.[5]

Although generally an uncommon complication of scleral buckling operations, we have observed anterior segment ischemia, in a very high percentage of patients with sickle cell-hemoglobin C disease (SC disease) who have undergone retinal detachment surgery. The following nine case reports illustrate this complication of scleral buckling in SC disease. Possibilities for prophylaxis and therapy are presented, based on hypotheses regarding the pathogenesis of anterior segment ischemia in eyes with a propensity for intravascular sickling.

From the Division of Medical Genetics and Wilmer Institute, Johns Hopkins Hospital, and from the Department of Ophthalmology, University of Illinois Eye and Ear Infirmary. This study was supported in part by Training Grant 5TO1EY00025-11 (Dr. Ryan), USPHS (NIH) Special Fellowship 2F11-NB-1675-02 VSN, by the Bailey Fund of the Wilmer Institute (A. E. Maumenee, M.D.), and by NIH Training Grant EY 24-13 (University of Illinois Eye and Ear Infirmary).

## MATERIALS AND METHODS

The hospital records of all hemoglobinopathy patients undergoing ocular therapy during the last five years (August, 1964, to September, 1969) were reviewed. Six patients from the Wilmer Institute Residents' Service were found to have had scleral buckling operations. One patient (Case 1) had bilateral retinal detachment procedures. The hemoglobinopathy of all six cases was found to be the SC type by hemoglobin electrophoresis. All patients had been personally examined by at least one of us by indirect ophthalmoscopy and biomicroscopy. During the same time interval, in which over 100 patients with various types of hemoglobinopathies (SS, SA, SC, SThal, SD, AC, CC) were actively studied for retinal abnormalities, no other hemoglobinopathy patient was found to have retinal detachment. An additional SC patient (Case 5), who had retinal detachment surgery prior to the five-year review period, is also included in this report. The pertinent clinical and surgical details of these seven cases (eight eyes) constitute part of the material of this report (Fig. 1). Cases 8 and 9, from the University of Illinois Eye

Fig. 1 (Ryan and Goldberg). Key to illustrations of Cases 1 through 7 (Figs. 2 through 9).

and Ear Infirmary, presented with retinal detachments after analysis of the results in Cases 1-7. They were operated upon using the prophylactic recommendations cited below, and are also included. To our knowledge, there have been no other SC cases that have had retinal detachment surgery in our hospitals.

Cases 2-7 are listed in increasing order of severity of the anterior segment ischemia (Table 1). Cases 8 and 9 did not develop ischemia (Table 2).

In order to compare the incidence of postoperative anterior segment ischemia in SC patients with that in patients with normal hemoglobin, a review was made of the first 20 consecutive retinal detachment cases on the Wilmer Residents' Service from each of the last five years.

## Case report

*Case* 1—This 26-year-old man had chronic reduction of vision in his right eye, and complained of loss of his superior field in his left eye.

*Left eye:* The extent of the retinal detachment and distribution of sea-fans[8] are shown in Figure 2. On July 1, 1969 a scleral buckling procedure was performed on the left eye (Fig. 2). Table 1 lists the technical factors that might have predisposed the patient to develop the anterior segment ischemia which occurred postoperatively (Fig. 2-bottom). The intense inflammatory response failed to respond to a multitude of therapeutic measures but subsided gradually over approximately three weeks. Vision returned to 20/25. Midstromal iris atrophy and a few scattered posterior subcapsular opacities in the lens were the only residua.

*Right eye:* His right eye had a virtually complete retinal detachment and extensive vitreous traction (Fig. 3). Preoperatively, the patient underwent partial exchange blood transfusion in addition to other prophylactic maneuvers (which are recommended below). The buckling procedure is described in Figure 3 and in Table 1. Due to laboratory error, the patient did not achieve the recommended[9] 60% hemoglobin A prior to surgery. Postoperatively, he developed anterior segment ischemia again. Low molecular weight dextran (Rheomacrodex), topical corticosteroids, and atropine were of no avail, as the eye went on to phthisis (Fig. 3).

*Case* 2—This 15-year-old girl developed a rhegmatogenous retinal detachment six weeks following heavy photocoagulation to sea-fan neovascularization in the temporal periphery of her right eye (Fig. 4). A scleral buckling operation was done under general anesthesia, during which mild systemic hypotension occurred (Fig. 4-bottom right). The lateral rectus muscle was temporarily detached; the area overlying the temporal long posterior ciliary nerve and artery was treated with scleral diathermy, and an encircling band was placed. Despite these events, the postoperative reaction was limited to modest swelling and tenderness of the conjunctiva and eyelids, and no definite signs of anterior segment ischemia were noted. The retina was re-attached. Five years later, vision was 20/30.

*Case* 3—This 22-year-old woman gave a presumptive history of recurrent vitreous hemorrhage in the right eye, and was found to have a retinal hole and localized retinal detachment at 9 o'clock (Fig. 5). A small scleral diathermy procedure was carried out over this area, and involved the temporal long posterior ciliary complex (Fig. 5-bottom). No muscle was removed at the time of operation, which was done under local anesthesia, and no encircling band was placed. The postoperative course was uneventful, except for ischemia of the retina anterior to the treated area. The retina was re-attached. Vision was 20/20-1.

*Case* 4—This 34-year-old woman had recurrent vitreous hemorrhages in both eyes. The patient underwent a limited trap-door procedure in the left eye under local anesthesia for a retinal hole which was under traction (Fig. 6). The lateral rectus muscle was temporarily removed during the procedure, but the long posterior ciliary nerve and vessel complex was spared. No encircling strap was placed (Fig. 6-bottom). Postoperatively, there was anterior chamber haze with keratic precipitates as well

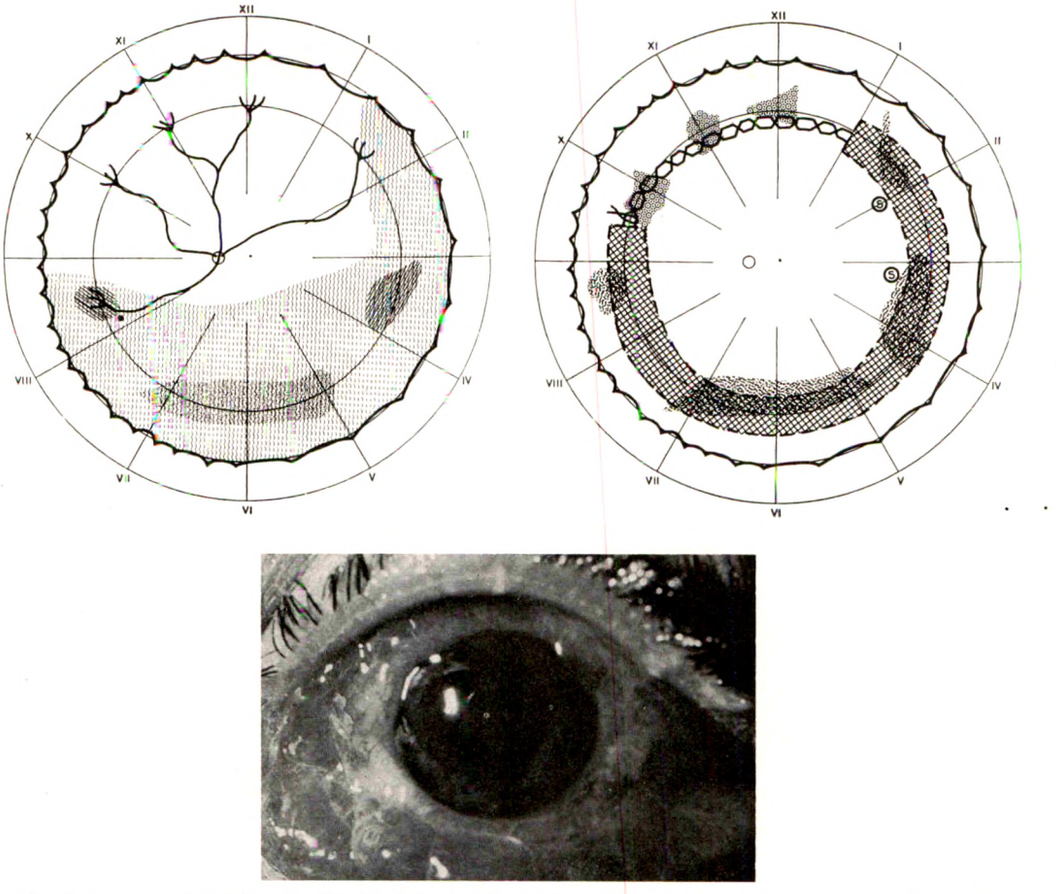

Fig. 2 (Ryan and Goldberg). Case 1, left eye. Top left: The retinal detachment in the left eye from 1:15 to 8:45 o'clock spares the macula. Sea-fans are present at 8:30, 10, 11, 12, 1:30 o'clock. Old white and fresh blood are present inferiorly, and glial proliferation is seen at 3:30 and 8:30 o'clock. At operation, holes were found at 3:30 o'clock, anterior and posterior to the glial scar. Top right: The operation is diagrammed. Sea-fans at 10, 11 and 12 o'clock were photocoagulated. Cryothermy (freeze and refreeze) was applied to sea-fans at 8:30 and 1:30 o'clock, to the glial scar at 3:30, where two holes were discovered, and to the region of the old hemorrhage from 5 to 7 o'clock. A No. 20 silicone strip was placed as an exoplant from 1:00 to 9:30 o'clock, and a No. 40 encircling band was placed around the globe, and clipped at 9:30 o'clock. Sclerotomies were performed at 2:00 and 3:15 o'clock with release of moderately xanthochromic fluid. This eye did well following resolution of anterior segment ischemia, and vision is 20/25. Bottom: The same eye is shown six days after scleral buckling. Anterior segment ischemia is manifested by chemosis and irregular necrosis of the iris (with production of an irregular pupil).

as vitreous haze. Since endophthalmitis was considered possible, and because systemic antibiotics were already being routinely administered, systemic steroids were added to the postoperative therapeutic regimen. Four years later, the retina was attached, and vision was 20/20.

*Case* 5—In 1961, this 19-year-old man underwent a scleral buckling operation with diathermy for a retinal detachment in his right eye (Fig. 7). The medial and inferior rectus muscles were temporarily detached. Postoperatively, there was corneal edema, aqueous ray and hypotony. Endophthalmitis was suggested, and a course of systemic penicillin, streptomycin, chloromycetin, and corticosteroids was begun.

One month later there were posterior synechiae, irregular dilatation of the pupil, moderate aqueous ray, cortical cataracts, and innumerable cells and dense haze in the vitreous. The retina was completely attached.

Five months later, when last seen, vision in the right eye was hand movements only. Only a red fundus reflex could be discerned, due to residual blood from several episodes of recurrent vitreous

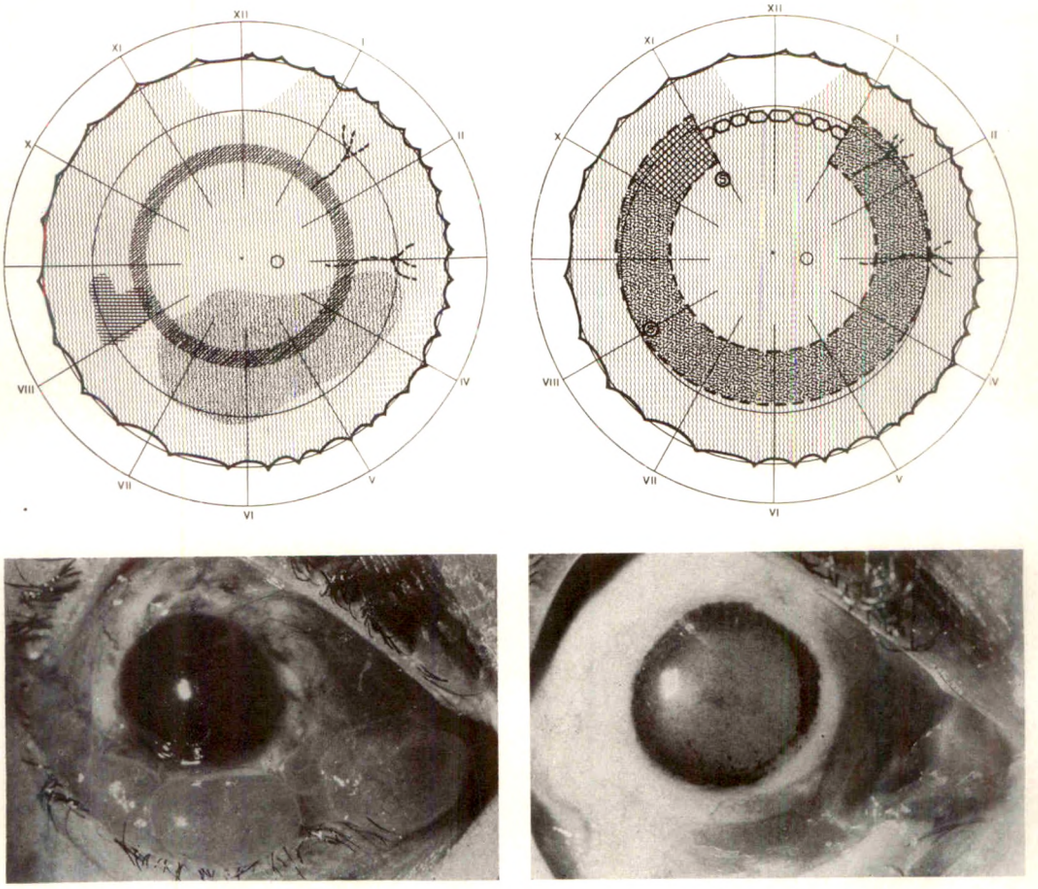

Fig. 3 (Ryan and Goldberg). Case 1, right eye. Top left: Only a small area of retina (from 11:30 to 12:30 o'clock) was attached in the right eye of Case 1. Marked vitreous traction, with an equatorial, circumferential band of condensed vitreous (resembling a purse string) was seen. Retinoschisis was present at 8:30 o'clock adjacent to a small hole, which was visualized only at operation. Obliterated old sea-fans were seen at 1:30 and 3 o'clock, and old vitreous blood obscured the fundus from 3:15 to 7:30 o'clock. Top right: The operative result is illustrated. Meridional rows of cryothermy were applied from 1 to 10 o'clock. A No. 281 silicone tire exoplant was secured from 1 to 11 o'clock with an encircling No. 240 band. A sclerotomy at 8 o'clock yielded large amounts of fluid, but no further fluid could be obtained from a sclerotomy at 11 o'clock. The retina never settled. Severe anterior ischemia developed, and the eye progressed to phthisis. Bottom left: The right eye of Case 1 is shown 14 days after scleral buckling. The cornea is clear, as it is in the later Figure to the right, but marked chemosis and irregular pupillary dilatation were present. Bottom right: The same eye is shown 11 weeks after scleral buckling. Phthisis bulbi, with cataract and extensive iris necrosis, has occurred.

hemorrhage. The intraocular pressure was 7 mm Hg. The prognosis for useful vision appeared hopeless.

*Case* 6—This 38-year-old man developed a total retinal detachment in his right eye (Fig. 8). At surgery, a normal blood pressure was maintained under general anesthesia. The patient underwent a scleral buckling procedure with diathermy, a buried implant, and an encircling band (Fig. 8-bottom). The long posterior ciliary neurovascular complexes were spared, but the inferior rectus muscle was temporarily detached. Postoperatively, conjunctival hyperemia, chemosis, shallow anterior chamber with choroidal effusion, keratic precipitates, fibrin clot and cataract developed. Thirteen days postoperatively, the patient was started on systemic corticosteroids. The eye had progressed to the prephthisical stage when last examined four months postoperatively.

*Case* 7—This 28-year-old man had a scleral buckling procedure under general anesthesia for a total retinal detachment in the right eye (Fig. 9).

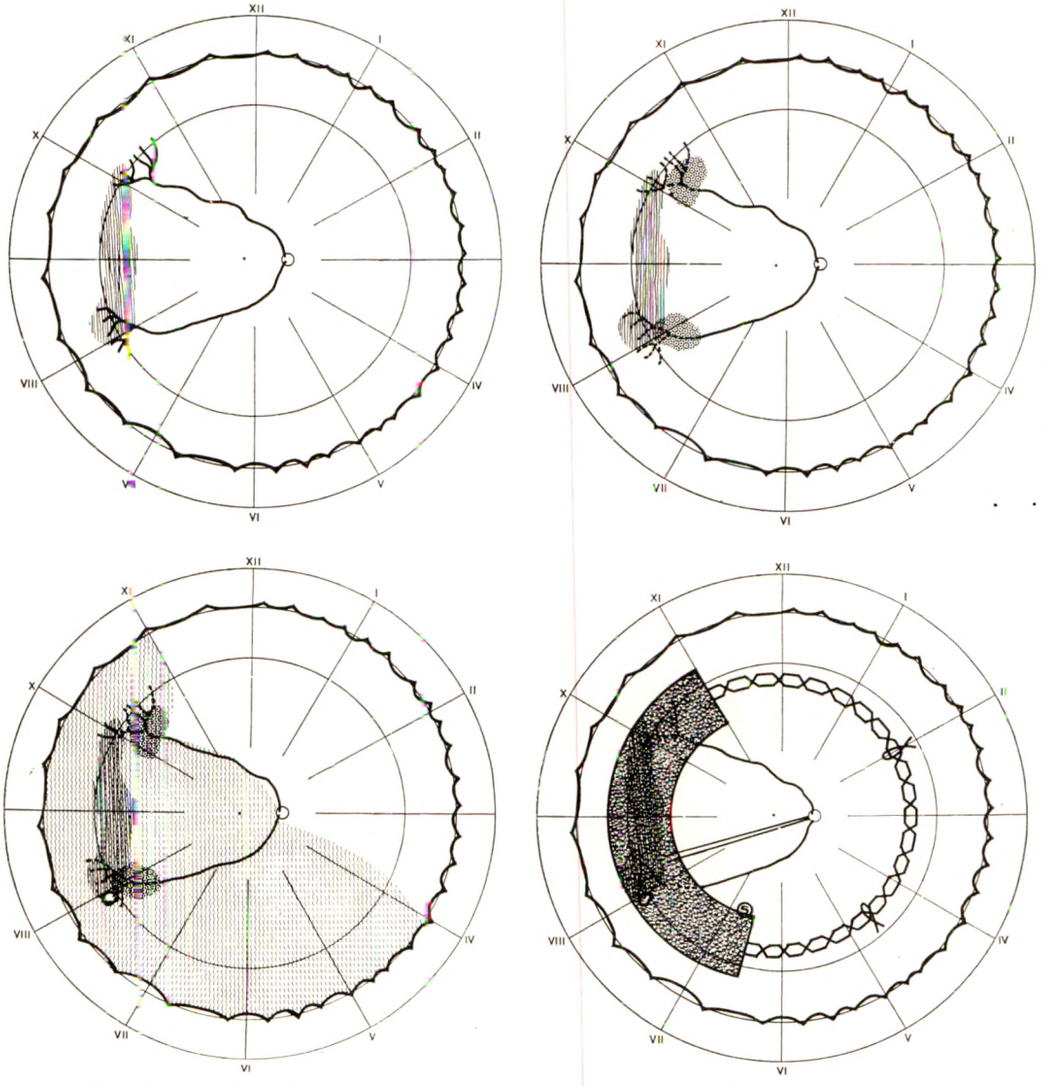

Fig. 4 (Ryan and Goldberg). Case 2. Top left: On initial examination, this patient had arborizing sea-fans at 8 and 10 o'clock, with glial membrane or vitreous sheet connecting the two areas of neovascularization. Top right: Photocoagulation (Zeiss) with overload No. 1 intensity and the 3° image field produced avascularity of the fans. Bottom left: Forty-four days after photocoagulation, retinal detachment with a hole at 8 o'clock was noted. Bottom right: The operation is illustrated. Diathermy was placed at the retinal hole at 8 o'clock and in the bed of a lamellar scleral dissection from 6:30 to 11 o'clock. An 8 mm wide silicone strip was implanted, and a No. 40 encircling band was clipped at 2 o'clock. The vitreous sheet remained over the buckle from 7:30 to 9:30 o'clock. A white retinal traction fold ran from the buckle at 8:30 to the disk, causing macular distortion and vision of 20/30. There was no anterior segment ischemia.

Blood pressure fell from 110/70 to 90/60 during surgery. Diathermy and cryothermy were applied to the retinal breaks. Silicone sponge exoplants were applied meridionally, and an encircling band was pulled tightly following subretinal fluid drainage (Fig. 9-center). No muscles were detached. Postoperatively, he developed chemosis, cloudy cornea, pigmented keratic precipitates, shallow anterior chamber, rapidly intumescent cataract, and yellow vitreous haze which prevented fundus examination. Because of a presumptive diagnosis of endophthalmitis, systemic therapy with penicillin, chloromycetin, and corticosteroid was instituted. Eight months later, the eye was phthisical, and had iris

necrosis, cataract, hypotony, and no light perception (Fig. 9/bottom). The eye was obtained at autopsy and demonstrated histopathologic signs of anterior segment ischemia.

*Case* 8—This 37-year-old man with SC hemoglobin, had a total, bullous retinal detachment of the left eye (Fig. 10). Partial exchange transfusion raised his hemoglobin A to 64%. A four and one-half hour exoplant and cryothermy procedure was carried out under local anesthesia. A stellate gan-

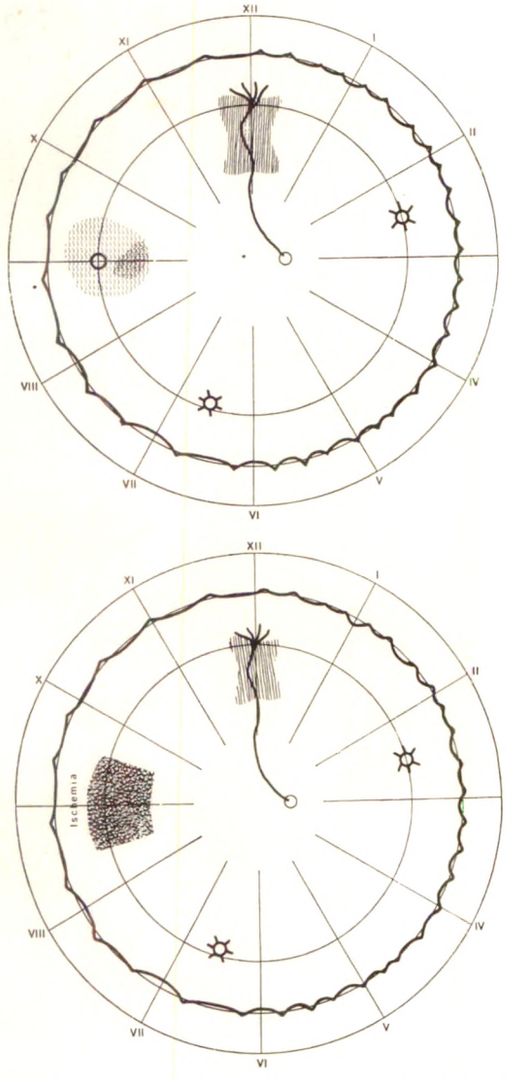

Fig. 5 (Ryan and Goldberg). Case 3. Top: The retinal hole, and localized retinal detachment and vitreous blood are seen at 9 o'clock in the right eye. A seafan is present at 12 o'clock, and two black sunbursts[8] are at 2:30 and 6:30 o'clock. Bottom: The operation was a trap door procedure with diathermy, but no implant was used. Ischemia developed in the retina anterior to the area of treatment, but central vision remained normal.

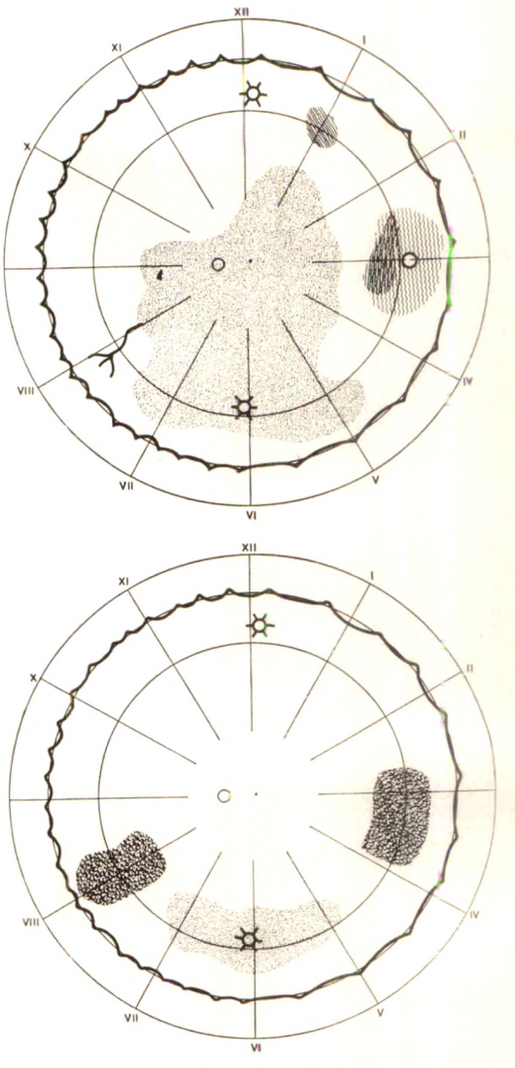

Fig. 6 (Ryan and Goldberg). Case 4. Top: A hemorrhage obscuring the posterior pole is shown. Black sunbursts are present at 12 and 6 o'clock. Glial retinal scars extending into the vitreous can be seen at 1 and 3 o'clock. A retinal hole with localized retinal elevation is present at 3 o'clock. A single sea-fan at 7:45 o'clock is also seen. Bottom: The operation is illustrated. Diathermy was placed at the 3 o'clock hole and at the 7:45 sea-fan. A temporal scleral trap door procedure was carried out, with diathermy placed in the bed of the trap door and with implantation of a sheet of silicone sponge. Minimal anterior segment ischemia resulted. Subsequently, vision was 20/20.

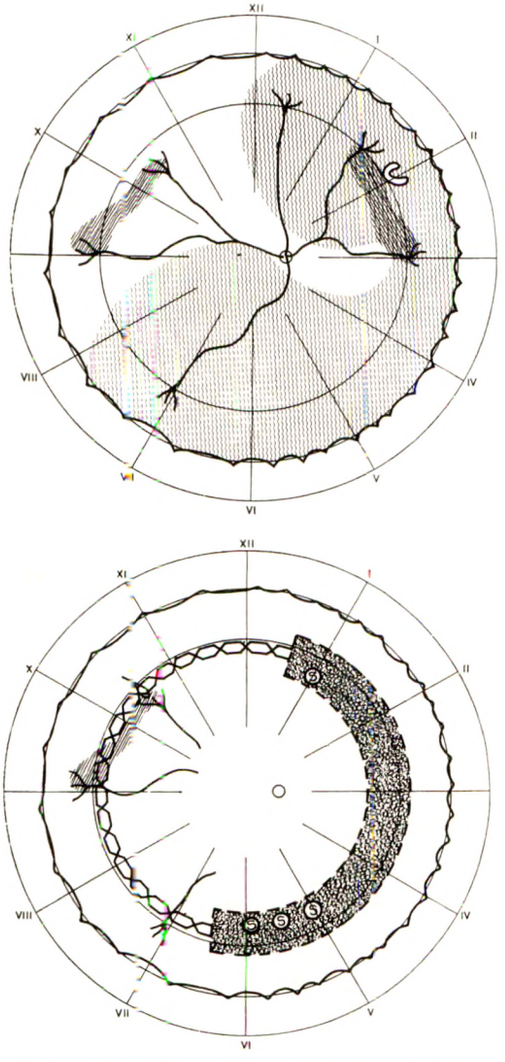

Fig. 7 (Ryan and Goldberg). Case 5. Top: A horseshoe tear at 2 o'clock and the retinal detachment are seen. Sea-fans are present at 12:30, 1:30, 3, 7, 9 and 10:30 o'clock, along with glial sheets at 2 and 9:30 o'clock. Bottom: At operation, a lamellar scleral bed was cut from 12:30 to 6:30 o'clock. Diathermy was placed in the bed, and an encircling polyethylene tube was tied at 10:30 o'clock. Sclerotomies were performed at 1, 5, 5:30, and 6 o'clock. Postoperatively the patient developed anterior segment ischemia, the visual results of which negated the successful reattachment of his retina.

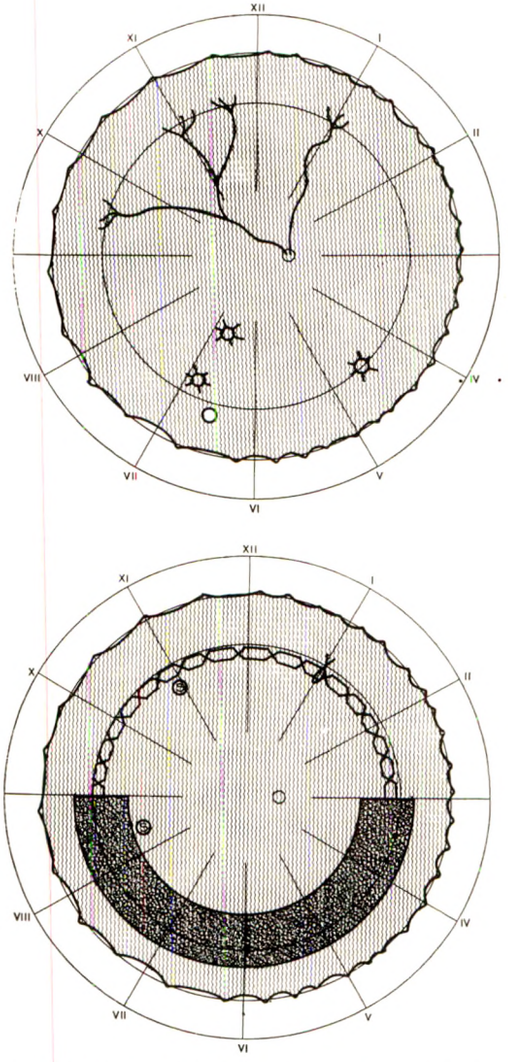
glion block, retrobulbar priscoline, intravenous papaverine, and continuous nasal oxygen (which was maintained during the operation and for the next two days) were administered. There were no sympathomimetics used for pupillary dilatation or retrobulbar anesthesia. One horseshoe tear at 1:30 o'clock was found adjacent to a sea-fan,[8] and was frozen. Two No. 279 silicone tires were sutured to



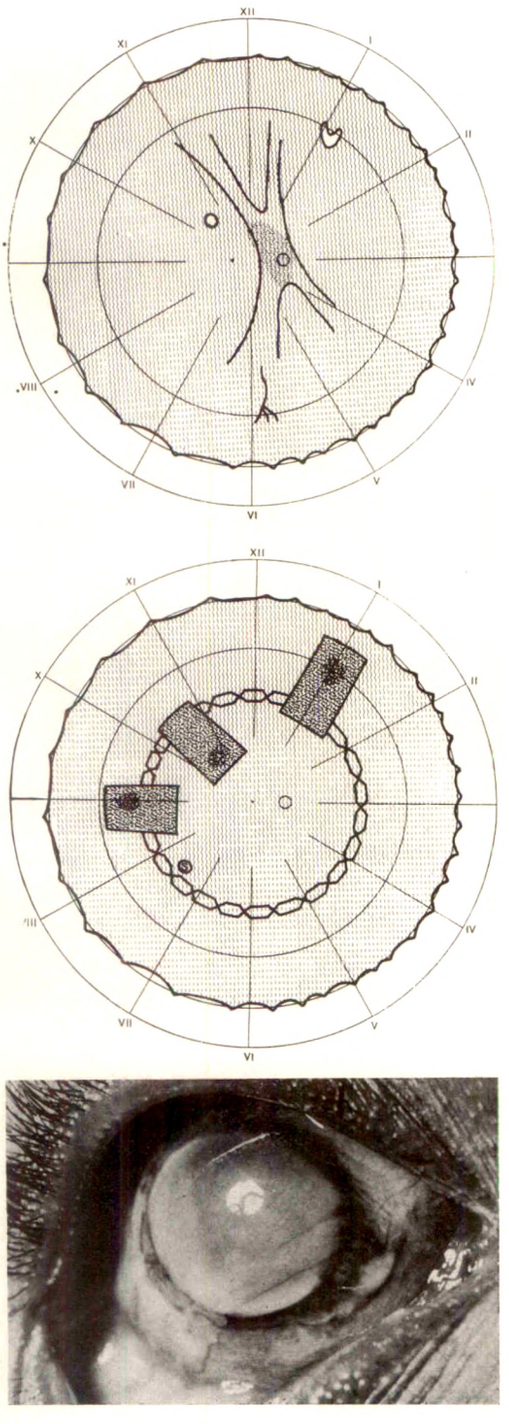


Fig. 8 (Ryan and Goldberg). Case 6. Top: A total retinal detachment and a hole at 6:30 o'clock are seen. Black sunburst scars are present at 4:30 and 6:45 o'clock. Numerous obliterated and patent areas of neovascularization are seen at 9:30, 11, 11:30, and 1 o'clock. Bottom: The operative procedure is shown. The inferior rectus was detached. A lamellar scleral bed was dissected from 3 to 9 o'clock and diathermy was placed in the bed. A No. 31 silicone implant was left in the bed, and a No. 40 encircling band was tied at 1 o'clock. Two sclerotomies were performed (at 8:30 and 11 o'clock). Postoperatively, the retina remained detached, and the patient developed severe anterior segment ischemia.

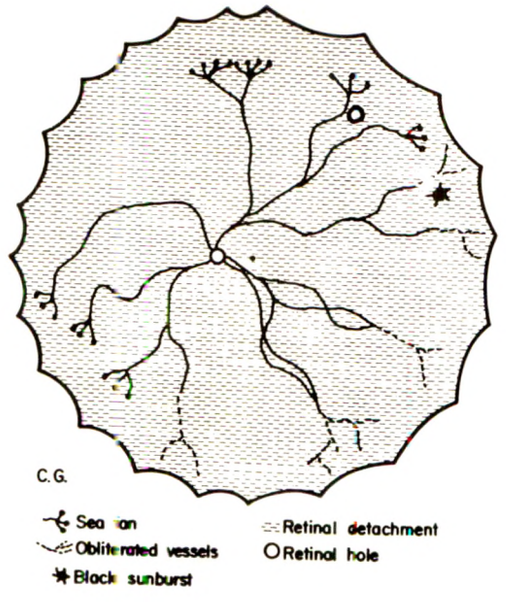
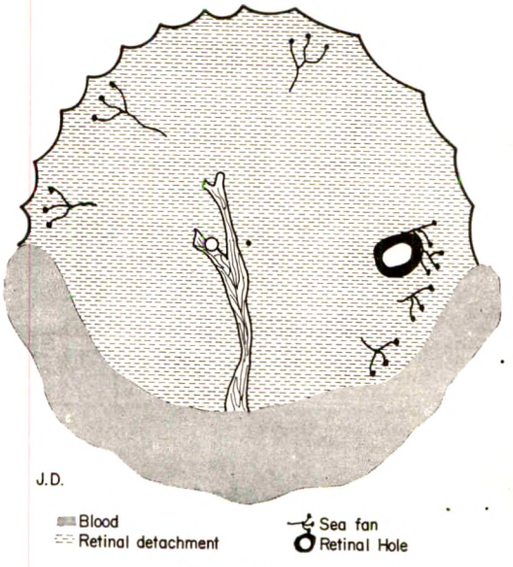
the sclera (Fig. 10-bottom), and subretinal fluid was drained. Intraocular pressure was slightly elevated at the end of the operation. Anterior segment ischemia did not occur. Ten months postoperatively, the retina was completely attached. Vision had improved from counting fingers at three feet to 20/400.



*Case* 9—This 37-year-old man had a total retinal detachment in the left eye. A dense vitreous traction band pulled on the retina above and below the macula (Fig. 11). Partial exchange transfusion raised his hemoglobin A to 67%. A four and one-half hour scleral buckling procedure was performed under local anesthesia. A stellate ganglion block, retrobulbar priscoline, intravenous papaverine, and continuous nasal oxygen (which was maintained during the operation and for the next two days) were administered. No sympathomimetics were used for pupillary dilatation or for retrobulbar anesthesia. One large tear adjacent to the 3 o'clock sea-fan was found, and was frozen. A 15 mm wide scleral undermining (Fig. 11-bottom) was dissected from 11 to 8 o'clock (clockwise), and cryothermy placed in its bed. The long posterior ciliaries were spared. A 13 mm wide implant was buried beneath the scleral flaps after subretinal fluid was drained. An encircling band raised the intraocular pressure slightly at the end of surgery. Muscles were not detached. Despite the extensive scleral dissection, anterior segment ischemia did not occur. Six weeks postoperatively, the retina was flat at the buckling site, but was elevated posterior to the implant due to extensive vitreous contraction.



## Comment

*Proliferative sickle retinopathy*—Fluorescein fundus angiography in SC cases has demonstrated an area of total retinal avascularity immediately peripheral to the characteristic neovascular proliferations (sea-fans),[8,10-13] where an occlusive process appears to involve retinal capillaries and small

Fig. 9 (Ryan and Goldberg). Case 7. Top: The total retinal detachment, dense vitreous bands, old vitreous blood, large retinal tears at 11 and 1 o'clock, and neovascularization at 5:45 o'clock are illustrated. Center: At operation, the retinal holes, plus an additional hole at 9 o'clock, were treated with a central spot of diathermy and encircling cryothermy. A 5 mm silastic sponge was placed under the 11 o'clock hole, and 3 mm sponges were placed under the 9 and 1 o'clock holes. A No. 240 band encircled the eye posterior to the equator. A sclerotomy was performed at 7:30 o'clock posterior to the band. The patient developed severe anterior segment ischemia, which progressed to phthisis. Bottom: The same eye as photographed eight and one-half months after scleral buckling. There is phthisis bulbi with cataract and extensive iris necrosis.

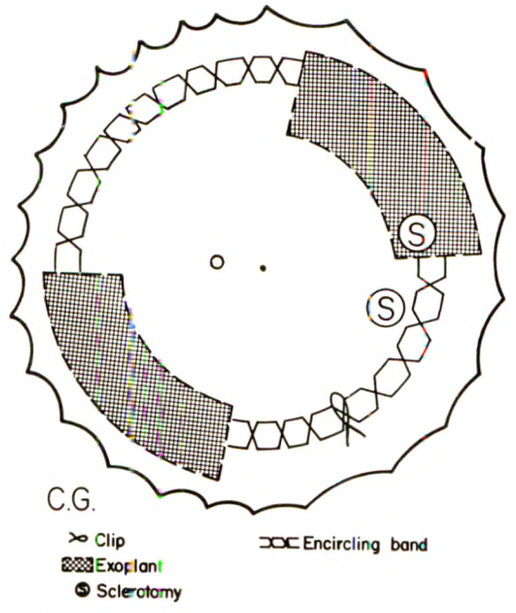


Fig. 10 (Ryan and Goldberg). Case 8. Top: The left eye of Case 8 had a total detachment with a single supero emporal retinal hole adjacent to a sea-fan. Bottom: Anterior segment ischemia did not develop postoperatively, despite two large buckles, prolonged operating time, elevated intraocular pressure and an encircling band. Several prophylactic measures, including partial-exchange blood transfusion, had been taken preoperatively.

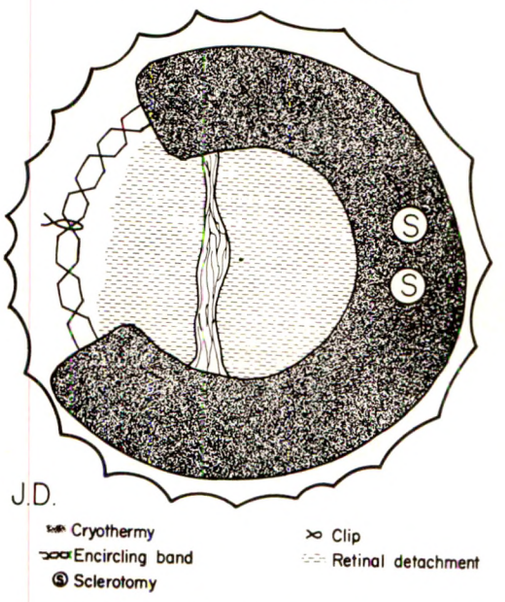

Fig. 11 (Ryan and Goldberg). Case 9. Top: The left eye of Case 9 showed extensive vitreous contraction and hemorrhage. A single retinal hole was found adjacent to a sea-fan at 3 o'clock. Bottom: A 15 mm wide scleral dissection was created for a 13 mm wide silicone implant from 11 to 8 o'clock. Despite prolonged operating time, elevated intraocular pressure, an encircling band and very extensive surgery, anterior segment ischemia did not occur. Several prophylactic measures, including partial-exchange blood transfusion, had been employed preoperatively. The retina reattached at the buckling site, but remained elevated posterior to the implant because of extensive vitreous membrane formation and contraction.

arterioles. Evidence suggests, therefore, that such eyes are ischemic even prior to therapeutic intervention.[11-13] Ischemia, itself, may contribute to the development of retinal detachment, even in individuals with normal hemoglobin.[14]

Over the last six years 45 SC patients have been studied by one of us at the Wilmer Institute and at the University of Illinois Eye and Ear Infirmary, during which eight patients developed or presented with retinal detachment. It is apparent that retinal detachment is a significant complication of SC disease (but seemingly not in other types of hemoglobinopathy), even allowing for bias of ascertainment of cases. A previous histologic report[15] confirms the severity of retinal pathology in SC disease.

An effort was made to determine the approximate frequency of SC hemoglobin in one of our hospital's Negro population with retinal detachment. Sixty-one Negroes had had retinal detachment surgery at the Wilmer Institute during the last five years. Therefore, our six SC patients originating from this hospital comprise approximately 10% of the Negro retinal detachment cases during this interval. The 10% frequency may actually be an underestimation, since hemoglobin electrophoresis was not performed on all Negro retinal detachment patients. The association of SC hemoglobin with retinal detachment is emphasized by the realization that it represents an approximately 33-fold increase over the frequency of SC hemoglobin in the general Negro population (which is about 0.3%).[16]

One of the alleged reasons that Negroes have less retinal detachments than Caucasians is their diminished frequency of vitreous degeneration.[17-19] Conversely, the high frequency in Negro retinal detachments of SC retinopathy is apparently related to the extensive vitreous degeneration, contractions, and hemorrhage which are seen in this disorder.[8,11,12]

In an attempt to compare the frequency and severity of anterior segment ischemia following scleral buckling in SC patients with similar parameters in the nonsickling population, the first 20 consecutive retinal detachment cases performed on the Wilmer Residents' Service for each of the last five years were reviewed. Of these 100 cases, 68 were Caucasians and 32 were Negroes without systemic or ocular evidence of sickle cell disease. There were three instances (one Negro) of anterior segment ischemia in these 100 cases (3%), as opposed to five of seven eyes in the SC cases (71%) during the same interval. Of the nonsickling cases, one was particularly severe, and developed phthisis bulbi. In the SC cases, two eyes were prephthisical and two were phthisical at the last follow-up examination.

*Anterior segment ischemia*—Six of the 10 eyes reported here showed some ischemic signs. The anterior segment ischemia syndrome consists of necrotic changes in the cornea, iris, ciliary body, lens and anterior chamber, presumably secondary to ischemia and hypoxia. Striate keratopathy, with folds in Descemet's membrane and corneal edema, is frequently the first and most prominent sign. Progressive conjunctival edema may then become apparent. Iris necrosis is often manifested by irregular dilatation of the pupil and shrinkage towards the area of greatest necrosis. Cataract formation may begin first on the side of greatest hypoxia, as indicated by the iris necrosis, and is usually complete in severe cases within three months. Hypotony is often marked. The anterior chamber may become shallow, possibly in association with ciliary body and choroidal detachment.

Haziness of the ocular media in this syndrome may mimic the appearance of postoperative, infectious endophthalmitis, and, when coupled with chemosis and keratopathy, may erroneously suggest a diagnosis of infectious panophthalmitis. It is instructive that in at least three of these patients (Cases 4, 5, and 7) an infectious etiology was considered seriously enough to warrant intensive therapy with systemic antibiotics.

The pathogenesis of anterior segment ischemia has been related to interruption of the anterior ciliary arteries (those major arteries, usually seven in number, coursing through the rectus muscles),[5] to occlusion of one or both of the long posterior ciliary arteries,[1,2] as well as to the constricting effect of an encircling band.[1-3,5] Various experimental methods have been employed[6,7] in an attempt to reproduce this syndrome. However, the exact pathogenesis is unknown, and any or all of the above factors may play responsible roles. It would seem, however, that this disorder is related to impaired circulation and hypoxia of the anterior segment. Similar clinical findings have been noted in patients who undergo no surgery, but who have ischemia on the basis of atherosclerosis or other disease processes affecting the vascular supply of the eye.[20]

*Surgical factors*—No positive, consistent correlation (Table 1) can be made in this series of patients between the development of ischemia and any one of the following technical aspects of the surgery: (1) Detachment of the rectus muscle. Two patients (Case 1, both eyes, and Case 7) developed anterior segment ischemia even though no rectus muscle was detached. (2) Use of an encircling band. Case 4 did not have an encircling element, and developed ischemia, whereas Case 2 had a band but did not become ischemic. (3) Treatment over the long posterior ciliaries. In Cases 1 (right eye), 4, and 6, these vessels were spared, but ischemia occurred, whereas the long posterior ciliary artery was diathermized in Case 2, but ischemia did not occur. (4) Cryothermy vs diathermy. Cases 1 and 7 were treated with cryothermy, whereas diathermy was used in Cases 4, 5, and 6, but all developed ischemia. (5) Exoplant vs implant. Cases 1 and 7 had exoplants without scleral surgery, but were ischemic nonetheless. (6) Ocular hypertension. No case had a significant elevation of tension. (7) Systemic hypotension. Normal blood pressure in Cases 1, 4, 5, and 6 did not prevent ischemia. The possibility that the extent of the retinal detachment and vitreous traction (and thus the extent of the required surgery) can be correlated with the development of anterior segment ischemia must be considered, since several eyes with the most difficult detachments developed the most severe ischemia. However, Case 2 had diathermy $> 120°$) and did not develop ischemia, whereas Case 4 had 60 degrees of diathermy and did develop ischemia. Case 2 did not develop anterior segment ischemia, despite the following technical maneuvers which might theoretically predispose to ischemia: systemic hypotension during anesthesia, scleral surgery and diathermy with involvement of the long posterior ciliary complex, detachment of a rectus muscle and placement of an encircling band. Also, Cases 8 and 9, with severe detachments and extensive surgery, did not develop ischemia (Table 2). Thus, it appears that no common surgical denominator can be derived from the technical aspects of scleral buckling in these cases which can be held responsible for postoperative anterior segment ischemia.

*Nonsurgical factors*—Certain nonsurgical factors can be correlated with lack of development or less severity of anterior segment ischemia following retinal detachment operations in SC patients. For example, Cases 2-4 are females (Table 1), and were affected either mildly or not at all. Cases 2 and 3 were also characterized by having a lower average age and a lower average hematocrit than those patients who did develop anterior segment ischemia (Table 3). Since vascular occlusions occur intermittently and progressively during the lifetime of SC patients, it is possible that enough patent vasculature existed in the younger patients to allow adequate perfusion of the anterior segment during and following surgery. However, even the factor of youthfulness in Case 5 did not prevent the development of anterior segment ischemia (which may have been related in his case to temporary detachment of two rectus muscles).

It appears possible that SC hemoglobin

TABLE 3

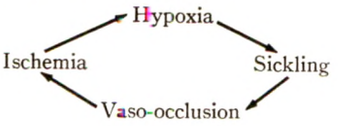
SCLERAL BUCKLING IN HEMOGLOBIN SC DISEASE
(Cases 1–7, eight eyes)

| | Age (avg. years) | Hct (avg. %) | Sex | | Anesthesia | | Rectus Off | Encirc. Band | Dia-thermy | Cryo-thermy | Im-plant | Exo-plant | Postoperative Vision | | Rx for Endoph-thalmitis |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | M | F | Loc. | Gen. | | | | | | | 20/30 | HM | |
| No ischemia (2 eyes) | 19 | 32 | 0 | 2 | 1 | 1 | 1 | 1 | 2 | 0 | 2 | 0 | 2 | 0 | 1 |
| Ischemia (6 eyes) | 29 | 39 | 5 | 1 | 2 | 4 | 3 | 5 | 4 | 3 | 3 | 3 | 2 | 4 | 3 |

plays a responsible role in the development of anterior segment ischemia. The clinical severity of the different sickle hemoglobinopathies is directly related to the rate of increase of viscosity of blood during deoxygenation.[9] The concentration of hemoglobin S and the degree of interaction between the various hemoglobins are the major determinants of this rate. The viscosity of blood containing sickled erythrocytes is proportional to the product of the percentage of sickle hemoglobin and the square of the hematocrit value.[9] A higher hematocrit with a concomitant, increased viscosity predisposes to the multiple thrombotic events characteristic of this disease. These considerations may be helpful in explaining the frequent occurrence of vascular occlusive manifestations in patients with certain heterozygous sickling disorders, such as SC, who do not have appreciable anemia.[9,21,22] The lower hematocrit in Cases 2 and 3 may have allowed less viscosity, better perfusion, and, therefore, improved oxygenation of the anterior segment as compared with those cases with higher hematocrits.

The phenomenon of intraoperative, intravascular sickling is well recognized, and is thought to be related to relative hypoxia in association with anesthesia.[23-28] While most sicklers are subject to this hazard, SC patients with their nearly normal hematocrits (frequently 35 to 40%) seem particularly prone to intravascular sickling under these conditions.

An instructive, though distressing, operation was that for the right eye of Case 1. This was the first instance, to our knowledge, in which the association between anterior segment ischemia and SC hemoglobin was known preoperatively. Thus, a large number of prophylactic measures (listed in Table 4) were utilized in the management of this eye. Despite all these measures, anterior segment ischemia developed postoperatively. Extensive cryothermy and a large exoplant, which were necessitated by the marked vitreous traction, may have contributed. However, similar surgery in Case 9 did not cause the ischemic syndrome. A laboratory error in Case 1, however, led to inadequate exchange transfusion preoperatively, such that only 20% of the patient's hemoglobin was normal hemoglobin A at the time of surgery. This is markedly less than the 60% hemoglobin A which is the recommended minimal preoperative goal of partial exchange transfusion in sickle cell disease. If nothing else, Case 1 underscores the association of postoperative anterior segment ischemia with SC disease, since a conscious and reasonable effort was taken to avoid or minimize most, if not all, of the other factors that might ordinarily predispose to ischemia.



Cases 8 and 9 represent, perhaps the strongest argument for the role of intravascular sickling in the development of anterior segment ischemia following scleral buckling. In these two patients extensive and prolonged operations were performed after exchange transfusion had provided greater than 60% hemoglobin A. Anterior segment ischemia did not develop in either case.

*Recommendations*—The data of Charache

TABLE 4

POSTOPERATIVE ANTERIOR SEGMENT ISCHEMIA IN SICKLE RETINOPATHY

Postulated pathogenesis:

Recommended prophylaxis:

Preoperative:
1. Local anesthesia without sympathomimetics
2. Stellate ganglion block, papaverine administration
3. Pupillary dilatation with parasympatholytics only
4. Partial exchange transfusion
5. Lowered intraocular pressure

Intraoperative:
1. Supplemental oxygen
2. Minimization of peritomy
3. Avoidance of rectus muscle detachment or traction
4. Avoidance of long posterior ciliary vessels
5. Diathermy vs cryothermy (?)
6. Exoplant vs scleral implant (?)
7. Subretinal drainage
8. Avoidance of encircling band if possible (one is frequently necessary because of extensive vitreous traction)

Recommended postoperative therapy:
1. Supplemental oxygen
2. Pupillary dilatation
3. Papaverine (?)
4. Low molecular weight dextran (?)
5. Adrenal corticosteroids (?)
6. Anticoagulants (?)

and Conley[9] support the concept that all the clinical manifestations of sickle cell disease are attributable to the consequences of intravascular sickling of erythrocytes. Because of the lack of any other consistent surgical factor in these patients which could be correlated with anterior segment ischemia (Table 1), it would appear that the sickling process is probably also related in some causal way to the development of anterior segment ischemia in our patients. That this may be so is underscored by the high percentage of sicklers who developed this disorder following scleral buckling in comparison with the nonsickling population. Also, as noted above, those patients previously transfused successfully tolerated the scleral buckling procedure well. Consequently, the recommendations in Table 4 for clinical management of SC patients who require retinal detachment surgery are based on attempts to avoid intraoperative and postoperative ischemia, hypoxia, and sickling. The onset of sickling in the eye, as elsewhere, sets up a vicious cycle of events leading to decreased perfusion, with further ischemia, hypoxia, and sickling (Table 4).

Since the effects of anterior segment ischemia are sometimes irreversible, prophylaxis is preferable to therapy. The common objective underlying these recommendations (Table 4) is increased perfusion and oxygenation, with decreased sickling and ischemia.

Because of the danger of sickling during parturition, pregnant women with SC disease have been effectively managed prior to delivery by partial exchange transfusion.[27] This exchange of normal red blood cells for those containing SC hemoglobin has also been recommended prior to general surgical

procedures.[26,28] Complications from parturition and surgery can usually be minimized if partial exchange transfusion results in a red blood cell mass in which about 60% of erythrocytes have normal hemoglobin A. It would seem reasonable, therefore, to treat scleral buckling cases similarly. Since even local anesthesia obviously does not eliminate all causes of ocular ischemia and hypoxia that occur during retinal detachment surgery, this recommendation applies even when retrobulbar anesthesia is employed. The possibility, however, of inducing serum hepatitis or septicemia by partial exchange transfusion must be considered.

Cryothermy with an exoplant would theoretically appear to be more advantageous than diathermy and a scleral disection. In any event, drainage of subretinal fluid will soften the eye and tend to counteract any tendency towards decreased vascular perfusion.

Other prophylactic and therapeutic measures with potential merit are listed in Table 4.[29-38]

## Summary

Ten eyes of nine sickle cell-hemoglobin C patients (SC) underwent retinal detachment surgery. Six eyes showed signs of anterior segment ischemia postoperatively, and one showed signs of retinal ischemia. Four eyes became phthisical or prephthisical. In three cases, anterior segment ischemia was erroneously thought to be infectious endophthalmitis.

In a sampled hospital population, 71% of buckled eyes of SC patients developed anterior segment ischemia, whereas only 3% of nonsickling eyes developed this postoperative complication during the same five-year period. Patients with SC hemoglobin thus appear particularly vulnerable to anterior segment ischemia following scleral buckling.

Lower hematocrit, younger age, and female sex were associated with clinically less severe postoperative findings.

Technical surgical factors did not seem to influence the presence or absence of postoperative anterior segment ischemia. Partial exchange blood transfusion and additional measures were employed in three cases. When the patients' hemoglobin A was increased to more than 60%, anterior segment ischemia did not develop despite extensive, prolonged scleral buckling operations.

# SURGICAL CATGUT FOR SEGMENTAL BUCKLE IN RETINAL DETACHMENT

A. DELLAPORTA, M.D., AND R. YUKINS, M.D.
*Stanford, California*

The introduction of the segmental scleral buckling procedure by Custodis[1,2] in 1951 revolutionized important concepts in retinal detachment surgery. The essential factor of this technique was that the sclerochoroidal buckle pushed the diathermized choroid into apposition with the retinal breaks during the actual operation. Presently, the aseptic and polymorphous silicone rubber has replaced most other implants. Experimental[3] and clinical observations showed that the sclerochoroidal buckle gradually flattened following the operation, but this had no adverse effect on a reattached retina. This observation and concern over the reported complications, mainly pressure necroses and infections,[4-7] prompted the introduction of absorbable scleral implants.

Chromic surgical gut was the first to be used,[8] followed by fascia lata,[9] and others.[10-17] Absorbable implants did not become popular, mainly because of their questionable sterility and the difficulty in obtaining most of them.

Experimental work[18] showed that thick chromicized surgical gut which was completely buried within a scleral fold created a scleral buckle which persisted for at least two months. Histologically, a mild transient inflammatory reaction of the uvea was noticed along the buried gut and this was considered an advantageous side effect for the reattachment of the retina. The duration of the buckle was thought to be adequate for use in idiopathic retinal detachments. The purpose of this paper is to report a suitable technique.

The present results were obtained in 21 successive operations. The detachments covered up to one-half of the retinal surface, had one or more breaks within the detached area, and included aphakic eyes and cases with detached maculas. Cases with fibrous vitreous bands, massive vitreous retraction, giant tears, and total detachments were not operated on with this method.

## DESCRIPTION OF OPERATION

General anesthesia was preferred but in about half of the operations local anesthesia with 2% xylocaine HCl with the addition of adrenalin 1:1000 was used satisfactorily.

After lateral canthotomy, the presenting rectus was detached, the sclera exposed, and traction sutures were placed under the adjacent recti in order to rotate the eye to the desired position. The retinal break was localized by transillumination and the first orientating diathermic coagulation applied with a blunt 1 mm diameter electrode (Storz E-5212). Additional ophthalmoscopically visible coagulations with a 0.5 mm long non-perforating diathermy needle with insulated base (Storz E-5262) were placed to surround the break. Instead of diathermy, cryo-applications were used in about half the cases for the additional treatment of the choroid.

Two millimeters behind the orientating coagulation a single-incision scleral groove was formed parallel to the limbus and involving one-third to one-half the circumference of the globe. The groove was formed by incising the external one-half of the scleral layers with a No. 15 Bard-Parker blade and then pushing the wound edges of the incision anteriorly and posteriorly with the blade until the base of the groove was 3 to 4 mm wide (Fig. 1). Occasionally, sharp undermining of the posterior scleral edge was necessary, especially when the groove was located behind the equator. For this a No. 66 angled Beaver blade proved safe in avoiding sceral

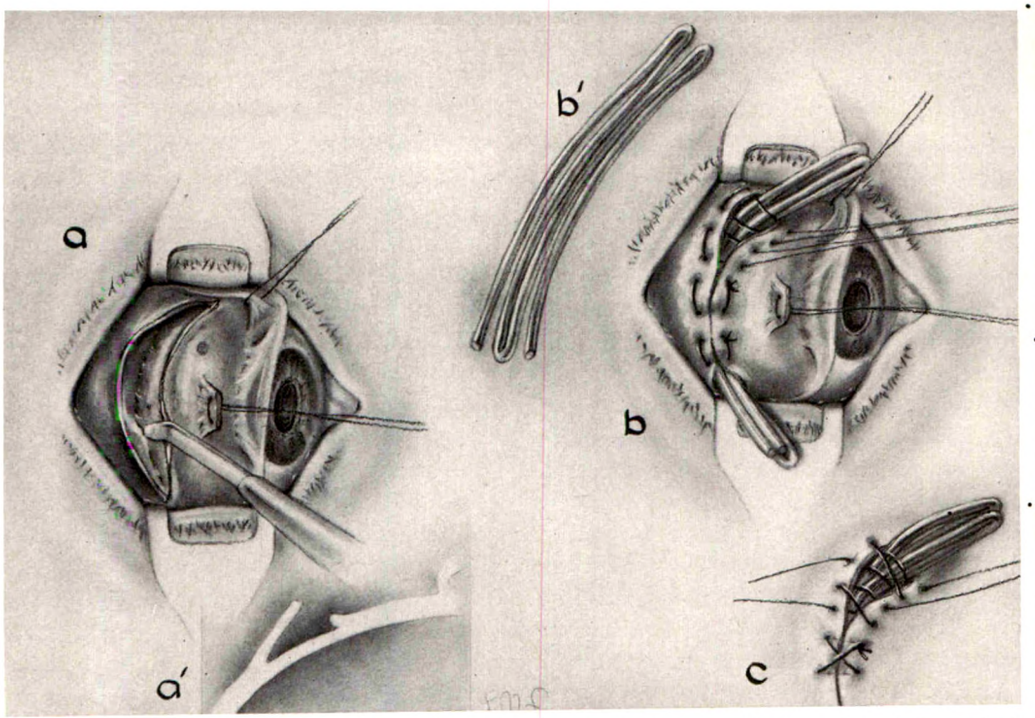

Fig. 1 (Dellaporta and Yukins). After the retinal break has been localized on the sclera, a single incision scleral groove is formed posterior to this area (a); by undermining mainly the posterior scleral lip, the groove can be placed easily behind the equator (a'); double-folded No. 2 chromic catgut (b') is enclosed within the groove (b). The mattress sutures may be the conventional U-shaped or the X type (c).

perforation. Four to five 4-0 silk mattress sutures were placed through the sceral wound edges over the groove. The overhanging scleral wound edges facilitated the safe placement of the sutures without danger of perforating the scleral wall. Additional surface or partially penetrating diathermy was placed within the bed of the scleral groove, and between both ends of the scleral groove and the ora serrata. At the present time, cryo-applications are preferred for this supplementary choroidal treatment.

Four threads of No. 2 chromic surgical catgut soaked in normal saline solution for 30 minutes were passed under the preplaced mattress sutures (Fig. 1-b).

Drainage was obtained by four to six Pischel pins inserted preferably within the scleral groove below the horizontal meridian in areas not treated with cryo-applications. The mattress sutures were pulled tight, double-looped but not knotted, burying the catgut threads within the scleral fold. In the event that this caused undesirable increase of intraocular pressure, one of the catgut threads was slipped out of the scleral fold. If ophthalmoscopic examination showed correct position of the buckle, the sutures were permanently knotted. The ends of the extruding catgut threads were cut and additional single 4-0 silk sutures were used to cover the catgut threads completely within the scleral fold. The detached muscle was resutured and the conjunctival and canthotomy wounds repaired.

## Remarks

The single-incision groove was formed well behind the retinal breaks. The aim was to have the breaks lie on the anterior slope of the buckle. This is technically easier, less time-consuming and more effective than attempting to place the breaks exactly on top of the buckle. The break positioned on the ante-

rior slope of the buckle offers an easy target for supplemental photocoagulation if this becomes necessary in the postoperative period. If ophthalmoscopic control showed the retinal breaks to be incorrectly placed, the temporarily looped mattress sutures were loosened, the posterior scleral flap was dissected further back and the buckle displaced posteriorly. No attempt was made to obtain complete drainage of the subretinal fluid. However, if the buckle was not ophthalmoscopically visible under a bullous detachment, and additional Pischel pins were of no avail, subretinal fluid was obtained by a meridionally placed scleral cut-down opposite the highest elevation of the retina. The sclera was dissected up to the choroid, the wound secured with a 4-0 single preplaced silk suture, and the choroid was perforated with a medium sized safety pin introduced tangentially (at an acute angle) into the globe and then retracted slowly as soon as subretinal fluid leaked. The blunt tip prevented perforation of choroidal vessels and possible injury to the retina in case it reached the latter. Anterior chamber paracentesis was occasionally performed to render the eye soft.

### Postoperative course

Binocular bandages were used for five to six days of bed rest, but the patients were allowed bathroom privileges and to sit up in bed during this time. Average hospitalization was eight to 10 days. The postoperative reaction and patient discomfort were similar to that seen after segmental buckling procedures using silicone rubber.

Ophthalmoscopically, the buckle diminished gradually within two to three months after surgery simultaneously with the consolidation and pigmentation of the chorioretinal scars.

### Results

Of the 21 operated eyes* only three (Cases 1, 3, and 7) were uncomplicated, prognostically favorable retinal detachments. There were 12 aphakic eyes, three had previous unsuccessful surgery, and the remainder showed some prognostically unfavorable pathology.

In two eyes (Cases 3 and 10), the buckle disappeared prematurely; in the first case, infection may possibly have caused the mattress sutures to cut through the scleral wound lips. Case 10 had an extensive juvenile detachment with atrophy of the retina and multiple ora breaks. Around the 14th postoperative day, the buckle began to diminish rapidly and increasing hypertropia was noted. Surgical exploration four weeks after the operation showed that the inferior rectus muscle, which was tenotomized during surgery, had detached and that the scleral mattress sutures had mostly cut through, leaving the scleral groove open; the enclosed catgut threads were found slightly eroded. The latter were removed, new mattress sutures were placed and pulled tight, converting the scleral groove into a single incision scleral infolding. Three months later a staphylomatous area along the operation site was repaired by a scleroplasty using preserved sclera, and the inferior rectus muscle advanced obtaining orthophoria. Both these cases were successful with resulting vision of 20/60 and 20/25, respectively. They indicate that premature disappearance of the buckle may happen as in similar procedures. If the buckle disappears after chorioretinal adhesions have formed, as probably occurred in these cases, it does not have unfavorable effects on the outcome of the operation.

Out of the 21 operations, 15 (70%) were successful within the follow-up period of seven to 18 months. Of the remaining six, in one (Case 12) the operation was unsuccessful; in three (Cases 4, 16, and 18), the detachment recurred within four to five months. These four eyes underwent successful encircling operations with a silicone rod, increasing the success rate to 89%. Two eyes (Cases 15 and 20) were unsuccessfully reoperated with the same method.

* Detailed table describing the cases may be obtained from the authors.

## Summary

The segmental scleral buckling technique with use of chromicized surgical catgut as implant offered the following advantages: Catgut is sterile and readily available; a buckle of the desired size could be easily obtained and its duration between two and three months was sufficient for curing a retinal detachment; the catgut caused a mild inflammatory reaction of the overlying choroid which promoted the formation of a contiguous area of chorioretinal adhesions between diathermy and cryo-applications.

The hydrated chromic surgical gut was a soft pliable material, did not cause pressure necroses of the structures of the eye, and finally absorbed leaving an undistorted eye. The possibility of late infections and late erosions through the sclera or conjunctiva was eliminated.

The method proved technically simple, brief, and caused little damage to the sclera. The results were as favorable as those obtained with more radical procedures.

# SEGMENTAL RETINAL PERIARTERITIS

NICOLA ORZALESI, M.D., AND LUIGI RICCIARDI, M.D.
*Cagliari, Italy*

Segmental periarteritis of the retina, a rare condition, is characterized by the appearance of whitish segmented plaques scattered along the retinal arteries. In most cases, an associated mild uveitis and hyalitis produce aqueous and vitreous haze, keratic precipitates, and vitreous floaters. Active or healed chorioretinal foci are frequently found near the involved vessels. It has been reported that Jensen's juxtapapillary chorioretinitis may also accompany the periarteritis.

Segmental periarteritis of the retina occurs most frequently in young adults, the average age being 34 years. It has a male/female ratio of 1.7:1. In 64.5% of cases, the condition is unilateral, the right eye being involved about 1.5 times more frequently than the left. The disease has a favorable prognosis. Within a few months, the arterial plaques disappear and recovery is complete.

Peters[1] reported the first case of segmental periarteritis of the retina in 1929. Between 1933 and 1969, 36 additional cases appeared in the literature.[2-23] If one were to include those cases in which severe uveitis, periphlebitis, or generalized vasculitis overshadowed the periarterial manifestations, those in which the course was unfavorable, or those in which the periarteritis was a localized manifestation of a systemic vascular disease (as in periarteritis nodosa), the number of cases would be greatly augmented.

This paper describes a typical case of periarteritis of the retina that showed some unusual clinical aspects, particularly in the vascular patterns demonstrated by fluorescein angiography.

## CASE REPORT

A 26-year-old man, a mason, sought treatment because of blurred vision in both eyes of eight days' duration. On admission, the anterior segment was normal in both eyes. There was slight vitreous haze and some vitreous floaters.

Examination of the fundi with the ophthalmoscope, the slit lamp, and the Goldmann lens revealed segmented, yellowish-white plaques scattered along the main arterial branches, often in a ring-like arrangement (Fig. 1). A thorough biomicroscopic examination clearly showed that the plaques adhered to the vessel walls, thereby demonstrating the classic periarterial deposition. Although segmented plaques were not seen in the smaller arterial branches, some sections showed a continuous white sheathing of the arterial walls. The caliber and the course of the arterioles were normal, but the veins appeared to be markedly enlarged and showed some segmental narrowing (Fig. 1). The optic disk appeared to be normal and the macular region somewhat edematous and blurred. Even at the extreme periphery of the fundus, no peripheral foci of chorioretinitis could be detected. The fundus findings in the right eye were not significantly different from those in the left eye.

The visual acuity, with a small hypermetropic correction, was 4/10 in the right eye and 6/10 in the left. The intraocular pressure was normal. Visual field examination with the Goldmann perimeter and the Bjerrum campimeter revealed some irregular central and paracentral relative scotomas. Dark adaptation with the Goldmann adaptometer and the electroretinographic tracing were both normal.

Fluorescein angiography showed decreased velocity of the retinal blood flow in both the arterial and the venous phases. Two minutes after the injection, the arterioles still showed fluorescence, and the veins fluoresced for more than six minutes. Some impregnation of the vascular walls with the dye could be responsible for this.

During angiography, the arterioles looked normal. The segmented white plaques seen ophthalmoscopically were not evident in the angiograms (Fig. 2). Fluorescein did not leak from the arterioles. The veins appeared to be greatly enlarged, and their walls showed a peculiar fluorescent soakage. Some extravasation of the dye became apparent about 100 seconds after the injection and lasted for more than 30 minutes (Fig. 2).

Detailed laboratory investigations, performed just after the patient's admission, gave the following results: hemoglobin, 107%; erythrocytes, 4.6 million; leukocytes, 8000 (neutrophils, 68%; lymphocytes, 27%; monocytes, 5%); glycemia, 98 mg%; azotemia, 31 mg%; blood cholesterol, 176 mg%; antistreptolysin titer, 400 units/ml; C-reactive protein, positive; serum proteins, 7.82 g%; fractionation by paper electrophoresis, normal; lipoprotein $\beta/\alpha$ ratio, 2:3. Urine was normal; erythrocyte sedimentation rate, 1-hour:4, 2-hour:8. Tests for rheumatoid arthritis, lupus erythematosus, the Wassermann and the Mantoux reaction were all negative.

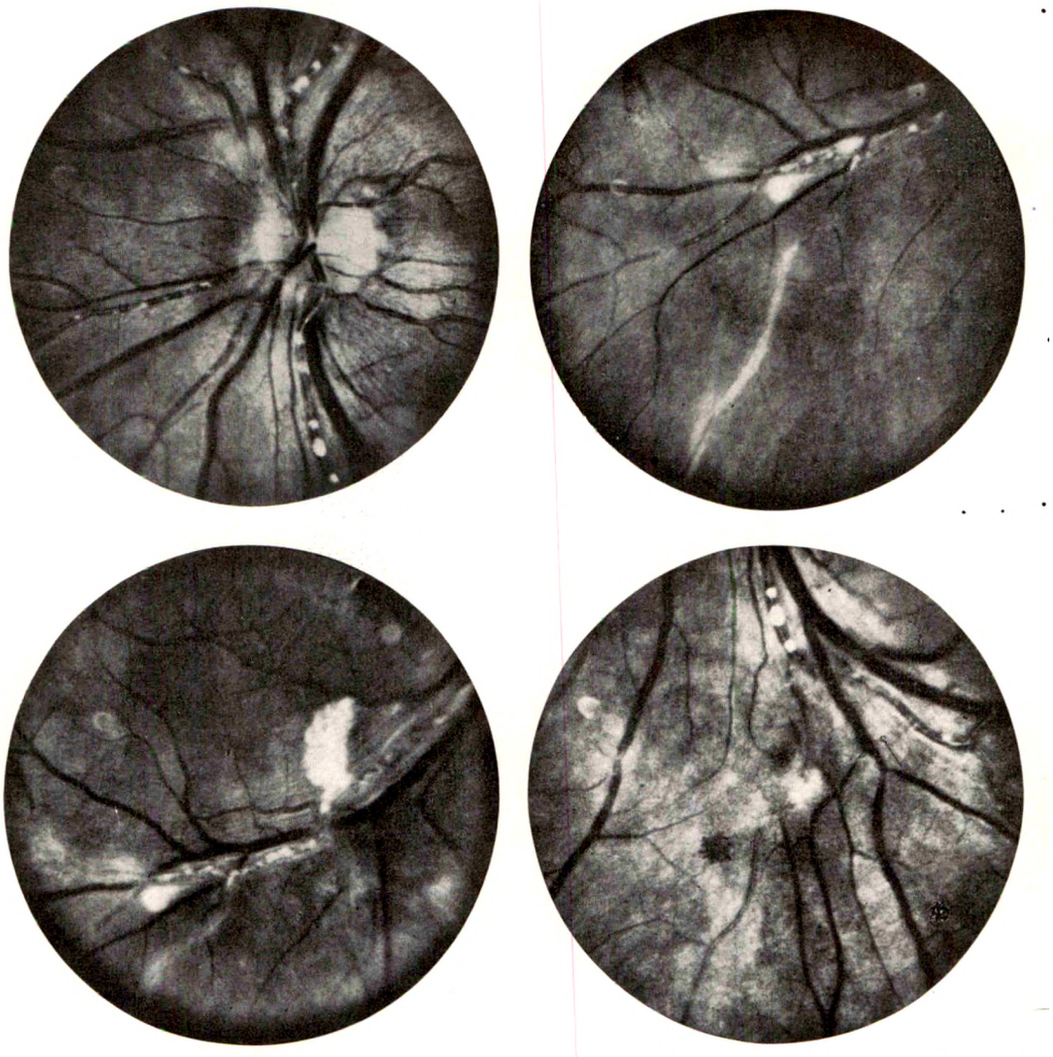

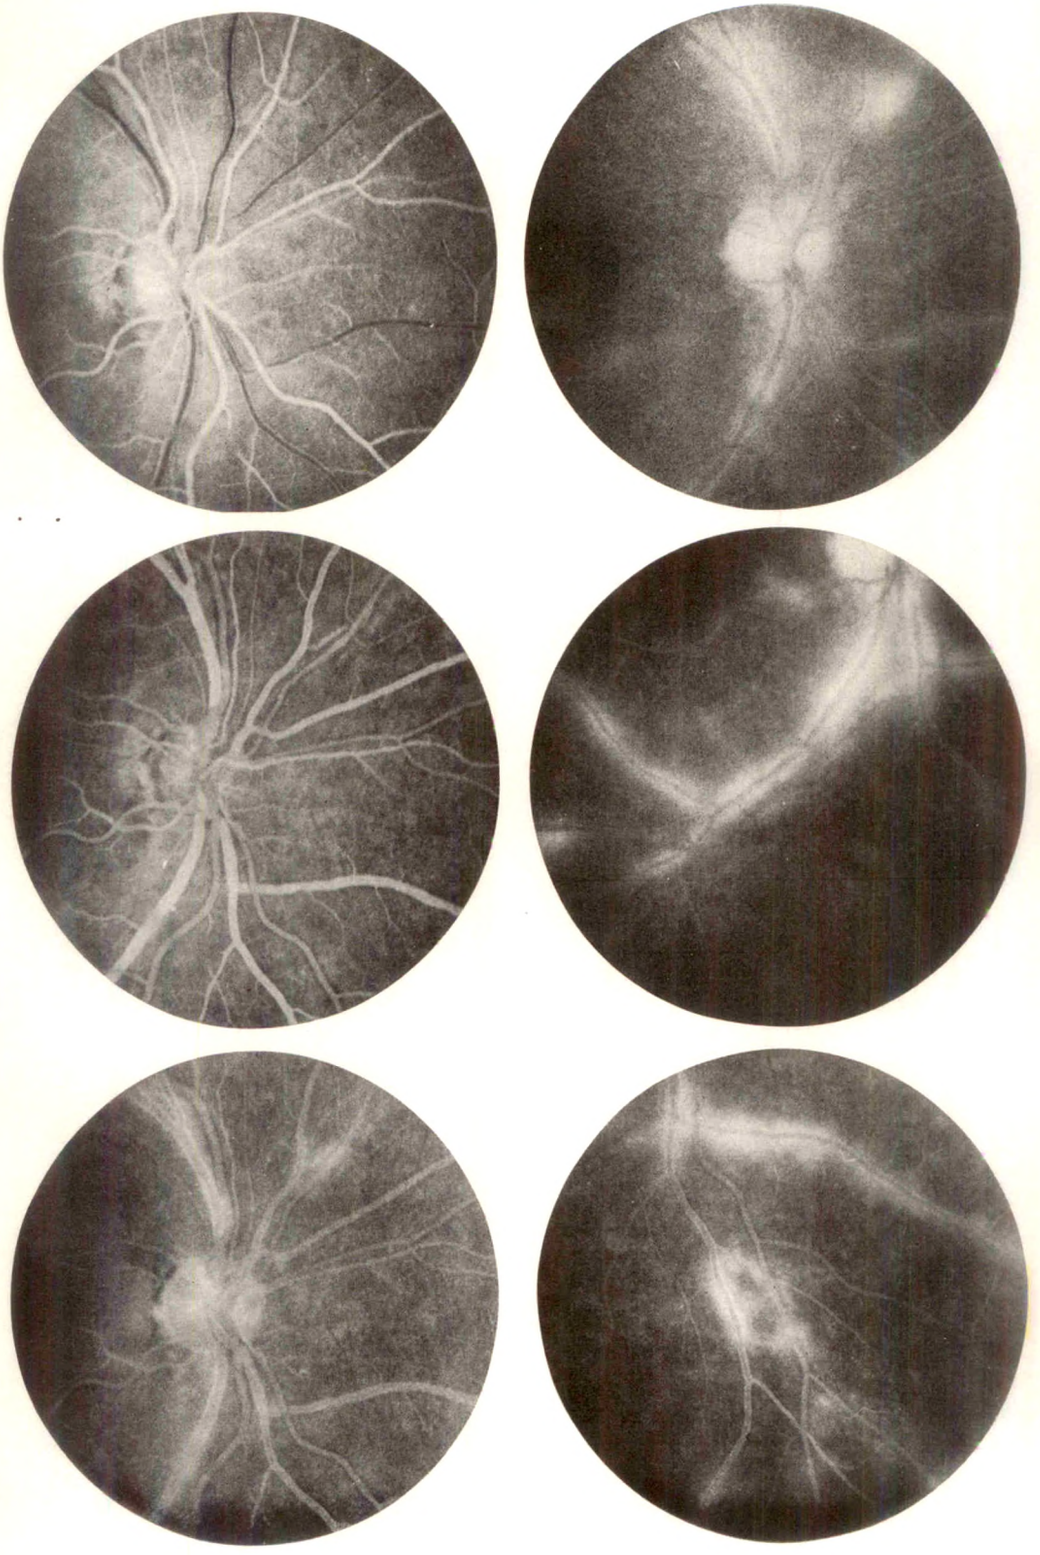

Fig. 1 (Orzalesi and Ricciardi). Ophthalmoscopic aspects of segmental periarteritis of the retina. Top left: Plaques of periarteritis ensheathing the large arterial branches. Top right: Continuous sheathing of the small arterial branches. Bottom left: Exudates. Bottom right: Hemorrhages observed during the period of recovery from segmental periarteritis of the retina.

General physical examination showed acute rhinitis, chronic tonsillitis, and gingivitis, as well as numerous dental caries. The neurologic examination disclosed no abnormality. Chest roentgenograms were normal but sinus films showed maxillary sinusitis. Oscillography of the arms and legs gave normal findings. Histologic examination of a temporal artery biopsy detected no disease.

The patient received intensive antiobiotic (streptomycin and tetracycline) and corticosteroid therapy, including intraorbital injections of dexamethasone. Fifteen days after initiation of therapy, the

Fig. 2 (Orzalesi and Ricciardi). Florescein angiography of segmental retinal periarteritis, showing the arterial and venous phases (left) and the late venous phases (right). During the venous phase, hyperfluorescence of the vein walls and leakage of the dye are clearly seen.

patient's eyes showed marked improvement. Uncorrected visual acuity was now 8/10 in the right eye and 10/10 in the left. Reduction in the number of vitreous exudates and in the extent of the macular edema fostered the visual improvement. With the exception of a few fluffy preretinal exudates bulging from the walls of the larger arterial branches (Fig. 1), the vascular findings were practically unchanged at this time.

Visual acuity improved to 10/10 in both eyes during the following days. The scotomas disappeared completely. As the signs of periarteritis began to fade, the continuous white sheathing of the small arteries disappeared first, then the preretinal exudates and, finally, the segmented plaques ensheating the largest retinal arteries.

During the three months between the start of therapy and complete recovery, some small hemorrhages were seen near the largest vascular branches. Repeated fluorescein angiographies during this period showed decreasing involvement of the retinal veins. The angiographic picture was again normal about one month after admission.

The marked decrease in the fluorescence of the retinal vessels that also occurred during recovery might have been produced by the healing process effecting a decrease in the transparency of the vascular walls.

Laboratory investigations showed that removal of the antral, dental, and tonsillar foci of infection by the antibiotic and corticosteroid therapy had normalized the antistreptolysin titer and the C-reactive protein.

## Discussion

Segmental periarteritis of the retina is a well-established clinical entity. The prevalence of segmental lesions of the retinal arteries, the principal feature of the clinical picture, the mild associated ocular signs, and the favorable clinical course separate this condition from others in which periarteritis occurs as an inconstant and secondary finding—for example, as in cases of uveitis with perivasculitis or in periarteritis nodosa.

Appelman and associates[13] and François and co-workers[21] discussed the etiology of segmental periarteritis of the retina at length. Since arteriosclerosis,[15] periarteritis nodosa,[24] and herpes[25] have none of the characteristics of segmental periarteritis of the retina, they can be excluded from etiologic consideration.

It seems more probable that most of the reported cases had an allergic etiology. The segmental changes in the retinal arteries could result from an immune reaction to a bacterial antigen or even to drugs.[22] The tonsillar, dental, and antral foci of infection, the increase in the antistreptolysin titer, and the positive C-reactive protein test in our patient indicate an allergic reaction to bacterial antigens. This patient's favorable response to intensive antibiotic and corticosteroid therapy support this contention.

An unusual aspect of this case was involvement of the retinal venous system, as shown by fluorescein angiography. This patient differed from those reported previously[21,22] in whom angiography demonstrated no abnormalities. The angiographic demonstration of hyperfluorescence of the vessel wall and seepage of the dye in patients with inflammatory cells in the vitreous, as in the present case, may be interpreted as evidence of retinal vasculitis and perivasculitis.[26]

A similar angiographic picture can also be observed in other conditions affecting the retinal veins, such as retinal vein obstruction, Eales' disease, and diabetic retinopathy.

To explain the retinal phlebitis, we suggest that the same noxious reaction which induced the periarteritis also affected the vein walls and caused an ophthalmoscopically invisible mild phlebitis to become associated with the dominant changes in the arteries. Slowing of the venous blood flow and stasis in the capillary and arterial network could facilitate formation of the arterial lesions.[15,27] Without fluorescein angiography, vascular alterations as vasculitis and perivasculitis might not be detected.

## Summary

In a typical case of segmental periarteritis of the retina, a peculiar alteration in the retinal veins was detected by fluorescein angiography that was not evident on ophthalmoscopic examination. The effectiveness of intensive antibiotic and corticosteroid therapy in erradicating the antral, dental, and tonsillar foci of infection suggests that an allergic reaction to bacterial antigens was the etio-

logic factor in this case. Three months after onset, the patient was cured.

# RHYTHMIC WAVELETS OF THE POSITIVE OFF EFFECT IN THE HUMAN ELECTRORETINOGRAM

YUTAKA TSUCHIDA, M.D., KAZUO KAWASAKI, M.D., AND JERRY H. JACOBSON, M.D.
*New York, New York*

The human electroretinogram (ERG), evoked with intense illumination, presents a sequence of rhythmic wavelets superimposed on the rising phase of the b-wave.[1,2] Similar rhythmic on wavelets are found in many vertebrates and are labeled the "oscillatory potentials.[3]" Studies of the nature of these oscillatory potentials[3-6] demonstrated their clinical importance.[7-9] Other studies demonstrated that the positive off effect is also divided into multiple peaks in frog,[10-13] turtle,[14] pigeon,[15-16] and human.[17-20] Because of technical and other problems resulting from their low amplitudes, the off effect and its subcomponents have not been closely examined in the human. This paper demonstrates how multiple off effects in man are easily recorded, using intense stimuli, an averaging computer, and short-time constant amplifier.

## METHOD

The stimulus light was derived from a tungsten lamp (1 kw, 100 v) passed through a series of heat and neutral density filters and brought to a focus at a magnetic shutter. Square-wave test flashes (stimulus duration 740 msec 0.7 Hz) were delivered from the shutter, driven by an electronic stimulator.

The adapting light was provided by another tungsten lamp (150 w, 117 v), also controlled by a series of heat and neutral density filters.

Stimulus and adapting lights were focused on each of the two input ends of a dichotomic (Y-shaped) glass fiber light guide. The glass fibers carrying the light from each source were mingled together at the output end (7 mm in diameter), which was held 2 cm from the cornea of the subject's eye. The intensity of the stimulus light without neutral density filter was $2.9 \times 10^3$ ft-L ($6.3 \times 10^5$ scotopic trolands, pupil diameter 7.5 mm). The maximum adapting light intensity was $1.8 \times 10^3$ ft-L ($4.0 \times 10^5$ scotopic tds.). Neutral density filters were interposed in the light path to decrease the luminance. Stimulus and adapting light intensities are represented in $\log_{10}$ units and they are directly comparable. The maximum stimulus intensity ($2.9 \times 10^3$ ft-L) is designated as 0.0 log units, the maximum adapting intensity ($1.8 \times 10^3$ ft-L) therefore corresponds to $-0.2$ log units.

In this study, with an averaging computer we used repetitive stimuli (740 msec duration) of 0.7 Hz which will cause a degree of light adaptation. This adapting effect was considered by matching (a) the amplitudes of b-waves evoked by repetitive stimuli with no background light and (b) the amplitude of b-wave evoked by a single flash with at constant levels of light adaptation. With our stimulus duration and frequency we found, for example, that repetitive stimuli of $-3.0$ log units produced a light adapting effect equivalent to a steady state adapting light intensity of about $-6.0$ log units, and repetitive stimuli of $-1.0$ log units produced about $-2.0$ log units of adapting light effect. Therefore, the term "with no adapting light" or "in the dark," as used in this paper, does not mean the fully dark-adapted state.

ERG potentials were detected with a low vacuum contact lens electrode,[21] referred to the combined earlobes, and led to a Grass EEG amplifier (7P511). Fifty or 100 re-

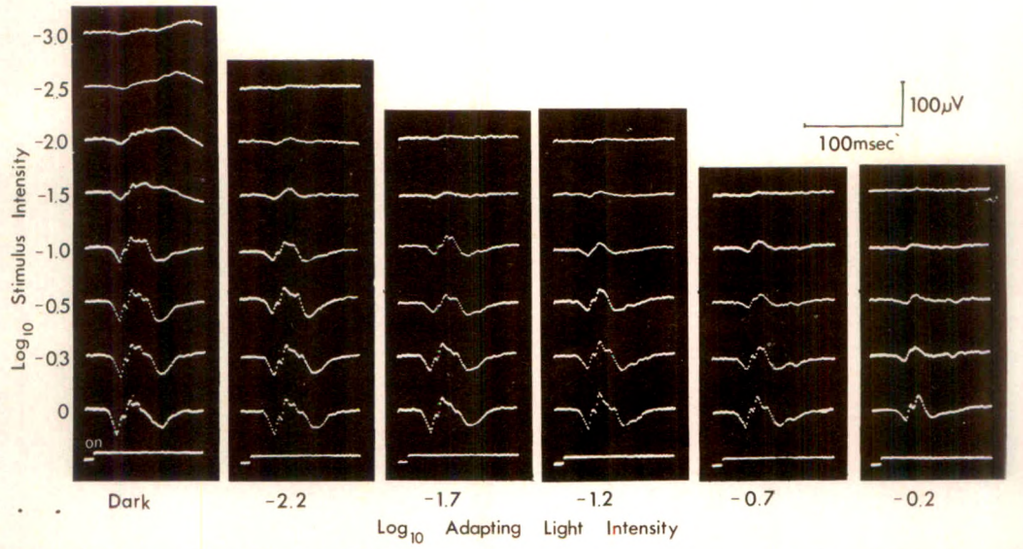

Fig. 1 (Tsuchida, Kawasaki, and Jacobson). On effects of the normal human ERG at varying levels of stimulus and adapting light intensities. Stimulus duration 740 msec. Stimulus frequency 0.7 Hz. Time constant 0.01 sec. Upward deflection indicates positivity of corneal electrode. Average of 50 responses.

sponses were averaged by a Mnemotron compute (CAT 400). The amplifier time constant is specified in each figure.

The normal data collected by one of us (K. K.) was confirmed by other normal subjects, including subjects under general anesthesia. Pupils were fully dilated with 1% tropicamide. The cornea was anesthetized with 0.5% tetracaine. Subjects were instructed to try not to blink and not to move the eye during recording. When the ERG was obviously contaminated by artefact due to blinking or other muscle movement, data was discarded.

## Results

A weak stimulus (−3.0 log units) evoked only a positive potential (b-wave) with no background light (Fig. 1). As the stimulus intensity was increased, a small negative deflection (a-wave) and a series of on wavelets (oscillatory potentials) superimposed on the b-wave, were recordable and their amplitudes increased progressively with increasing stimulus intensity. These oscillatory potentials are conventionally labeled $0_1$, $0_2$, $0_3$, and $0_4$ (Fig. 2-A).

With no background light, as stimulus intensity was increased to −2.5 log units, the positive off effect became recordable (Fig. 3). More intense stimuli made the positive off effect prominent and its initial ascending slope steeper. At maximum stimulus intensity (0.0 log units), the latency and the peak latency of the initial positive off effect were about 10 and 21 msec, respectively.

The positive off effect is divided into three main peaks when the stimulus is brighter than −1.0 log units. We call them $d_1$, $d_2$, and $d_3$ for the convenience of description (Fig. 2-B). However, $d_3$ was absent in all three normal subjects under general anesthesia, and not always present in conscious normal subjects. $D_3$ might be an artefact due to blinking or other muscle movement. It is also possible that general anesthesia might eliminate $d_3$. Because of these ambiguities, we will not further treat $d_3$ in this paper.

With intense stimulus, fast rhythmic wavelets were superimposed on $d_1$ and $d_2$. These fast off wavelets were observed in all normal subjects tested, and their inverted shape resembled that of the oscillatory potentials

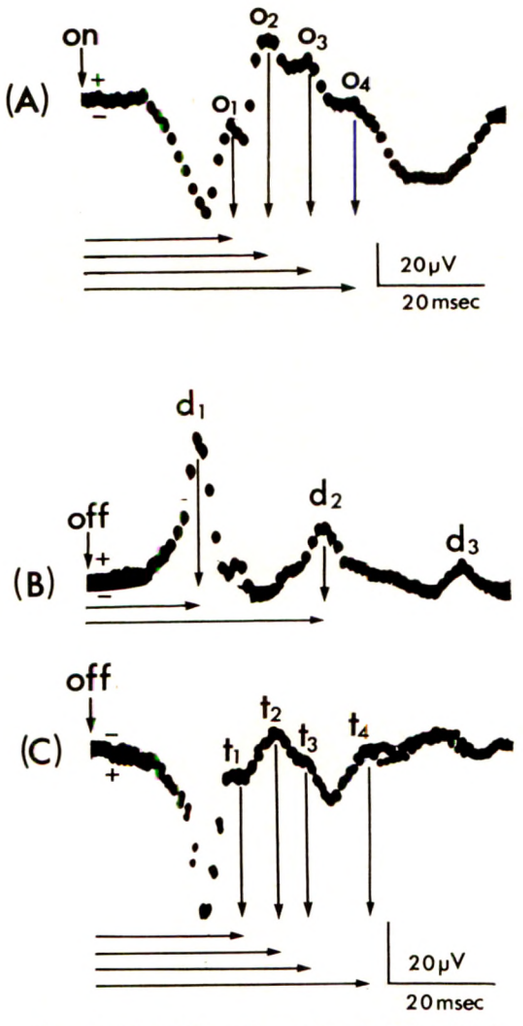

Fig. 2 (Tsuchida, Kawasaki, and Jacobson). Sample records of on (A) and off effects (B, C). Upward deflection indicates positivity of the corneal electrode in traces A and B, and negativity in trace C. Two responses to same stimulus were superimposed in trace C. Oscillatory potentials ($O_1$-$O_4$), $d_1$-$d_3$ waves and troughs of the off wavelets ($t_1$-$t_4$) are designated. Note that troughs of the off wavelets ($t_1$-$t_4$) correspond to peaks of oscillatory potentials ($O_1$-$O_4$). Stimulus intensity 0.0 log units. No background light. Stimulus duration 740 msec. Stimulus frequency 0.7 Hz. Time constant 0.01 sec. Average of 50 responses.

superimposed on the b-wave. Figure 2-C presents the off effects in reversed polarity to facilitate comparison of its waveform with that of the on effect. We call the negative peaks of the fast off wavelets as "troughs" of off wavelets ($t_1$, $t_2$, $t_3$, and $t_4$) for the convenience of description.

The amplitudes and the peak latencies of the on and off components recorded with no background light are plotted against stimulus intensity (Figs. 4 and 5). The amplitudes of the oscillatory potentials ($O_1$-$O_4$) were measured from the bottom of the a-wave (Fig. 2-A). The amplitude of $d_1$ was measured from the baseline and that of $d_2$ from the negative trough between $d_1$ and $d_2$ (Fig. 2-B). The amplitudes of the troughs of the off wavelets ($t_1$-$t_4$) were measured from the peak of $d_1$ (Fig. 2-C).

The amplitudes of the a-wave and the oscillatory potentials increased linearly to the log stimulus intensity within the stimulus range tested (Fig. 4-A). The amplitudes of $d_1$, $d_2$ and troughs of the off wavelets increased approximately linearly to log stimulus intensity (Fig. 4-B). The threshold (10 μv criterion) of $d_1$ is about 0.8 log units lower than that of $d_2$. A gross parallelism exists between the amplitudes of a-wave and $d_1$ (Figs. 4-A and B).

The peak latencies of the a-wave and the oscillatory potentials decreased slightly as the stimulus intensity increased, but the intervals between the individual peak of the oscillatory potentials underwent no remarkable change (Fig. 5-A). The peak latencies and, hence, the intervals between successive waves of $d_1$, $d_2$, $t_1$, $t_2$, $t_3$ and $t_4$ remained fairly stable regardless of stimulus intensity (Fig. 5-B).

Varying the level of light adaptation through the range of $-2.2$ to $-0.2$ log units did not alter these findings (Figs. 4 and 5).

The amplitudes and the peak latencies of the on and off components recorded with maximum stimulus intensity (0.0 log units) are plotted against adapting light intensity (Figs. 6 and 7).

The amplitudes of the a-wave, $O_3$ and $O_4$ decreased as the light adaptation level increased (Fig. 6-A). The amplitude of $O_1$ was little affected by adapting light and that of

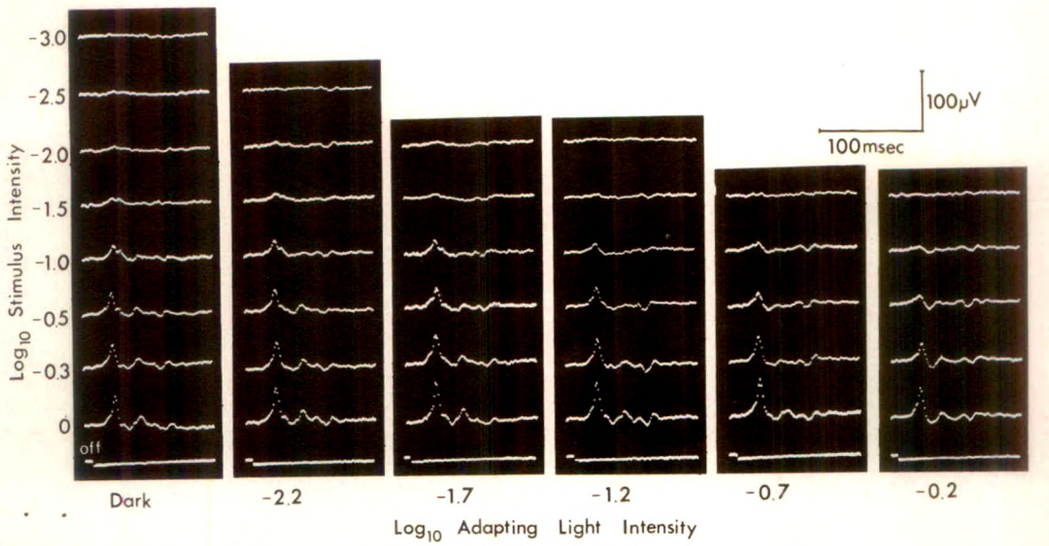

Fig. 3 (Tsuchida, Kawasaki, and Jacobson). Off effects of the normal human ERG at varying levels of stimulus and adapting light intensities. Recording conditions same as Figure 1.

$0_2$ was augmented with increasing adapting light intensity, up to −1.2 log units, beyond which it decreased. The amplitudes of $d_1$ and $d_2$ increased slightly with a weak adapting light (−2.2 to −1.7 log units), as compared with their amplitudes with no background light (Fig. 6-B). When adapting light intensity was increased to maximum intensity (−0.2 log units), the amplitude of $d_1$ remained almost the same as in the dark, while the amplitude of $d_2$ was reduced to about two-thirds of the original value. The amplitudes of the troughs of the off wavelets gradually increased as the adapting light intensity was increased, up to −1.7 log units, then decreased.

The peak latencies of the a-wave and the oscillatory potentials were slightly prolonged as the light adaptation level was increased (Fig. 7-A). The peak latencies of $d_1$, $d_2$, and the troughs of the off wavelets remained almost constant throughout the entire range of light adaptation tested (Fig. 7-B).

The entire ERG response, including the oscillatory potential and off wavelets, was extinguished in a case of primary pigmentary degeneration of the retina in a 57-year-old woman (Fig. 8-A). The amplitudes of the a- and b-waves were moderately decreased in a case of diffuse chorioretinal degeneration in a two year-old girl under general anesthesia. The oscillatory potential and off wavelets of this patient were almost absent (Fig. 8-B). The amplitudes of the a- and b-waves were moderately decreased in a case of chloroquine retinopathy in a 36-year-old woman (total dosage of hydroxychloroquine, 182 g). In this case, both the oscillatory potential and off wavelets were markedly decreased (Fig. 8-C). In a case of diabetic retinopathy (a 64-year-old woman, severe in left eye and somewhat less severe in right eye), the amplitudes of the a- and b-waves were greatly decreased in the left eye and almost normal in the right eye. Both the oscillatory potential and off wavelets of this patient were decreased to the same extent (Figs. 8-D, E). The normal ERG response, including the oscillatory potential and off wavelets, was obtained in a case of optic nerve atrophy in a four-year-old boy under general anesthesia (Fig. 8-F).

## Discussion

Heck[17] described the multiple off effects as "doppelte positive Off-Effekt," referring to the first and second off effects. His first

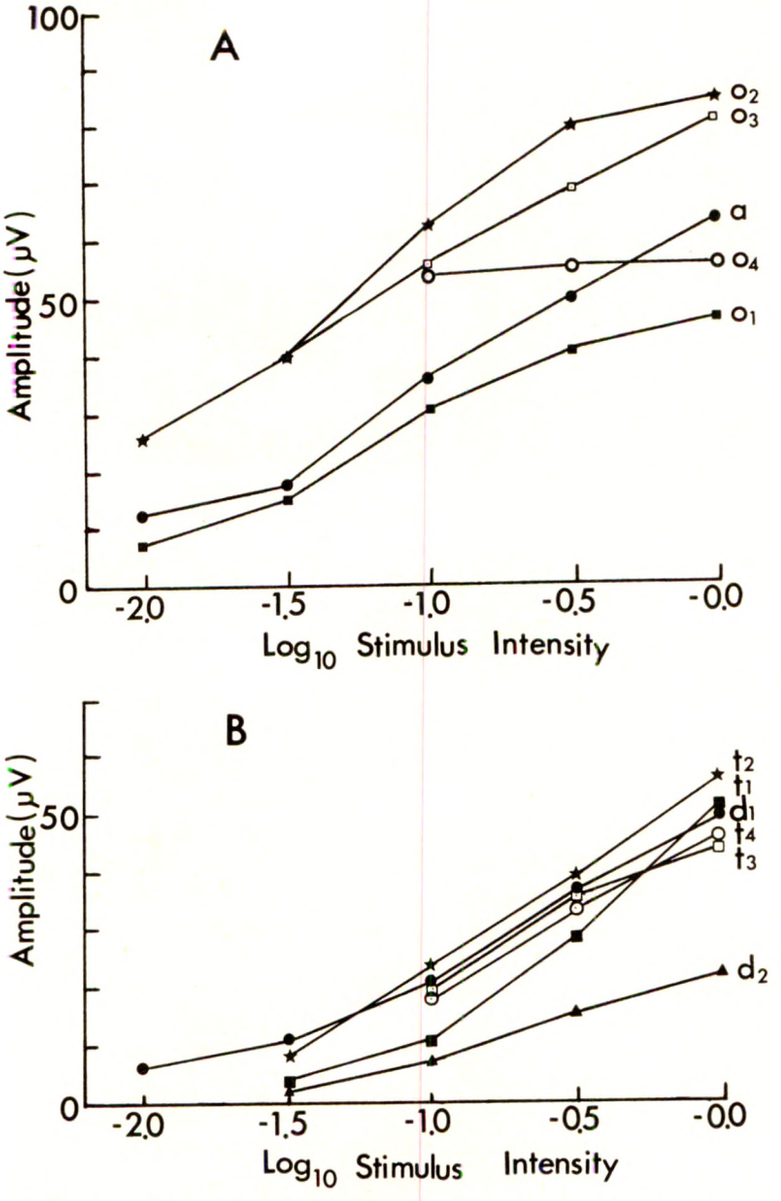

Fig. 4 (Tsuchida, Kawasaki, and Jacobson). Amplitudes of oscillatory potentials (A), and multiple off effects (B) as function of stimulus intensity. Amplitudes of these potentials were calculated from the data with no background light. Note that amplitudes of all responses increase linearly to log stimulus intensity.

and second off effects would seem to correspond to our $d_1$ and $d_2$, respectively (Fig. 2-B). He attempted to relate the first and second off effects to photopic and scotopic components, respectively.

In considering this concept, one must recognize that: (1) The threshold of $d_2$ is higher than that of $d_1$ (Fig. 4). (2) $D_2$ was present, although of slightly less than maximum amplitude, under our maximum adapting light intensity ($-0.2$ log units, $4.0 \times 10^5$ scotopic tds), which is strong enough to

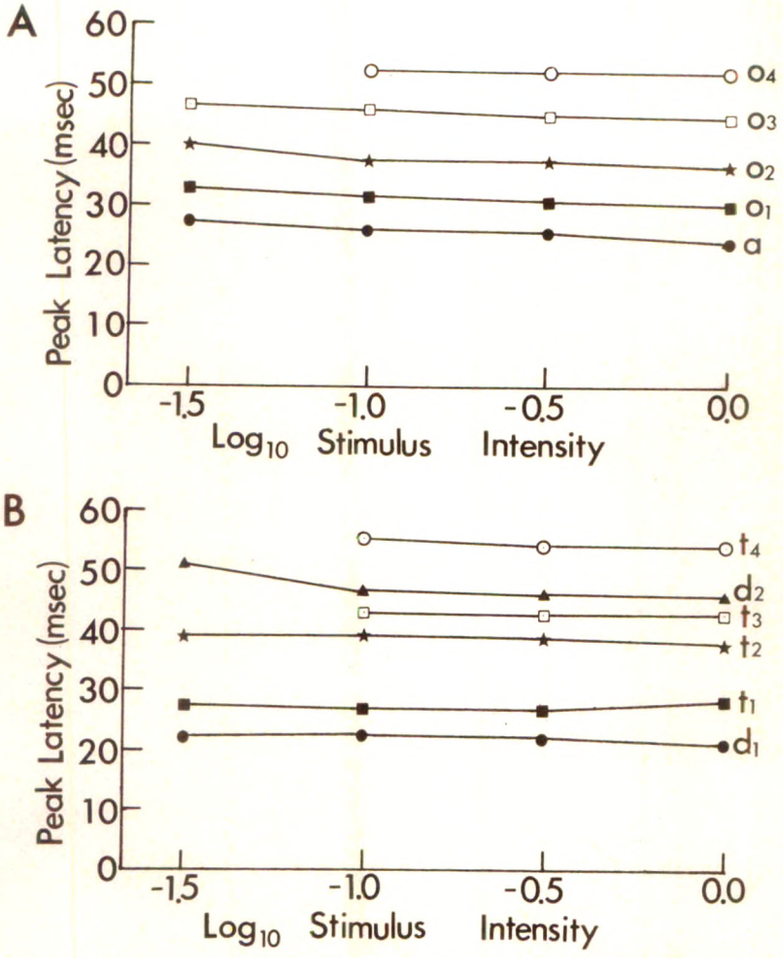

Fig. 5 (Tsuchida, Kawasaki, and Jacobson). Peak latencies of oscillatory potentials (A) and multiple off effects (B) as function of stimulus intensity. Latencies calculated from data with no background light. Note constancy of intervals between oscillatory potentials and troughs of off wavelets, regardless of stimulus intensity.

saturate the human rod system (2000 to 5000 scotopic tds).[22] (3) In stationary congenital night blindness, $d_2$ was recordable.[19,20] (4) $D_2$ has been recorded in the pigeon, which has a pure cone fovea and a cone-dominated peripheral retina,[23] and was highly resistant to light adaptation.[15] These facts do not support the assumption that $d_2$ is indicative of scotopic function.

It has been suggested that the off effect is a mirror image of the on effect.[17,24] The troughs of the off wavelets ($t_1$, $t_2$, $t_3$, and $t_4$), resemble the oscillatory potentials ($0_1$, $0_2$, $0_3$ and $0_4$) in the following points: (1) The threshold of both wavelets are relatively high and approximate each other, although the thresholds of the oscillatory potentials are slightly lower (Fig. 4). (2) The peak latencies of the individual oscillatory potentials and those of the troughs of the off wavelets approximate each other, and their intervals are stable regardless of the stimulus and adapting parameters (Figs. 5 and 7). (3) Both oscillatory potentials and off wavelets, and especially their early portion, are highly resistant to light adaptation (Fig. 6).

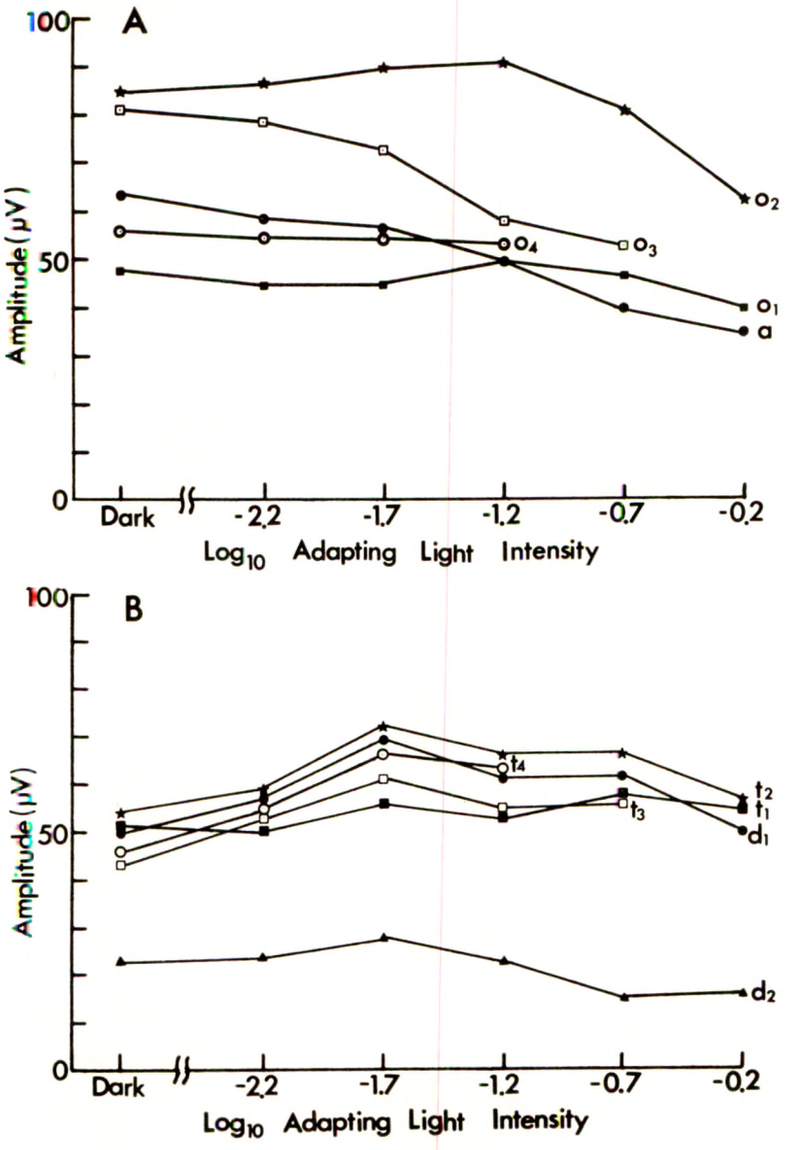

Fig. 6 (Tsuchida, Kawasaki, and Jacobson). Amplitudes of oscillatory potentials (A) and multiple off effects (B) as function of adapting light intensity. Curves obtained from data with maximum stimulus intensity (0.0 log units).

(4) Both oscillatory potentials and off wavelets are equally diminished in retinal diseases we studied (Fig. 8). There are, however, some differences between the oscillatory potentials and the off wavelets: (1) The troughs of the off wavelets, especially $t_3$, are not as prominent as the oscillatory potentials. (2) The intervals between the troughs of the off wavelets are not as regular as those of the oscillatory potentials.

According to Brown's analysis of the mammalian cone ERG,[6] the positive off effect is composed of two different components of opposite polarity; the onset phase appears to result from decay of the cone receptor potential, while the falling phase appears to re-

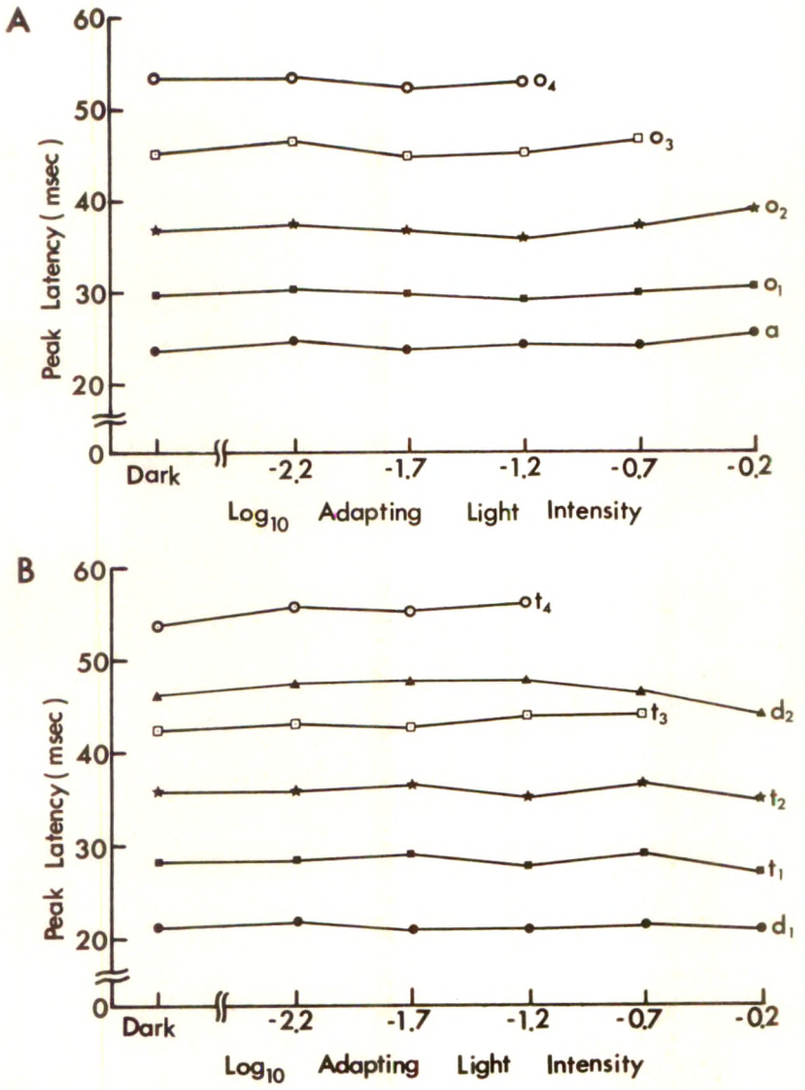

Fig. 7 (Tsuchida, Kawasaki, and Jacobson). Peak latencies of oscillatory potentials (A) and troughs of off wavelets (B) as function of adapting light intensity. Curves obtained from data with maximum stimulus intensity (0.0 log units). sult from decay of the d.c. component. Off wavelets are not considered in his analysis, although he did describe the oscillatory potential as one of the minor components of the ERG. The off wavelets must be considered as a new component of the ERG.

The origin of the oscillatory potentials has been inferred to be at the bipolar cell layer.[3-5,7,25] The many similarities between the oscillatory potentials and the off wavelets make it conceivable that the origin of the off wavelets is also in the bipolar cell layer.

## Summary

Intense stimuli of 740 msec duration evoked a sequence of fast rhythmic wavelets superimposed on the positive off effect. These off wavelets were observed in all nor-

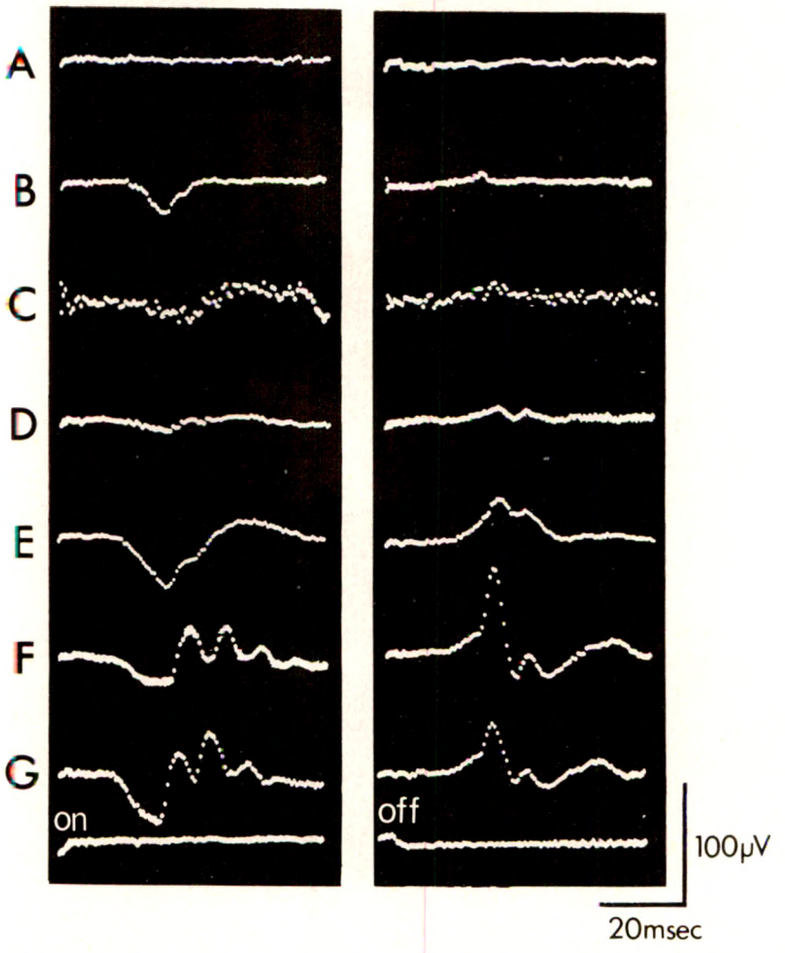

Fig. 8 (Tsuchida, Kawasaki, and Jacobson). Oscillatory potentials and off wavelets in pathologic cases. (A) Primary pigmentary degeneration, (B) diffuse chorioretinal degeneration, (C) chloroquine retinopathy, (D and E) diabetic retinopathies (Scott III and II), (F) optic nerve atrophy, and (G) normal control. Stimulus intensity 0.0 log units. No background light. Stimulus duration 740 msec. Stimulus frequency 0.7 Hz. Time constant 0.003 sec. Upward deflection indicates positivity of corneal electrode. Average of 100 responses.

mal subjects tested, and their shape, inverted, resembled that of the oscillatory potentials superimposed on the b-wave. Close similarity exists in amplitude and latency from stimulus off and on, respectively, between the troughs of the off wavelets and the peaks of the oscillatory potentials. Studies of several pathologic cases indicated gross parallelism in effects upon the off wavelets and upon the oscillatory potentials in the diseases in question.

# OCULAR PIGMENTATION AND PRESSURE AND OUTFLOW RESPONSES TO PILOCARPINE AND EPINEPHRINE

HARROUT E. MELIKIAN, M.D., THEODORE W. LIEBERMAN, M.D., AND IRVING H. LEOPOLD, M.D.

*New York, New York*

In 1929 Chen and Poth[1] compared the pupil dilating effect of several mydriatics (cocaine, euphthalmine, ephedrine) in Caucasians, Chinese, and Negroes. They found that Caucasians were the most responsive, Negroes the least, and Chinese intermediate to the mydriatic action of these drugs. Scott[2] has reported similar racial differences.

Studies by Howard and Lee[3] and Guist[4] have also demonstrated that mydriatics are more effective in individuals with light irides than in those with dark.

There has been no conclusive evidence as to whether the degree of responsiveness is racially determined or secondary to the quantity of pigmentation. It does, however, point out a specific pattern for drug response variation.

The purpose of this study was to determine if the quantity of pigmentation in the skin, iris, trabecular meshwork, or fundus could be correlated to the intraocular pressure response to pilocarpine or epinephrine.

## MATERIALS AND METHODS

Twenty-three women volunteers between the ages of 20 and 40 years were given complete eye examinations by one investigator. Subjects were disqualified for the following reasons: (1) a history of systemic or ocular disease, (2) a history of eye trauma, (3) a present history of drug therapy except for oral contraceptives, (4) physical evidence of previous ocular inflammation, iris atrophy, pigment dispersion, lens pseudoexfoliation or chamber angle abnormalities, or (5) a spherical refractive error of three diopters or more, or a cylindrical error of one diopter or more.

During the first visit the pigmentation of the volar forearm skin, iris, trabecular meshwork, and fundus was evaluated visually. The skin pigment was recorded as light, medium, and heavy. The irides and fundi were described by color. The trabecular meshwork was graded as translucent, or with light, medium, or heavy pigmentation.

As a check, photographs of the volar forearm skin, iris, trabecular meshwork, and fundus of each subject were taken under standardized conditions. These were later compared with the recorded visual evaluations. If there was a discrepancy between the written and photographic evaluation, the subject was re-examined visually and this evaluation was considered as final.

At the second visit, each volunteer underwent Goldmann applanation tonometry and tonography on both eyes. Immediately upon completion of the tonography, one drop of 4% pilocarpine was instilled in the lower fornix of the right eye. The subject was requested to blink for several seconds and then sit with eyes open. Approximately 15 to 30 seconds later a second drop was instilled in the right eye. After a few blinks both eyes were kept closed for five minutes. The subject was then allowed to leave, but told to return in exactly two hours at which time applanation tonometry and tonography were repeated on both eyes.

About two weeks later this same procedure was again followed except the pilocarpine was instilled only in the left eye.

During the fourth and fifth visits the same format was again followed except that 2%

epinephrine was used instead of the pilocarpine.

The pre- and post-medication Goldmann applanation pressures (Tap), opening tonographic pressures ($P_0$), and outflow facilities (C) were recorded for each subject at each visit. The initial Tap, $P_0$ and C values were subtracted from the second set of values obtained two hours after treatment of the one eye.

Positive (+) Tap and $P_0$ values indicated increase in the intraocular pressures after treatment whereas minus (−) values indicated a fall in pressure. Positive (+) C values indicated an increase in the outflow facility after treatment whereas minus (−) C values indicated a decrease.

Before the final analysis of results, the medium pigmented group in each category (skin, iris, trabecular meshwork, and fundus) was discarded and only the extremes of pigmentation (light and heavy) were compared.

Using a P level of 0.05, a student's t-test for unpaired samples of unequal numbers was used for statistical evaluation comparing the treated to the untreated eyes.[5]

The average change for the treated and untreated eyes and their differences were also calculated and recorded.

## RESULTS

Table 1 shows that normal subjects with lightly pigmented skin, irides, trabecular meshwork, and fundi respond with a greater fall in intraocular pressure and increase in

outflow facility to 4% pilocarpine than subjects with heavily pigmented structures.

Similar results were obtained after the use of 2% epinephrine, except that insignificant changes were found in the initial tonographic tension irrespective of pigmentation (Table 2).

When the responsiveness of Negroes to 4% pilocarpine and 2% epinephrine was compared to that of Caucasians with all degrees of pigmentation, the Negro subjects appeared less responsive to these agents (Table 3).

## DISCUSSION

The results of these single-dose experiments indicate that persons with heavily pigmented skin, irides, trabecular meshwork; and fundi are less responsive to the pressure and outflow facility effects of 4% pilocarpine and 2% epinephrine than those with lightly pigmented structures.

Most of the subjects in the heavily pigmented categories were Negroes. A valid comparison between the responsiveness of Negroes versus darkly pigmented Caucasians could not be made because of the insufficient number of darkly pigmented Caucasians in each category.

A comparison was made between the lightly pigmented and medium pigmented Caucasian groups. There was no significant difference between the two in their response to the pilocarpine and epinephrine. This may be due to the lesser contrast in the quantity of pigmentation in the two groups. The

question of whether the degree of responsiveness is related to race or simply to the amount of pigmentation could not be determined.

A follow-up study will be made in which a group of Caucasians with irides as dark brown as possible will be compared to the lightly pigmented Caucasian group. This may still not give a conclusive answer since the subjective evaluation made in this study indicates that the quantity of pigment in the Negro iris is far greater than that found in the dark brown Caucasian iris.

## SUMMARY

Twenty-three subjects with normal eyes were evaluated as to the amount of pigment in their skin, irides, trabecular meshwork, and fundi. The tonometric and tonographic response of each eye to 4% pilocarpine and 2% epinephrine was made. The differences in the pre- and post-medication applanation pressures, opening tonographic pressures, and outflow facilities were calculated. The values obtained in the lightly and heavily pigmented treated eyes were compared to their untreated eyes.

It was found that the tonometric and tonographic response of darkly pigmented normal eyes to 4% pilocarpine and 2% epinephrine was less than the response of lightly pigmented eyes.

## ACKNOWLEDGMENT

We thank Mrs. Karin Berman for her technical assistance.

# SYSTEMIC VASODILATORS, INTRAOCULAR PRESSURE, AND CHAMBER DEPTH IN GLAUCOMA

José D. Peczon, M.D., W. Morton Grant, M.D., and Brent W. Lambert, M.D.
*Boston, Massachusetts*

The present tests were made to evaluate the effects of the systemic vasodilator agents nicotinic acid, cyclandelate, and carbon dioxide on intraocular pressure in open-angle glaucoma, and to attempt in patients with abnormally narrow angles to induce angle-closure glaucoma by means of carbon dioxide, as previously unsuccessfully attempted with nitrate and nitrite vasodilators by Becker,[1] and by Whitworth and Grant.[2] Nicotinic acid was chosen for testing because it is a well-known vasodilator, and cyclandelate because of its current popularity. A 10% carbon dioxide-90% oxygen mixture was chosen for testing because this is reputed to be one of the most effective agents to induce dilation of vessels in the eye and in the brain, and might provide an indication of the maximum effect to be expected from any type of vasodilator agent that did not simultaneously cause severe changes in blood pressure.

Intraocular pressure was measured by applanation tonometry, using variously the Goldmann, Draeger, and Perkins optical instruments, with the patients in both sitting and prone positions, but always comparing measurements with the same tonometer and same position with and without test drug. When the effects of nicotinic acid and cyclandelate were being evaluated, pressure was measured hourly during five hours, with and without drugs, on separate days at the same times of day in order to take diurnal variations into account. Axial depth of the anterior chamber was similarly repeatedly evaluated with the standard Jaeger depth measuring attachment on the Haag-Streit 900 slit lamp with and without test medications.

When the effect of carbon dioxide inhalation was to be evaluated, a mixture of carbon dioxide 10% with oxygen 90% was delivered at a rate of 15 liters per minute to a face mask equipped with a rubber breathing bag and check valves to minimize variation or elevation of pressure within the mask. Intraocular pressure was measured in both eyes every one to two minutes with the patient in the supine position, using portable Draeger or Perkins applanation tonometers. The measurements were started 10 to 12 minutes before beginning inhalation of the carbon dioxide mixture, continued for eight to 10 minutes during inhalation, and for a variable period thereafter. Variations of axial depth of the anterior chambers were not measured during the tests with carbon dioxide because the time of exposure was short and was pre-empted by frequent applanation tonometry.

## Test results

Nicotinic acid in a single 100 mg oral dose was given to 14 patients. In 12 of these, chronic primary open-angle glaucoma was bilateral; in another patient, glaucoma was definite in only one eye, and in still another, the disease was borderline. Of these patients, 10 were receiving no antiglaucoma medication during the testing, but the other four were maintained under constant treatment with standard antiglaucoma medications (various combinations of miotics, epinephrine, and carbonic anhydrase inhibitors). In the absence of nicotinic acid, the tensions of all patients remained within the range of 20 to 35 mm Hg, most being close to 30 mm Hg. During the first two hours after administration of the nicotinic acid, most patients ex-

perienced sensations attributable to cutaneous vasodilation. The axial depth of the anterior chambers measured hourly during four to five hours showed no change significantly different from the range of variation established in the absence of the test drug. Intraocular pressure measured hourly during the same period and compared with tension curves established in the absence of nicotinic acid at the same time of day showed no appreciable change in nine of the 14 patients. In the other five patients, the average level of the test curves for individual eyes differed from the curves without test medication by 1.5 to 3 mm Hg, but the test curves were no more often higher than lower. The extremes of transient differences between pressure curves for individual eyes with and without nicotinic acid ranged from 6 mm Hg briefly higher in one eye to 7 mm Hg briefly lower in another eye. The results are summarized in Table 1. Results with nicotinic acid in patients in the supine position were not appreciably different from those in patients who were sitting upright.

Cyclandelate in a single dose of 200 mg was given by mouth to 17 patients, of whom 14 had chronic primary open-angle glaucoma in both eyes, and two had what appeared to be the same type of glaucoma in only one eye, and one was considered an open-angle glaucoma suspect. Standard topical antiglaucoma medications were taken by five of these patients in the same manner before and during testing with cyclandelate; the other 12 were not under antiglaucoma treatment. During five hours after the dose of cyclandelate, no effects were noted by the patients, and during this time the axial depths of the anterior chambers did not change significantly, varying no more than ± 0.1 mm, the same as in the absence of cyclandelate.

† A + indicates higher tension with nicotinic acid.

By inspecting the pairs of curves of hourly intraocular pressure measurements for each eye with and without cyclandelate we could discern no tendency for either a rise or a fall of pressure after cyclandelate. There appeared to be no distinguishing characteristics in the wanderings of the curves during the corresponding hours of the day with or without the drug. The same conclusions were indicated whether measurements were made with patients sitting or recumbent. During the five hours after administration of cyclandelate a fall of pressure occurred as frequently as a rise, and in all but one eye the changes in intraocular pressure during the five hours after administration of cyclandelate were within a range of ± 5 mm Hg of the starting pressure. The mean of the changes in intraocular pressure during the five hours after cyclandelate was a rise of 0.21 mm Hg. The one exceptional eye that had a change in pressure outside of the ± 5 mm Hg range had a rise of 9 mm Hg, but this corresponded almost exactly to the spontaneous rise of pressure in the same eye without cyclandelate on the control day, and appeared therefore not to be attributable to the medication.

The influence of cyclandelate on the intraocular pressure was further evaluated by determining in each of the 34 eyes of the 17 patients the difference between the pressures with and without the cyclandelate at hourly intervals for five hours following the administration of the drug. The mean difference for each eye with and without the drug was calculated by averaging the five hourly differences. The frequency distribution of these

mean differences, rounded to the nearest mm Hg is listed in Table 2. The mean of all the mean differences in intraocular pressure with and without cyclandelate indicated that during the five hours after administration of the test drug the intraocular pressure was 0.36 mm Hg higher with the cyclandelate than without. The initial premedication pressures on control days and drug test days ranged from 6 mm Hg higher to 7.8 mm Hg lower, but the mean difference was very small—0.13 mm Hg lower on the test days than on the control days. At each hour after the administration of cyclandelate the mean differences in the control and test pressure curves were as follows: end of first hour, +0.32 mm Hg difference; second hour, +0.47; third hour, −0.13; fourth hour, +0.58; fifth hour, +0.47 mm Hg.

We conclude from the observations on cyclandelate that a 200 mg oral dose has so little influence, if any, on intraocular pressure in glaucoma that it presents no appreciable danger to use in the presence of this disease.

Carbon dioxide, as a mixture of carbon dioxide and oxygen, was administered to four patients who had untreated chronic primary open-angle glaucoma in both eyes, and to five patients who had normal intraocular pressures but angles so narrow that gonioscopically it was difficult to ascertain that they were not closed. In four out of five of the latter group of patients, darkroom tests were negative and they had no known spontaneous elevations of pressure, but the fifth patient, whose angles looked almost totally closed, was known to have had spontaneous rises of tension to 30 and 32 mm Hg. In response to inhalation of carbon dioxide the intraocular pressure behaved essentially the same in the patients with open-angle glaucoma as in the patients with initially normal pressures but extremely narrow angles. Characteristically, the pressure rose during the first two minutes to an average peak 3.3 mm Hg above the start, then gradually subsided during five to six minutes toward the pre-inhalation level despite continued breathing of the carbon dioxide-oxygen mixture. The maximum transient rise was 8 mm Hg in one eye. When ordinary air was breathed again after eight to 10 minutes of inhalation of the carbon dioxide mixture, the intraocular pressure in all patients dropped transiently below the pre-inhalation level, usually 2 to 4 mm Hg below, but as much as 7 mm Hg in one patient. Then gradually, during 15 to 20 minutes of ordinary air breathing, the intraocular pressure came back up to the same level as before carbon dioxide inhalation. The carbon dioxide-oxygen mixture failed to provoke angle-closure glaucoma in any of the eyes.

## CONCLUSIONS

We believe that the literature has so far provided no valid evidence that vasodilator drugs such as those used in treatment of coronary or peripheral vascular disease have adverse effects on eyes with primary open-angle glaucoma, or on eyes that are anatomically predisposed to or subject to angle-closure glaucoma. References to literature on vasodilator drugs in relation to intraocular pressure are given in a review by Grant.[3] In

addition, Zahn[4] has reported that any rise of intraocular pressure after orally administered nitroglycerin or nicotinic acid was "insignificant," and Hayatsu and associates[5] have reported that cyclandelate given orally had no adverse effect on ocular pressure in normal or diseased human eyes, including glaucomatous eyes.

In the present study, tests of nicotinic acid and cyclandelate in patients with chronic open-angle glaucoma have shown no consistent influence on intraocular pressure, either good or bad, during four to five hours after single standard doses.

Our tests of 10% carbon dioxide inhalation have, however, shown this to cause a rise of intraocular pressure detectable within a minute or two and averaging 3.3 mm Hg, but as high as 8 mm Hg in one patient. This provides evidence that vasodilation, if sufficiently rapid and intense, can cause a transitory elevation of intraocular pressure. The time course of the pressure rise and subsidence associated with inhalation of carbon dioxide is consistent with a rapid but small increase in blood volume and with the expected effect of automatic compensatory expulsion of an equivalent volume of aqueous humor from the eye. When the inhalation of carbon dioxide is terminated and the vasodilating influence is removed, the volume of the intraocular vessels apparently promptly decreases, as indicated by the drop in pressure immediately after stopping the inhalation. A gradual compensatory reaccumulation of the small volume of aqueous that was expelled earlier then brings the intraocular pressure back to the original steady state.

These observations with carbon dioxide seem consistent with those on the slower and longer-acting vasodilator drugs, pointing to the capability of the human eye, even when afflicted with chronic open-angle glaucoma, to compensate rapidly for finite changes in intraocular vascular volume. These observations suggest that the maximum change in intraocular pressure to be expected from vasodilator drugs that do not greatly alter blood pressure is of the order of a few mm Hg, and may be expected to be transitory. If vasodilator drugs had an influence on either facility or pseudo-facility of aqueous outflow, or on orbital or episcleral venous pressure, they presumably could exert a sustained influence on intraocular pressure different from the transitory influence of finite change in intraocular blood volume. A mechanism for interfering with aqueous outflow has not yet been demonstrated in connection with systemically administered vasodilator drugs, although in explaining the action of vasodilators injected subconjunctivally, such a mechanism may need to be considered.

Failure to provoke angle-closure glaucoma by means of carbon dioxide-oxygen mixture in the five patients with initially normal intraocular pressures but extremely narrow angles was disappointing from the standpoint of search for better provocative tests for angle-closure glaucoma, but it was consistent with the fact that there is an absence of adequately documented reports that establish a relationship between vasodilator drugs and precipitation of acute angle-closure glaucoma. Probably the volume of expansion of intraocular vessels induced by vasodilator drugs is generally too small to induce significant forward bulging of peripheral iris. Neither nicotinic acid nor cyclandelate caused appreciable forward movement of the lens. The angle may have to be extremely critically narrowed before drug-induced change in volume of blood vessels posterior to the lens-iris diaphragm is likely to complete the closure.

It is noteworthy in this connection that attempts by Segal and associates[6] to induce angle-closure glaucoma by utilizing pressure breathing have been unsuccessful, although it has been demonstrated by Pilz and Comberg[7] that this procedure raises intraocular venous pressure and volume.

It appears that the literature and the present clinical testing have provided no valid grounds for withholding coronary and peripheral vasodilator drugs from patients with

chronic primary open-angle glaucoma. Also it appears, contrary to old ideas, that precipitation of angle-closure glaucoma by systemic vasodilator drugs must be a rare occurrence, if indeed it does occur. Further testing would be worthwhile in subjects who have well-established intermittent spontaneous episodes of angle-closure glaucoma.

## Summary

Nicotinic acid (100 mg) was administered to 14 patients and cyclandelate (200 mg) to 17 patients, most of whom had untreated open-angle glaucoma. There was no appreciable influence on anterior chamber depth and so little influence on intraocular pressure that it was concluded that use of these medications in the presence of glaucoma should present no significant danger. Inhalation of 10% carbon dioxide-90% oxygen mixture by four patients with open-angle glaucoma and by five patients with normal pressure but extremely narrow angles caused the intraocular pressure to rise a few mm Hg within two minutes, but this was transient and subsided within five to six minutes. It did not induce angle-closure glaucoma. These tests, and a comprehensive search for published clinical evidence, indicate that if there is a risk of inducing angle-closure glaucoma or of aggravating open-angle glaucoma by systemic vasodilators, it has not yet been demonstrated and the risk must be extremely small.

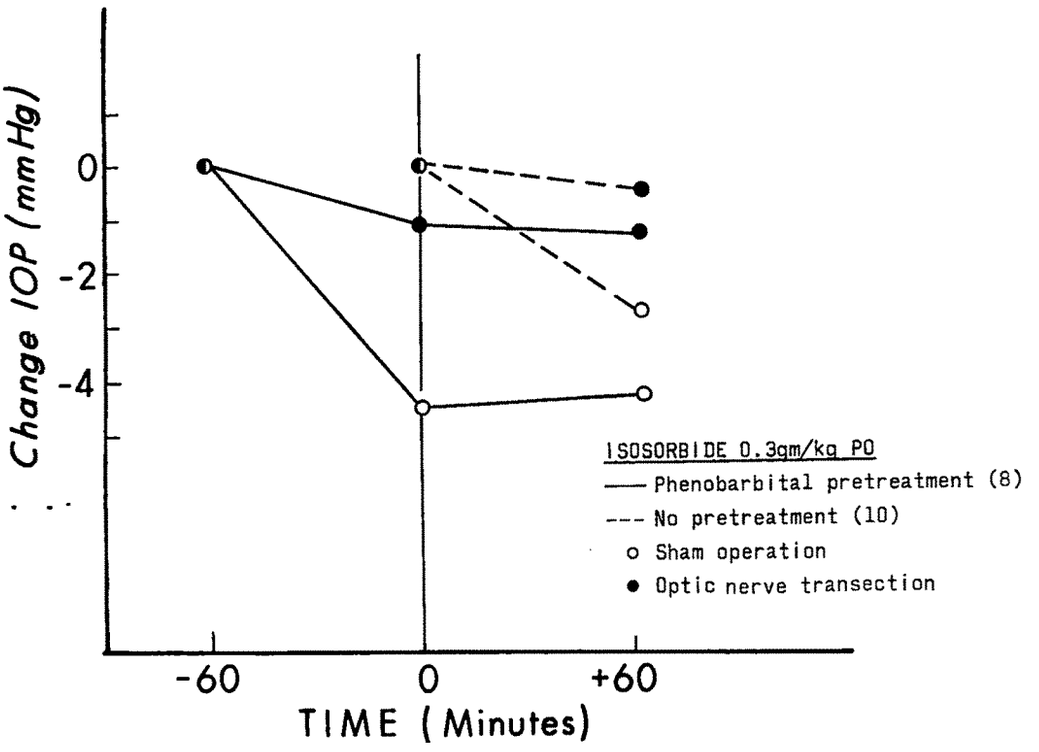

Fig. 2 (Podos, Krupin, and Becker). Influence of pretreatment with intravenous phenobarbital, 52 mg/kg, on the change in intraocular pressure of rabbits with unilateral optic nerve transection after oral administration of isosorbide, 0.3 g/kg. (n = number of animals.)

the decrease of intraocular pressure after phenobarbital, 13 mg/kg, and isosorbide, 0.3 g/kg, remained significantly ($p < 0.001$, $p < 0.01$) less in eyes with transected optic nerves than in their mates with intact optic nerves (Table 2).

### Intravitreal experiments

The half lives of $^{131}$I-iodohippurate injected into the vitreous of three rabbits did not differ between the eyes subjected to sham operation and optic nerve transection (Table 3). The concentration of $^{131}$I-iodohippurate in the anterior chamber aqueous humor remained negligible in all eyes tested.

## Comment

A number of possible explanations exist for the lesser intraocular pressure response to certain agents of an eye that has had its optic nerve and sheath transected. One can suspect that other orbital structures are being damaged. However, the same procedure with exception of actual transection is carried out on the control fellow optic nerve of rabbits[1] and intracranial transection is performed in the monkey.[2] In both, no visible change of retinal blood supply occurs.

A direct effect on the eye is certainly feasible. Alterations of permeability, either vascular or bulk via the cut optic nerve, or of some transport mechanism, anterior or posterior, are possible explanations. However, many pieces of information do not fit this hypothesis. Baseline intraocular pressure and outflow facilities are consistently symmetrical in animal eyes with transected and intact optic nerves. Differences in these parameters might be expected if one eye is "leakier" than the other. In addition to the

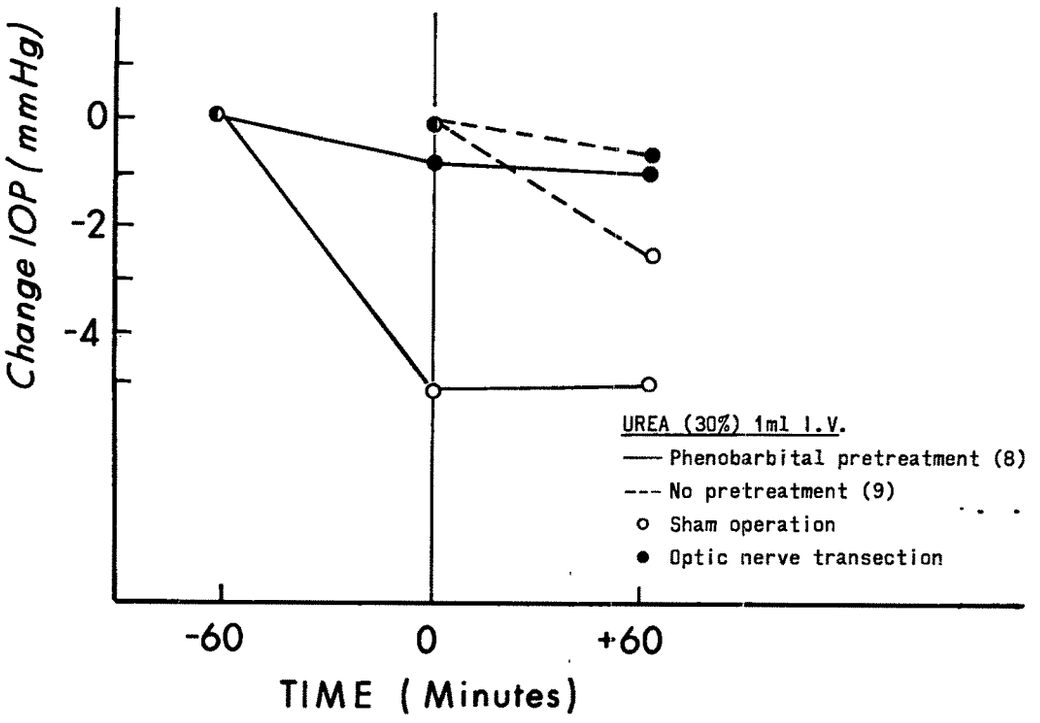

Fig. 3 (Podos, Krupin, and Becker). Influence of pretreatment with intravenous phenobarbital, 52 mg/kg, on the change in intraocular pressure of rabbits with unilateral optic nerve transection after small single bolus intravenous administration of urea, 1 ml per animal. (n = number of animals.)

osmotic agents, barbiturates produce a differential response.[2,4] Permeability changes are not expected to affect the action of the barbiturates. Furthermore, large doses of hyperosmotic or hypo-osmotic agents do not produce a differential intraocular pressure response in these animals.[1] The effective agents given in excess appear to overload the system or act in different fashion. Acetazolamide or topical agents also produce bilateral symmetrical changes.[3] Thus, certain drugs reduce intraocular pressure equally in both eyes of this animal preparation. After administration of isosorbide in an amount that produces less diminution of intraocular pressure in the eye with a cut optic nerve, vitreous and aqueous osmolarity is the same in both eyes of rabbits.[1] However, this may be too gross a test to detect the small potential differences of permeability necessary to account for intraocular pressure differences.[8] An ocular transport system secretes intravitreal organic acids out of the eye.[7] The half-life of $^{131}$I-labeled iodohippurate is not significantly different in the vitreous of eyes with and without intact optic nerves (Table 3) and $^{131}$I-iodohippurate does not accumulate in anterior chamber aqueous. This suggests that optic nerve transection does not alter the posterior pump for iodohippurate.

Therefore, a reasonable working hypothesis involves a central nervous system pathway responsive to some agents and not to others. One can postulate a dual mechanism with separate mediators for elevating and lowering intraocular pressure. Interruption of the tonus of both paths results in no change of baseline intraocular pressure. Stimulation or inhibition of one pathway would lead to the observed differential responses of eyes with transected and eyes with intact optic nerves.

If the same receptor is responsible for all of the intraocular pressure lowering re-

ceptors,[9] receptive to small injections of hypertonic solutions.[10] Electric stimulation of hypothalamic nuclei alters intraocular pressure.[11] Barbiturates have depressant effects on the hypothalamus.[12] Similarly, the pathway from the hypothalamus to the eye is obscure, but efferent fibers in the optic nerve are described[13,14] and traced from the anterior hypothalamus.[15] Histopathologic degeneration studies and hypothalamic stereotactic stimulation experiments in animals with unilaterally transected optic nerves are in progress.

| 230 | 250 |
| 210 | 220 |
| Mean 220 | 227 |
| SEM ±5 | ±10 |

It is certainly not yet clear how the postulated pathway affects aqueous humor dynamics. Hypothalamic stimuli do affect sympathetic nerve activity in a number of organs.[16] Histochemical staining of adrenergic and cholinergic nerves is found to be weak but present in the optic nerve and strong in adjacent ciliary nerves,[17] ciliary body, and filtration area.[18] Species variation is noted. Moreover, cholinergic centrifugal nerves are demonstrated in the optic nerve of the rat.[19]

In the present study, chemical adrenergic or cholinergic blockade of the response of the rabbit eye subjected to a sham operation, to low-dose osmotic agent, or phenobarbital occurs so that the intraocular pressure differential between eyes with and without intact optic nerves is no longer apparent. Parasympathetic paralysis with systemically administered atropine does not alter the pressure elevating response to water ingestion in the sham-operated eye as compared to the

eye with a transected optic nerve. However, the decrease of intraocular pressure induced by low-dose isosorbide and phenobarbital is reduced in the intact eye so that both eyes now respond equally after pretreatment with atropine (Table 1). The small decrease after isosorbide or phenobarbital in the sham-operated eyes of atropinized rabbits compares favorably to prior results in nonatropinized eyes with transected optic nerves.[1,4] In experiments with topical application of atropine, this blocking effect is not found.[8]

Utilization of adrenergic blockade is complicated by the fact that the sympathetic system appears to have two types of adrenotropic receptors.[20] In the eye, for instance, the transient effect of norepinephrine released by superior cervical ganglionectomy on outflow facility is greatly reduced by systemically administered phentolamine (an α-adrenergic blocking agent,)[21] but not by propranolol (a β-adrenergic blocking agent).[22] Less is known about the presence of these two types of receptors in the aqueous secretory apparatus. Intravenous phentolamine decreases intraocular pressure equally in eyes with and without intact optic nerves.[8] Systemic pretreatment with phentolamine has little or no effect on the greater decrease of intraocular pressure of the eye with an intact optic nerve after isosorbide or phenobarbital as compared to the fellow eye with a cut optic nerve. However, no significant difference occurs between the elevation of intraocular pressure of the transected and sham-operated groups induced by water ingestion in animals so pretreated (Table 2). Superior cervical ganglionectomy seems to provide equivocal data, somewhat similar to that with phentolamine but not statistically significant.[8]

Thus, it is tempting to speculate that the end-organ response in eyes with intact optic nerves for the agents that lower intraocular pressure differentially is mediated through a cholinergic system. The intraocular pressure elevating effect of water appears to be mediated through an α-adrenergic mechanism. Optic nerve transection obliterates both types of responses. The specific effects on inflow and outflow, by either conventional or unconventional routes, are not completely understood, but available information favors effects on secretion of aqueous humor. The decrease of outflow facility induced by water is symmetrical in the two eyes of our animal preparations.[1] Isosorbide does not alter outflow facility.[23] There is evidence that barbiturates decrease aqueous humor secretion and do so more in rabbit eyes with intact optic nerves than in their fellow eyes with transected optic nerves.[4]

## Summary

Mechanisms were investigated for the lesser intraocular pressure response to barbiturates, hyperosmotic and hypo-osmotic agents of rabbit eyes with transected optic nerves as compared to their sham-operated fellow eyes. Phenobarbital pretreatment prevented the subsequent diminution of intraocular pressure in eyes with intact optic nerves after administration of small doses of oral isosorbide or intravenous urea, but did not alter the intraocular pressure elevation after water ingestion. The greater intraocular pressure fall in eyes with intact optic nerves after isosorbide or phenobarbital did not occur in atropinized rabbits but the differential rise in intraocular pressure after water persisted. In rabbits pretreated with phentalomine, the greater diminution of intraocular pressure in sham-operated eyes after isosorbide or phenobarbital remained, while the elevation of intraocular pressure after water was similar in eyes with and without transected optic nerves. The half-life of intravitreal $^{131}$I-labeled iodohippurate sodium was similar in eyes after transection of the optic nerve and after sham operation, and in neither group did the isotope accumulate in anterior chamber aqueous.

# CORNEAL HEMOCHROMATOSIS

## A Unique Type of Corneal Dystrophy Involving the Anterior Stroma and both Limiting Membranes

Alberto Urrets-Zavalía, Jr., M.D., and Celia Katz, M.D.
*Córdoba, Argentina*

The variety of degenerative processes of the cornea encountered in clinical practice seems to have no end. The changes seen in the patient herein reported did not conform either biomicroscopically or pathologically to those recorded in any of the types described in the literature.

### Case report

A 41-year-old man of Italian descent, who had always had decreased visual acuity sufficiently low to exempt him from military service, suffered further visual disability over approximately six months. At no time did he have pain, discomfort, or other subjective disturbances. He was alert, well developed and in good health. His one sibling, a sister aged 38 years, was normal, as were both parents. There was no consanguinity.

When the patient was first seen on June 14, 1967, uncorrected visual acuity was 20/200- in the right eye and 4/100- in the left. The eyes showed no congestion; no blepharospasm or lacrimation were present. Upon applanation, intraocular pressure was 18 mm Hg in both eyes.

External examination disclosed bilaterally a fine, diffuse, grayfish cloudiness of the entire cornea (Fig. 1). Corneal sensitivity was undisturbed.

*Biomicroscopic study*—Corneal luster was preserved and the epithelium appeared to be normal. The opacity, of uniform density throughout, was confined to the anterior third of the stroma. It seemed to be composed of a multitude of minute refringent dots resembling lipid droplets. No changes were seen in the posterior two-thirds of the stroma. Descemet's membrane appeared to be somewhat thickened and slightly irregular. There was no neovascularization. The corneal thickness, measured with the Haag-Streit pachometer, was normal.

The iris, lens and internal media were normal.

*Ophthalmoscopic study*—Examination under wide dilation of the pupils failed to reveal any gross abnormality. Although the corneal opacity obscured fundus details, the disks and maculas seemed to be normal.

*Physical examination*—Full medical examination excluded the presence of any systemic disorder. In particular, there was no hepatomegaly, splenomegaly, or diabetes, and no abnormal pigmentation of the skin. The patient was impotent. Repeated urinalyses, blood cell counts, blood sugar determinations and x-ray studies of the skull and chest were all negative. Total protein plasma content was 6.6 g/100 ml and the albumin-globulin ratio was normal, as were also the serum iron level estimated by the method of Barkan (136 μg/ml) and the glucose tolerance test. The liver function tests were normal: serum bilirubin was 0.70 mg %, the thymol turbidity test 6.1 units and the cephalin flocculation test ++ (48 hrs).

*Treatment*—On October 5, 1967, a 7-mm penetrating keratoplasty was performed on the left eye under local anesthesia. Fresh donor material and 16 appositional 7-0 black silk sutures were used. At the end of the procedure, air was injected into the anterior chamber. Sutures were removed on the 31st day, and the eye was left unpatched 48 hours later. The postoperative course was uneventful and the graft remained clear. On September 11, 1968, refraction of the left eye was −3.00 sph⊃ −2.25 cyl ax 25°. Although fully corrected vision was only 20/60, a clear view of the fundus, which was normal, could now be obtained.

Examination of the right eye at this time showed that its condition had worsened. The corneal opacity was more dense. Vision was now reduced to 4/200 and visualization of the fundus was no longer possible. Accordingly, on November 16, 1968, a 7-mm full-thickness corneal transplantation was performed on the right eye. Eight interrupted virgin silk sutures and a running monofilament Perlon suture were used, and the anterior chamber filled with air. The postoperative course was uneventful. The direct sutures were removed on the 14th day but the running suture was left in place for 60 days.

When the patient was last seen, on July 28, 1969, vision in the right eye was 20/60 with +4.50 sph⊃ −4 cyl ax 10°. The graft was clear. The fundus appeared to be normal and no explanation for the diminished visual acuity could be found. The condition of the left eye was unchanged.

### Pathology

The specimens taken from the recipient eyes were fixed in formalin and embedded in paraffin. In addition to the routine stains, a number of differential staining techniques were used.

The sections colored with hematoxylin-eo-

Fig. 3. (Urrets-Zavalía and Katz). Broad gap (arrow) in Bowman's membrane, where the superficial stromal layers seem to be continuous with the newly formed plaques underlying the basement membrane. This dehiscence should not be confused with the numerous pores which are normally present in Bowman's membrane (hematoxylin-eosin, ×400).

sin showed irregularities in the underlying stratum which caused the epithelium to vary greatly in thickness (Fig. 2). The normal arrangement of cells was disrupted and there was slight edema with bulla formation. The epithelium had a tendency to become detached in places where a delicate, avascular fibrous tissue, similar to that of the substantia propria, separated it from Bowman's membrane. This was uneven and frayed; it showed some gaps where the superficial stromal layers appeared to be continuous with the newly formed plaques beneath the epithelium (Fig. 3).

The posterior two-thirds of the stroma was unaltered. In the anterior third, however, was an accumulation of amorphous granules which stained a dark violet; at no place between the epithelium and Bowman's membrane did the stain demonstrate this material. Although the deposits caused separation of the corneal lamellae, these showed only minor and nonspecific degenerative changes. A strongly basophilic membrane of a barely discernible fibrillar nature replaced Descemet's membrane; it was about twice the thickness of Bowman's membrane. The endothelium appeared to be extremely thin and was absent in some places; its irregularly distributed cells exhibited pleomorphism and severe pyknotic changes.

With Masson's trichrome the microdeposits in the stroma took on a deep purple color (Fig. 4). It is interesting that with this stain, the posterior membrane appeared to be situated in front of what remained of Descemet's membrane. It was composed of two layers, each with a different tinctorial affinity: the anterior layer was pink; the posterior one blue. A faint transverse striation could be seen in both layers (Fig. 5). There were some stromal changes adjacent to that membrane.

The granules appeared red, as did the nuclei, with Mallory's stain (Fig. 6).

The toluidine blue stain revealed no metachromasia (Fig. 7). Both the interlamellar deposits and the posterior membrane stained a brilliant blue.

The alcian blue and the periodic acid-Schiff (PAS) reactions failed to stain the nodules (Fig. 8). However, PAS showed that the posterior membrane consisted indeed of two distinct layers: an anterior one which stained magenta and a faint blue posterior one (Fig. 9). Both layers stained more intensely than the parenchyma.

The Perls test, used with an erythrosin counterstain, gave a green color to the stromal accumulations, strongly suggesting that hemosiderin—or at least iron—was present (Prussian blue reaction). The membrane seen

Fig. 11 (Urrets-Zavalía and Katz). In the completely incinerated specimen, iron oxide imparts to the ash a bright orange color (areas marked with black rings). Oblique illumination on dark field (×640).

posteriorly exhibited the curious doubling already noted, the anterior half being a pale green, the posterior half pink (Fig. 10).

The Johnson method for iron (microincineration) was also positive: When examined with oblique illumination on a dark field, the completely incinerated specimen showed many dark red deposits in the anterior stroma and an orange discoloration of the anterior half of the membrane (Fig. 11). Direct observation of the Prussian blue reaction on ash revealed that iron oxide was present.

The Feulgen test for nucleic acid was strongly positive, the interlamellar material staining a deep pink (Fig. 12); it was negative at the level of the posterior membrane, which stained a very light pink, as did the stroma. The purpurin reaction for calcium was negative; the entire cornea, including the nodules and Descemet's membrane, assumed a uniform coloration when counterstained with methanile yellow (Fig. 13).

## Comment

Franceschetti and Babel[1,2] first discussed the histopathologic differentation of the three classic corneal dystrophies involving the corneal stroma—granular, lattice, and macular. Jones and Zimmerman[3,4] and Smith and Zimmerman[5] later detailed the differences more clearly. They resorted to certain histochemical reactions in addition to the standard staining techniques and their findings are the yardstick for appraisal of any observation that is deemed unusual. We have used these criteria to assess the observation reported above.

In the granular, lattice, and macular corneal dystrophies, there is in the stroma a characteristic accumulation of an anhistous material, which is more or less eosinophilic and stains pale gray or pink with hematoxylin-eosin. This is in marked contrast to the results obtained in the case described, where the specific lesions were strongly basophilic and stained violet, being almost black with Masson's trichrome. With this reaction, the typical lesions of the granular and macular degenerations turn red, those of lattice degeneration a faint blue. The PAS reaction was negative in our case, as it is in granular dystrophy, revealing absence of mucopolysaccharides in the deposits. On the other hand, in the lattice and macular degenerations the lesions usually color a dark magenta with PAS. The deposits in the present case did not stain with Alcian blue, which makes the lesions in granular dystrophy turn pink, those in lattice dystrophy pinkish-red, and, owing to the presence of an acid mucopolysaccharide, those in macular dystrophy a deep blue.

But not only in its singular staining properties did the homogeneous material in the case being discussed differ from that existing in the more familiar forms. In these more familiar forms, it seems to result from the destruction and subsequent transformation of

the substantia propria, whereas in the case under discussion it was more in the nature of an inclusion between the fibers themselves. Moreover, the abnormalities we found in Descemet's membrane deserve special consideration as there is no previous report of a dystrophy in which this membrane exhibited a greater thickness and a striated appearance. In primary Fuchs' dystrophy, an additional laminated membrane overlying the *posterior* surface of Descemet's membrane, with excrescences between the two layers, has been reported as a rare finding by Chi, Teng, and Katzin.[6] This new membrane differed in its tinctorial properties from that seen in our case. Besides, it was covered with endothelium, which had abnormally large, thin, elongated nuclei, and contained fine granules of pigment.

If, in addition, one notes that the lesions in the patient under consideration differed clinically from those seen in the hereditary dystrophies studied by Bücklers,[7] it should be concluded that the condition in this case represents a separate morbid entity.

Franceschetti and Babel[8,9] mentioned a congenital corneal dystrophy in which the pathologic process invaded the whole cornea and showed little or no tendency to progress. It was characterized by a diffuse cloudiness and, in this one respect, resembled the picture observed by us. There the analogy ceases, for Franceschetti and Babel found the stromal lamellae ill-defined, dissociated into a mass of fine fibrils and drowned in a basophilic, edematous material. The basophilic granules they saw in the anterior layers of the stroma were small and few in number, and appeared to be attached to the stromal cells; they turned orange with the Mallory stain, which, in our case, dyed the granules red. The only other similar case in which a pathologic examination was made is that of Offret reported by Etienne.[10] In this case, the basophilic granules were more numerous and appeared in the interlamellar spaces. The lamellae were indistinct and poorly limited. A fine acidophilic intralamellar dust was also seen.

From the viewpoint of their staining properties, the stromal accumulations of granular dystrophy may be characterized as areas of hyaline degeneration, those of macular dystrophy as areas of mucoid degeneration, and those of lattice dystrophy as areas of amyloid degeneration.[5] Although the nature of the stromal inclusions found in the present case is not clear, the results with the Masson and Mallory stains, as well as the Feulgen reaction, seem to indicate the presence of nucleic acid. The Perls test and the microincineration test revealed that both the inclusions and the anterior layer of Descemet's membrane contained a ferrous compound.

This latter fact suggests that one could be dealing with an iron storage disturbance such as hemochromatosis (bronze diabetes, pigmentary cirrhosis), a rare condition which has been known to involve the eye occasionally and which results from an inborn error of the metabolism wherein excessive deposits of iron are laid down throughout the body in the form of brown granules. The accretion of iron is gradual, so that the symptoms do not usually appear until mid-adult life[11] (90% of the patients are over 35 years of age). It appears predominantly in the male (90%), the obvious explanation for this sex disparity being the ability of the female to unload considerable amounts of iron through menstruation, pregnancy and lactation[12]; thus, in women the disease is relatively more frequent after the menopause.[13]

It has not been demonstrated that huge accumulation of iron in the tissues will bring about by itself the pathologic changes and clinical manifestations of this morbid process. It seems more reasonable to consider that iron, which is not converted to the proper kind of ferric hydroxide, may cause cell destruction with consequent fibrosis by precipitating proteins indiscriminately, or perhaps by inactivating one or more specific enzymes.[14-16]

The tetrad of hepatomegaly with eventual liver insufficiency, slowly progressive diabetes mellitus, cardiac failure and a slate-

gray pigmentation of the skin is characteristic. A nontender, firm spleen is palpated in about one-half of the patients. Loss of hair, palmar erythema, testicular atrophy, and particularly loss of libido are often seen.[12] Elevation of the plasma iron concentration and of the iron-binding capacity are considered the most valuable presumptive diagnostic signs in hemochromatosis. Needle biopsy of the liver—which is highly demonstrative when the specimen contains an excess of hemosiderin—should be undertaken only when the former tests are positive.

While hemochromatosis is usually encountered sporadically, there is adequate evidence to indicate that it may occur as a familial disorder. Debré and co-workers[17] and Finch and Finch[12] point out that among the relatives of patients with the overt disease about 20% have elevated serum iron levels. The disorder is probably the result of an autosomal genetic defect of incomplete penetrance or variable expressivity, or both, which is transmitted as a Mendelian dominant.[18] Davidson[19] believes that it is probably transmitted as an autosomal recessive trait, whereas Powell[20] maintains that if an intermediate form of inheritance exists, there is as yet no clear distinction between the heterozygous and early homozygous states.

Idiopathic hemochromatosis must be distinguished from other iron storage diseases such as dietary and transfusion hemochromatosis, which are obviously the result of environmental factors. It should be noted that there is a definite association of alcoholism and Laennec's cirrhosis with hemochromatosis. Although the implications of this are not entirely clear,[12] the findings of Powell[20] support the notion that the idiopathic hemochromatosis and alcoholic cirrhosis are separate entities.

In its primary form, the condition is generally visualized as an enterogenous process, connected with the absorption of abnormally large amounts of iron in the absence of excessive intake. It has been shown to result from an intrinsic defect dependent upon an enhanced ability of the mucosal cells to let iron move from the duodenal tract into the blood stream.

In a review of the literature since 1930, Hudson[21] found very few references to the ocular changes, which for the most part are similar to those of diabetes such as retinal and conjunctival microaneurysms. A picture of early diabetic retinopathy was also observed by Galton.[22] Maddox[23] described in four cases a grayish-blue discoloration of the retina. The pigment deposition was of a diffuse and uniform character, but was especially concentrated around some or all of the disk margin. The pigment itself was not the common black color seen in the dark-skinned

TABLE 1

IRON CONTENT OF THE CORNEA[25]

| | Wet Tissue (μg/100 g) | | | Dry Tissue (μg/100 g) | | |
|---|---|---|---|---|---|---|
| | Minimum | Maximum | Average | Minimum | Maximum | Average |
| Whole cornea | 208 | 296 | 257* | 1000 | 1380 | 1160 |
| Stroma | 166 | 220 | 197 | 720 | 1000 | 890 |
| Epithelium | 552 | 680 | 616 | 2200 | 2720 | 2460 |

* Oksala's[24] figure for the overall iron content of the cornea is of 500 μg/100 g of the wet weight.

races but a deep slaty color through which the retina appeared as a kind of ochre background. To the best of our knowledge no corneal changes due to hemochromatosis have ever been detected.

In the propositus, nothing seemed to warrant a diagnosis of hemochromatosis, either primary or secondary. There was no demonstrable dysfunction or enlargement of the liver, which is the first organ to be affected, no diabetes or prediabetes, no pigmentation of the skin, and no excess iron in the serum. The corneas, nevertheless, were laden with iron, which was attached to a nucleoprotein.

Under normal conditions, iron is present in the cornea only as a trace element,[24] the average content being lower in the stroma than in the epithelium. Table 1, which is based on the determinations made by Tauber and Krause[25] in the eyes from freshly slaughtered cattle, gives the relative proportions of this metal in the cornea. In the case of the so-called Hudson-Stahli line, the Stocker line, and the Fleisher ring seen in keratoconus, there is a demonstrable focal deposition of intracytoplasmic iron in the corneal epithelium, although in minute quantities.[26]

Why the corneas in our patient should have such large stores of an iron protein in the stroma is a matter of speculation. The simplest view should be that this resulted from a purely local disturbance akin to that which leads to the appearance of a nonsystemic amyloidosis in the case of lattice dystrophy.[27-30] It ought then to be considered a variety of hemochromatosis restricted to the cornea wherein the deposition of iron in the form of clusters of a probably non-heme compound produces a degradation of collagen with degeneration of the fibroblasts. Alternatively, it might be that the insoluble protein in the stromal nodules picks up iron on a selective basis. It must be made clear at this point that by using the term "hemochromatosis" we are not postulating a connection as to the origin between the corneal deposits and the systemic affliction, or even the blood pigment. We seek only to provide the condition with a label which immediately brings to mind the idea of an accumulation in the tissues of an abnormal iron protein.

Figs. 7-10, 12, and 13 (Urrets-Zavalía and Katz). Figure 7 (top left): The corneal accumulations take on the same color as the surrounding stroma when treated with a metachromatic stain (toluidine blue, ×400). Figure 8 (top right): The stromal deposits do not stain with PAS-alcian blue (×400). Figure 9 (center left): Doubling and faint striation of posterior membrane (PAS, ×400). Figure 10 (center right): Hemosiderin present in stromal granules and anterior half of posterior membrane (Perl's test with erythrosine counterstain, ×60). Figure 12 (bottom left): Interlamellar deposits contain nucleic acid (Feulgen's test, ×400). Figure 13 (bottom right): No calcium is present in stromal granules (purpurin reaction with methanile yellow counterstain, ×400).

For the time being, one can only describe the peculiar changes in Descemet's membrane, not elucidate them, or correlate them with those in the outer cornea.

## Summary

A type of corneal dystrophy not previously described was found in both eyes of a 41-year-old man. A diffuse opacity in the anterior third of the stroma consisted of an accumulation of minute, slightly refringent dots. Partial penetrating keratoplasty performed on both eyes yielded specimens which, when examined histologically, showed (1) that the granules consisted of an amorphous material containing nucleic acid and hemosiderin, and (2) that Descemet's membrane was replaced by, or transformed into, a thick membrane composed of two distinct layers with different staining properties. The condition is regarded as a nonsystemic form of hemochromatosis which affects only the eye.

# SPONTANEOUS CONGENITAL IRIS CYST

FREDERICK H. ROY, M.D., AND CALVIN HANNA, PH.D.
*Little Rock, Arkansas*

This paper presents a case of spontaneous congenital iris cyst. In addition, the microscopic, ultramicroscopic, autoradiographic, and free amino acid findings of the cyst are also reported.

## CASE REPORT

This Negro boy was born to a 20-year-old woman, gravida 3, para 3, by forceps delivery on March 19, 1969. His birth weight was 3.17 kg and he had an Apgar rating of 10 at five minutes. On examination, the infant was adjudged to be normal and he was discharged at three days of age. He was readmitted eight weeks of age with a diagnosis of diarrhea and dehydration. At that time, the left eye, which had remained closed for the previous three weeks, revealed an abnormality. An examination revealed a normal right eye and a bilobated, slightly turbid, pigmented cystic structure which occupied about the lower half of the anterior chamber of the left eye. It touched the endothelium of the lower cornea and was present on the surface of the iris. Over a period of two weeks, the cyst appeared to fill 75% of the anterior chamber (Fig. 1). The horizontal corneal diameter in both eyes was 11 mm, while the intraocular pressure (Schiøtz) was two scale readings higher in the left eye than in the right. Under general anesthesia (halothane), a limbal-based conjunctival flap was laid inferior from four to six o'clock. A syringe with a 27-gauge needle was used to aspirate 100 ml of fluid from the cyst through a 4 mm incision of the limbus. Smooth, non-toothed forceps were used to bring the cyst out through the opening. The cyst appeared to be attached to the inferior mid-portion of the iris and a sector iridectomy was made inferiorly to remove the attachment of the cyst with the iris. The cyst was not attached to the pupillary margin and there was no lens defect. Following surgery, the inferior cornea of the left eye was hazy and by three months after surgery the inferior cornea was slightly cloudy, the intraocular pressure was 7/7 (7.5) mm Hg and a small semitransparent mass was noted at six o'clock with a contact lens. One year later this mass was not further enlarged.

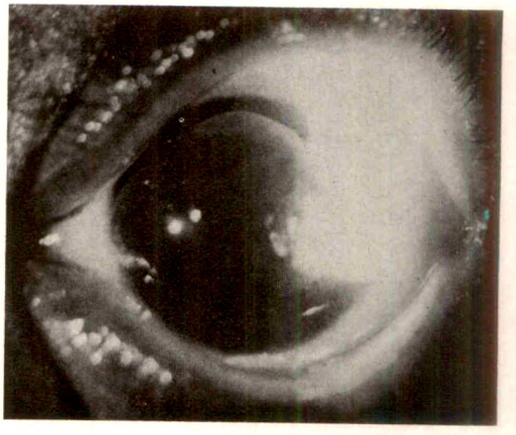

Fig. 1 (Roy and Hanna). Left eye, with bilobated, slightly turbid and pigmented cystic structure occupying lower 75% of anterior chamber. Light at superior temporal limbus is artifact.

## MATERIALS AND METHODS

On removal of the cyst, the tissue was immersed in a solution of tissue culture medium (TC-199) containing 1 μCi/ml of $^{3}$H-thymidine and 5μCI/ml of $^{3}$H-1-leucine both of sp. act 5 Ci/mmole.* After one hour's incubation at 37°C, the tissue was fixed for one day in freshly prepared 4% formaldehyde. The tissue was cut into six pieces and stained with osmium tetroxide and then embedded in epoxy (Araldite) plastic for microscopic, ultramicroscopic, and autoradiographic studies. The thick sections (0.1 to 4μ) were usually stained with toluidine blue, the thin sections (about 0.06 μ) were stained with uranyl acetate and lead citrate, and for autoradiography thick sections were coated with NTB2 Kodak liquid emulsion.[1] The cyst fluid sample was precipitated with 15% (w/v) aqueous sulfosalicylic acid, centrifuged and subjected

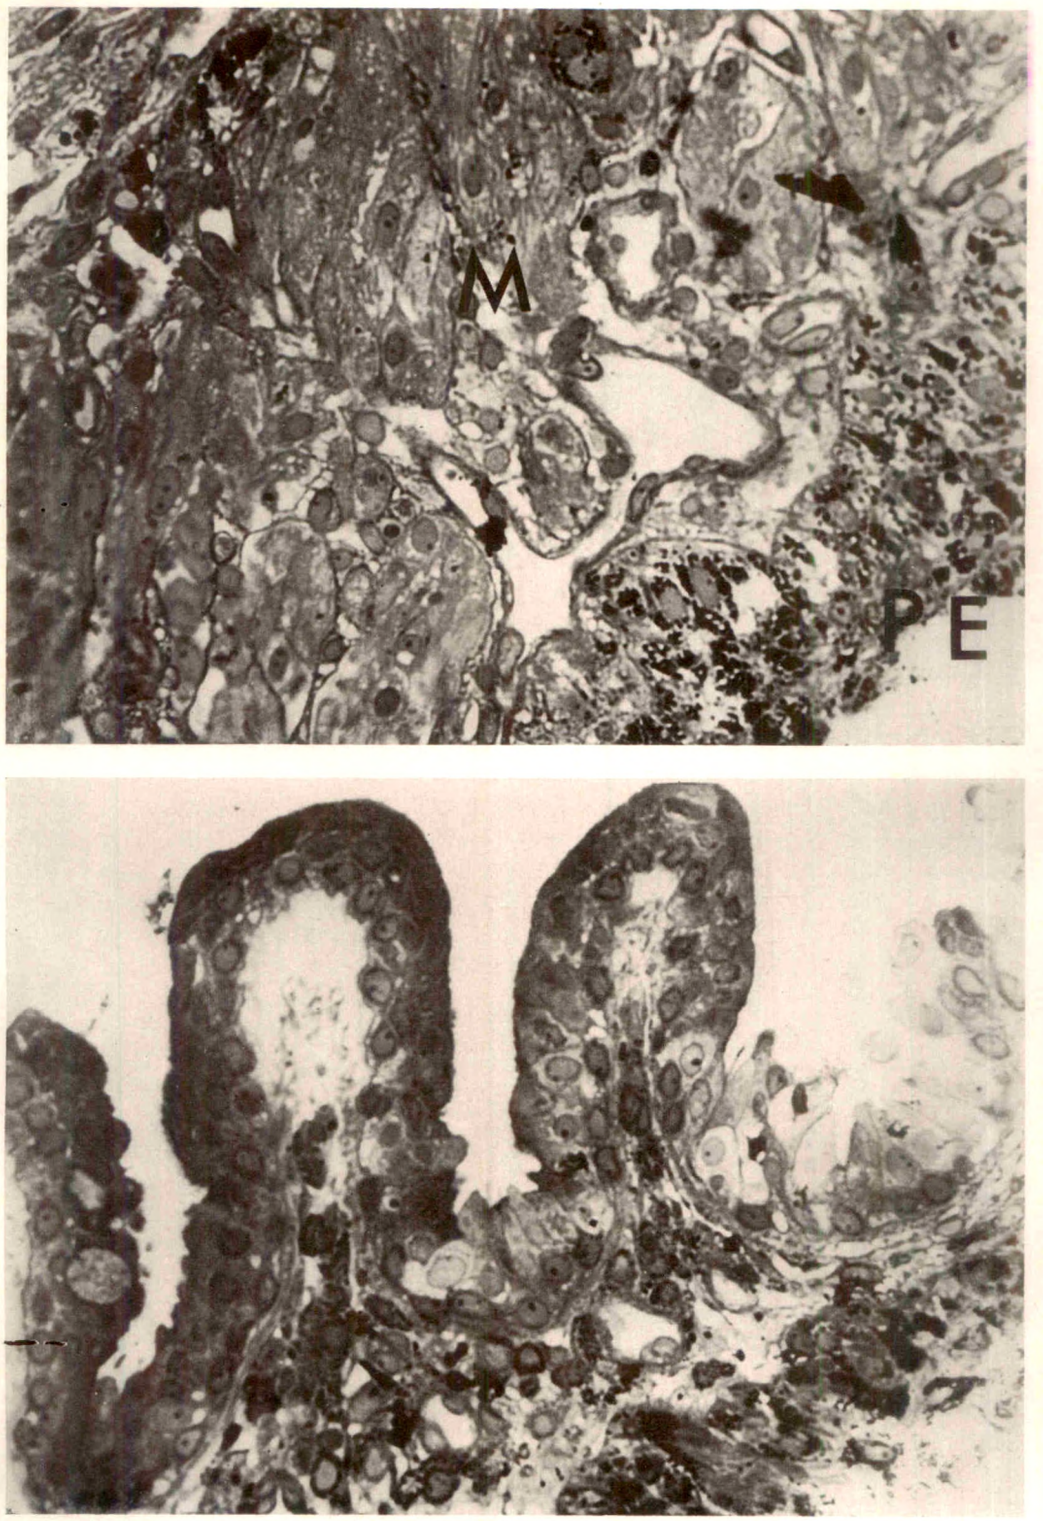
to ion exchange chromatography, using the Beckman Spinco Model 120C amino acid analyzer.[2]



## Results

The cyst wall consisted of two or three layers of nonpigmented epithelial cells on the anterior side overlying one or two layers of pigmented cells (Fig. 2). The cyst was attached to the anterior surface of the iris below which were located normal appearing iris cells (Fig. 3). On the posterior side, remnants of the embryonic ciliary processes were found at the root of the iris (Fig. 4).

The epithelial cells covering the cyst took on many shapes. The innermost epithelial cells contained larger round nuclei and they closely resembled the basal epithelial cells of the cornea. No goblet or mucin cells were found.

The amino acid leucine is incorporated almost exclusively into newly synthesized protein. To estimate the relative rates of overall protein synthesis by various cell types, the cyst was incubated for a short period of time in leucine with a radioactive tracer ($^3$H-leucine). The autoradiograph was used to estimate the relative uptake of the radioactive

Fig. 4 (Roy and Hanna). Posterior surface of iris containing villi projecting into the posterior chamber These villi appear to be remnants of the embryonic ciliary process that may extend to the posterior surface of the iris. The surface of the villi are covered with nonpigmented epithelial cells. The outermost epithelial cells are covered by microvilli. Inside the villi are brightly red-staining collagen fibers (the red stain is so light that it appears in this photograph as white). Below the collagen layer are pigmented stromal cells. Further toward the pupil, the nonpigmented epithelial cells and villi disappear and become pigmented epithelial cells on the posterior side of the iris (basic fuchsin and methylene blue, ×800).

PE

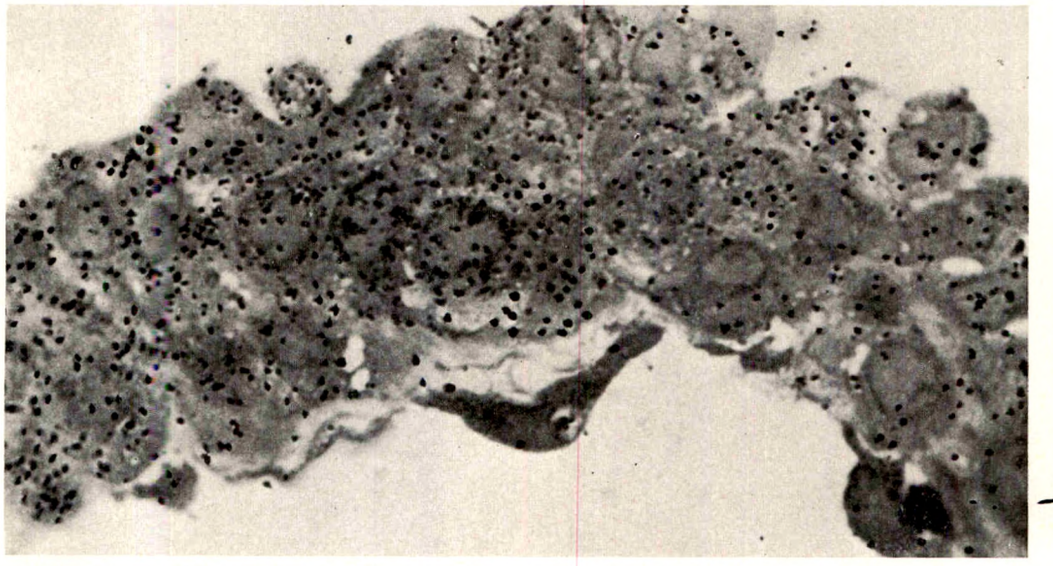

Fig. 5 (Roy and Hanna). The number of reduced silver grains (black dots) overlying the incorporating $^{3}$H-leucine into protein was higher for epithelial cells than for the pigmented stromal cells (inferior portion of photograph). In this autoradiographic photograph the focus is on the silver grains, and as a result the possibly confusing melanin granules are out of focus (autoradiogram stained with toluidine blue, ×900).

leucine taken up into protein. The cells of the cyst incorporated $^{3}$H-leucine into protein (Figs. 5 and 6). There was a relatively high grain count from the autoradiogram over the individual epithelial cells of the cyst that was similar to that of normal epithelial cells of the cornea.[3]

The free surface of the epithelial cells contained microvilli (Figs. 7-10). The cytoplasm of the epithelial cells contained various types of junctions, i.e., desmosomes, tight and gap junctions (Figs. 8-11), and intracellular filaments (Figs. 7-14). Similar junctions between stromal cells or epithelial and stromal cells were not noted (Figs. 11, 12, and 15) and the extracellular space between the epithelial and stromal cells contained banded filaments (Figs. 12-13).

The pigmented stromal cells of the cyst contained nuclei that were of varying shapes (Figs. 2, 12, and 15). These cells incorporated $^{3}$H-leucine into protein to give a low grain count in comparison with the epithelial cells of the cyst (Figs. 5, 6). These stromal cells incorporated $^{3}$H-leucine at a rate comparable to the stromal cells of the cornea.[3] The pigmented stromal cells were surrounded by collagen fibrils (Figs. 12, 13, and 15). These pigmented stromal cells did not have the characteristics of the pigment epithelial layer found on the posterior surface of the iris (Fig. 3). A piece of the iris that was tightly attached to the cyst was removed with the cyst. This iris tissue contained two layers of pigmented epithelial cells on the posterior surface, several layers of nonpigmented epithelial cells over the anterior surface and heavily pigmented and lightly pigmented (stromal) cells in the remainder of the tissue along with muscle cells (dilator iris) above the pigmented epithelium (Fig. 3).

Only a few mitotic figures were observed in the sections of the cyst. Only an occasional basal epithelial cell, and rarely a stromal cell, of the cyst incorporated $^{3}$H-thymidine into newly forming DNA. This indicates that a slow rate of cell division was taking place in the cells of the cyst compared to basal epithelial cells of the normal cornea that are undergoing a moderate rate of cell turnover.[3]

The piece of iris tissue adjacent to the cyst contained several layers of nonpigmented

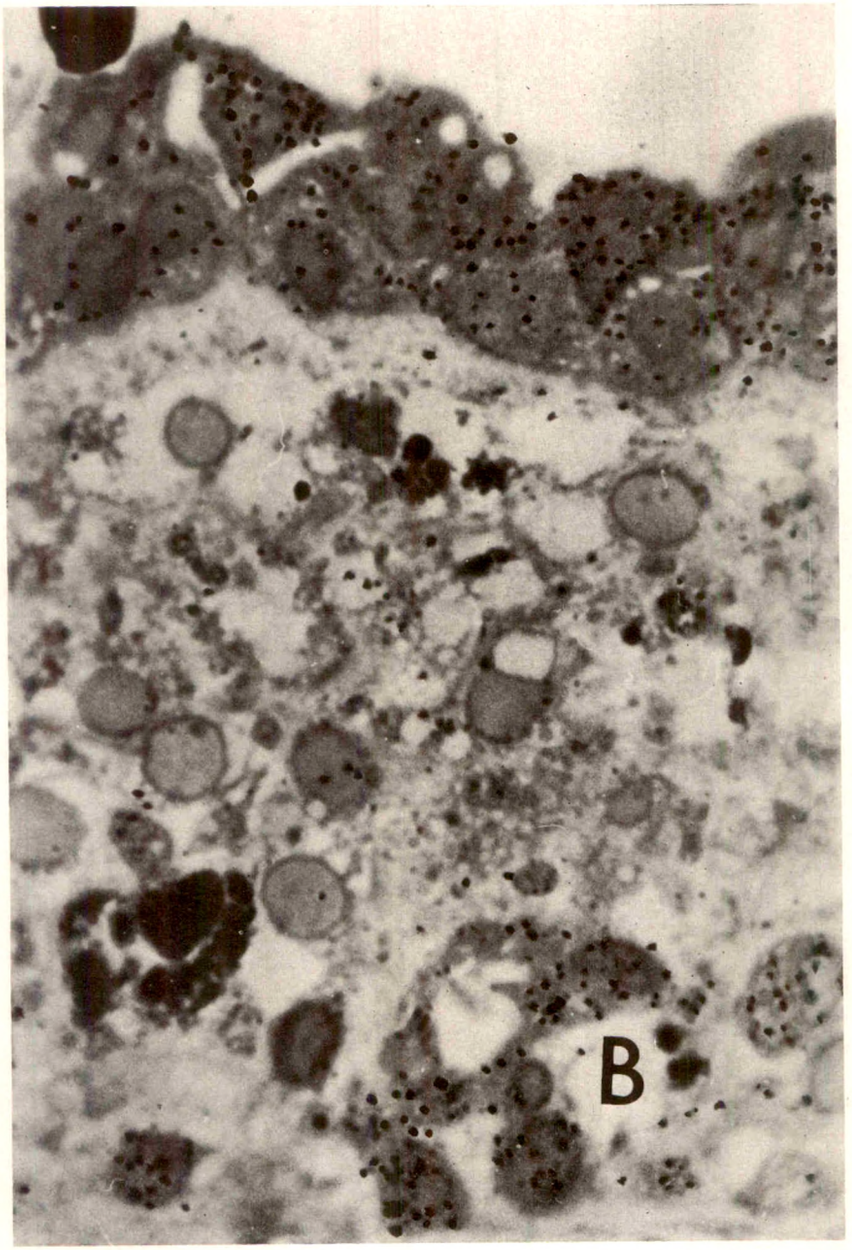

Fig. 6 (Roy and Hanna). The number of reduced silver grains over the endothelial cells surrounding a blood vessel (B) that had incorporated $^{3}$H-leucine into protein was similar to the number of reduced silver grains over the surface epithelium (top) overlying the iris (autoradiogram stained with toluidine blue, ×900).

epithelial cells on the anterior surface and two layers of heavily pigmented epithelial cells on the posterior surface. Between these layers were pigmented stromal cells. Heavily and lightly pigmented stromal cells were present beneath the epithelial layer (Fig. 15). These stromal cells were not generally in contact with adjacent cells. Collagen fibrils were found between the stromal cells and no cell junctions or tonofibrils were found.

Fig. 7 (Roy and Hanna). The surface epithelial cells of the cyst contain striated or brush borders or microvilli (V). These microvilli are covered with plethora of delicate branching filaments (F) which forms an almost continuous coating. These filaments appear to be continuous with the unit membrane of the microvilli (×45,000).

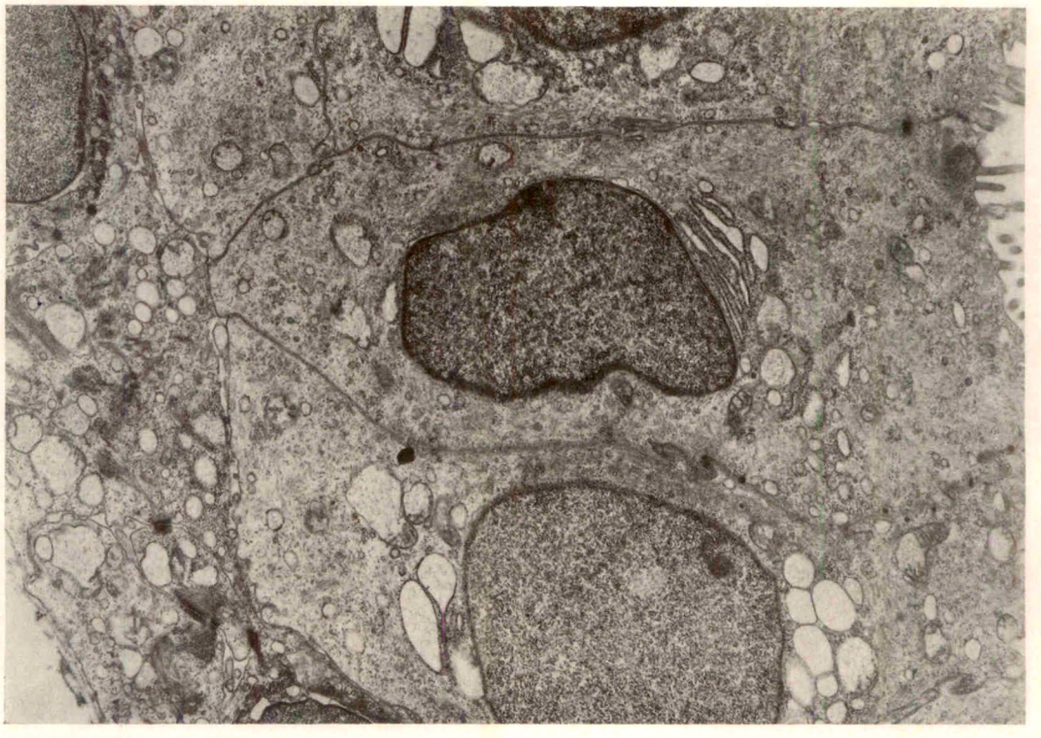

Fig. 9 (Roy and Hanna). Epithelila cells of cyst sectioned through area shown in Figure 2. Note the microvilli on the right side ×15,000).

The anterior chamber fluid contains a full spectrum of free amino acids similar to that found in the peripheral blood. The cyst itself, being an almost avascular sphere, may contain a fluid that has limited nutrients. The concentration of free amino acids in the cyst fluid was low.

Free amino acids are presented in Table 1. With the exception of histidine and cystine, the concentration of free amino acids in the aqueous humor of the adult human[2] was in all cases higher than that of the cyst.

## Comment

The origin of spontaneous iris cysts is still controversial.[4-7] Since both the cyst from the iris stroma and from the neural epithelium may occur in the stroma of the iris, Duke-

Fig. 8 (Roy and Hanna). Junction between two epithelial cells, left center, demonstrating desmosome (macula adherens) (D) surrounded by prominent tonofibrils. Part of a microvillus (V) with branching filaments (F) can be seen in upper right corner. Dark black spots throughout the cell are ribosomes (×100,000).

Fig. 10 (Roy and Hanna). Surface epithelium of the cyst contain unusually long microvilli and typical microvilli, cell junctions (tight junction, zonula occluden) (T), and many ribosomes (×45,000).

Elder[4] states that "differentiation between them on clinical grounds is impossible, and on histological grounds is difficult, the existence and separation of the two types rest more upon a theoretical than on an observational basis." Even with electron microscopic studies, we feel that one cannot positively determine how the nonpigmented epithelial cells arrived over the stromal cells of the cyst. The epithelial cells covering the cyst and part of the iris appear to be typical epithelial cells from the standpoint of ultrastructure with numerous polysomes, tonofibrils, desmosomes, and the high rate of incorporation of leucine into protein compared to adjacent stromal cells. The pigmented fibrocytes of the cyst contain intracellular collagen fibrils of various sizes. These cells could have a similar origin as did the stromal cells of the iris to which the cyst was at-

tached. The resultant of the uptake and incorporation of $^{3}$H-leucine into protein by pigmented cells of the cyst and stromal cells of the noncystic part of the iris were also similar.

Several possibilities should be considered in the histogenesis of the cyst: It may derive from (1) pigment epithelium, (2) conjunctival epithelium, (3) ectopic lacrimal gland ductal epithelium, (4) from nonpigmented neuroepithelium, or (5) from iris stroma. Since the epithelial layer of this cyst lacks pigment granules, mucous glands (goblet cells),[6] and glandular tissue, the first three possibilities are unlikely. The most likely histogenesis of this spontaneous congenital cyst is nonpigmented neuroepithelium covering stromal cells derived from the iris.

Fine[7] reported a free-floating pigmented cyst in the anterior chamber of a 22-year-old man. In his patient, the cyst was composed of pigmented epithelial cells that were delineated on one side by a basement membrane and contained diastase sensitive granules (glycogen deposits). In the study reported here, neither pigmented epithelial cells, a basement membrane, nor glycogen deposits were detected in the cells of the cyst.

The extent and length of the microvilli covering the epithelial cells to the cyst were extraordinary. These microvilli were visible

under microscopic observation. Such villi have not previously been reported for iris cysts. The presence of very low free amino acids in the fluid of the cyst, compared to the normal anterior chamber fluid, suggests that the cyst contained no opening to the anterior chamber, or at the most, only a small opening. The microvilli are similar in structure to the absorptive cells of the small intestine[8] and the concentration of nutrients inside the cyst might be expected to be low. It is of interest that in the presence of a very low free amino acid concentration, the cells lining the inside of the cyst were viable. Possibly this is due to the fact that the pigmented cells lining the cyst are undergoing a low rate of protein synthesis as indicated by the relatively small uptake and incorporation of $^{3}$H-leucine into the protein of these cells.

## SUMMARY

A spontaneous cyst in the anterior chamber and attached to the iris was found in an eight-week-old infant. Microscopic, ultramicroscopic, and autoradiographic features of the cyst are presented. The cyst wall is composed of several layers of pigmented stromal cells covered by multiple layers of nonpigmented epithelial cells. The surface epithelial cells were covered with unusually long microvilli and there was no evidence of goblet cells. An occasional epithelial cell was observed to be undergoing DNA synthesis and a few mitotic figures were found; however, these cells readily incorporated radioactive leucine into protein. The free amino acid content of the cyst fluid was low compared to the free amino acids in the aqueous fluid. We concluded that the cyst developed from the anterior surface of the iris and the cells covering it are derived from the nonpigmented neuroepithelium.

## ACKNOWLEDGMENTS

Jerome Sherman and Catherine Dodd, Department of Anatomy, aided in the electron microscopic observation, and Juan Sanchez, Department of Ophthalmology, determined the free amino acid composition of the cyst. We wish to acknowledge their contributions to this study.

# LATE RESULTS OF KERATOPLASTY FOR FUCHS' DYSTROPHY

MAX FINE, M.D., AND CAROLE E. WEST, M.D.
*San Francisco, California*

The success of penetrating keratoplasty in Fuchs' dystrophy is well documented. Clear grafts have been reported in from 70[1] to 85%[2] of cases, with a considerable difference between those with early disease as compared to those with advanced disease (good results expected in 85% of early cases but only 50% of advanced cases).

Most of the patients, however, have been followed for a relatively short period of time. Stocker and Irish,[3] in a recent report, suggest that the long-term fate of these grafts is quite poor. All of the 12 cases they reported became cloudy in one to eight years.

The purpose of this study is to report the long-term follow-up of penetrating keratoplasties for Fuchs' dystrophy and to examine the causes of failure in those grafts which became cloudy.

## MATERIAL

This report reviews a total of 193 penetrating grafts done on 150 patients with Fuchs' dystrophy. All operations were performed by one surgeon (M.F.). Follow-up ranged from six months to 15 years. This study reports all patients in which the diagnosis of Fuchs' dystrophy was made, including cases with preoperative complications, aphakia, regrafts, combined graft-cataract procedures, and all postoperative complications. In cases in which the patient was not available for follow-up observation, information was obtained from the referring ophthalmologist by letter.

From the Department of Ophthalmology, University of California School of Medicine, San Francisco, California. Dr. West was a Heed Fellow in the Department of Ophthalmology and the Francis I. Proctor Foundation for Research in Ophthalmology, University of California School of Medicine. Her present address is: Department of Ophthalmology, University of Florida School of Medicine, Gainesville, Florida.

Reprint requests to Max Fine, M.D., 2233 Post Street, San Francisco, California 94115.

The indication for keratoplasty was the existence of corneal edema in a degree which reduced the visual acuity in the better eye to 20/50 or less. The great majority of cases had a corrected acuity of 20/200 or less. No cases were accepted for keratoplasty with simple endothelial dystrophy without stromal edema.

Preoperatively the patient was placed into one of three prognostic categories: I. mild (area of edema less than 6 mm), II. moderate (area of edema 7-8 mm), and III. severe (cornea completely edematous or in need of reoperation, anterior synechiae, glaucoma, aphakia with complicating factors).

## DONOR MATERIAL

Since specific information on donors has been recorded only for the past four years, this information is not available on all patients. The practice has always been, however, to use cadaver eyes removed up to 10 hours after death and refrigerated at 2-4° C in a moist chamber. Selection has been random for all penetrating keratoplasties, without regard to age of donor. The mean age of donor material used for all types of grafts has been 61 years.[4] Ninety-nine percent of donor corneas were transplanted within 48 hours of death; 51% were transplanted within 24 hours, and 39% between 25 and 36 hours post mortem.

## SURGICAL TECHNIQUE

The technique used is essentially as previously described for phakic[2] and for aphakic patients.[5] Most grafts were 7 or 7.5 mm in diameter, except for a few 8 mm in size.

## RESULTS

The overall incidence of clear grafts in Fuchs' dystrophy is 85% and the incidence of clear grafts eight years or longer after keratoplasty is the same (85%). A clear

* Prognostic classification.

graft was considered to be one in which there was no biomicroscopic evidence of central or peripheral edema and in which the transparency permitted vision of 20/40 or better. A subephithelial haze of varying severity is present in many homografts performed for all types of corneal disease and usually does not reduce the visual acuity appreciably. Such grafts were classified as clear if the visual acuity with correction was 20/40 or better. Corneas associated with cataract, or with ocular abnormalities, were classified as clear if their transparency was compatible with 20/40 vision. Opacities surrounding the suture sites were not considered in the classification. Table 1 details the results by year and according to preoperative prognostic classification. When studied according to prognostic classification, even the least favorable cases have an overall result of 71% clear grafts, with the eight patients followed more than eight years having 75% (six out of eight) clear grafts. The most favorable category, Group I, has 96.7% overall incidence of clear grafts (Table 2).

*Analysis of failed grafts*—There were 29 grafts of the 193 which became cloudy and these are analyzed as to the cause of failure (Table 3). These 29 grafts were performed in 24 eyes of 22 patients. Ten patients had two keratoplasties in one eye, five of which became cloudy and five of which remained clear for a follow-up ranging from six months to eight years. Two of the five in which the second graft failed had a third graft done, and these two have remained clear for one and two years, respectively.

When studied according to prognostic groups, two failures were in Group I (3.3%), nine failures were in Group II (12.5%), and 17 failures were in Group III (27.9%).

*Group I (mild)*—Of the two cloudy grafts in Group I, one had a graft reaction at one month but was regrafted, with the second graft remaining clear for eight years thus far. The other in Group I had a combined graft-lens extraction which was complicated postoperatively by pupillary block and subsequent glaucoma. This graft became cloudy after two years.

TABLE 2

GRAFTS FOLLOWED EIGHT TO 15 YEARS
(20 Cases)

| Outcome | I* | II* | III* | Total |
|---|---|---|---|---|
| Clear | 4 | 7 | 6 | 17 (85%) |
| Cloudy | 0 | 1 | 2 | 3 (15%) |

* Prognostic group

*Group II (moderate)*—Of the cloudy grafts in Group II, two were cloudy from the first postoperative day, which is attributed either to poor donor tissue or technical problems at the time of surgery. One of these two, however, had a combined graft-lens extraction with hemorrhage on the posterior surface of the graft. Two of the nine were clear until they had lens extractions one year and two years, respectively, after the keratoplasty. Both of these cataract extractions were complicated. Three were cloudy after graft reactions, occurring at one month, one year, and six months post-grafting.*

The remaining two patients had a chronic iridocyclitis following surgery with clouding of the graft at six months and three years.

*Group III (severe)*—There were 17 opaque grafts of the total of 61 grafts in Group III (27.9%). Two of this group were clear for two and five years postoperatively at which time they had a lens extraction with clouding of the graft following this procedure. One of these had a second graft which has remained clear one year. Graft reactions leading to clouding of the graft occurred in five patients. One of this group was a re-operation for a previous graft reaction in that eye (one month). The two graft reactions which occurred at nine months were both in the same patient, one in the right eye and one in the left eye. The one occurring at two years was a regraft after a failure due to iritis with anterior synechias. Of the four grafts which were cloudy from the first post-operative day, one was a combined graft-lens extraction in a patient with glaucoma who had had prior glaucoma surgery, one was a regraft of a previous graft reaction, one was a regraft following failure due to trauma of lens extraction, and the fourth was in an aphakic patient. The postoperative course in two patients was complicated by uncontrolled glaucoma; one of these patients was aphakic with preoperative glaucoma and vitreous adhesion. The other was also aphakic with iris adhesions and a dense pupillary membrane. For the remaining five patients, there was insufficient information from the referring physician to explain the failure. It was felt, however, that they should be included in this study.

* The criterion for the diagnosis of an immune homograft recation was the sudden onset of edema in an uncomplicated graft which had been perfectly clear for at least two weeks from the time of operation, accompanied by a mild to moderate iridocyclitis. The diagnosis was not made when the edema was preceded by a severe uveitis, uncontrolled glaucoma or evidence of technical complications.

TABLE 3

CAUSES OF GRAFT FAILURE

| Cause | No. Patients |

| Postoperative glaucoma | 3 |
| Postoperative iridocyclitis | 2 |
| No explanation available | 5 |
| Total | 29 |

* Cloudy first postoperative day.

### CAUSES OF FAILURE

The causes for failure in all groups are summarized in Table 3.

Immune homograft reactions resulting in permanently opaque grafts occurred in nine patients, a 4.6% incidence, as compared to the usually accepted incidence of 8 to 10%. The actual incidence of graft reactions was 12%, but about half of these responded to corticosteroid treatment and remained clear. Routine corticosteroid treatment to prevent immune reactions consisted of the daily instillation of a corticosteroid-antibiotic ointment at the time of surgery and with the daily dressing. If manipulation of the iris was required during the keratoplasty (iridectomy, freeing of adhesions, etc.), a subconjunctival injection of 20 mg of repository methyl-prednisilone was made at the close of the operation. When the eye showed more

than the average postoperative reaction corticosteroid drops were instilled three to six times daily in addition to the ointment. This medication was reduced to a maintenance dose as soon as a response was obtained. Topical corticosteroid drops were continued one to three times daily for three to four months following operation, depending on the degree of irritation.

In a suspected or actual immune reaction, topical corticosteroid drops (1% prednisilone or equivalent) were given every one or two hours and a subconjunctival injection of 20 mg of repository methyl-prednisilone every 10 to 14 days to a maximum of three injections, depending on response.

Systemic corticosteroids were not used since we have not observed any advantage from systemic medication over intensive local medication in controlling the homograft reaction.

Of the four grafts lost following subsequent lens extractions, one cannot guess how long they would have remained clear. This must still be regarded as an exogenous factor in graft survival. Grafts which are opaque from the first postoperative day, as mentioned previously, are felt to be due either to poor donor material or unsuspected surgical trauma to the endothelium. Gross technical problems should be obvious to the surgeon at the time of surgery.

The emphasis again is made that the majority of failures was in patients in the poorest prognostic category, and here there was still an incidence of 71% clear grafts. For those grafts followed eight years or longer there is an overall prognosis of 85% success with a low of 75% success in those of the poorest prognostic classification.

Regrafts in cases of Fuchs' dystrophy appear to have about the same prognosis as regrafts in other categories of corneal opacities of similar severity. The important factors determining the result of the second graft are the presence or absence of complications such as adherent iris, glaucoma, and severe edema with vascularization. Table 4 summarizes the information on the 29 cloudy grafts in which 14 regrafts were performed. Nine of the regrafts were clear during the period of follow-up of one to eight years. It is of interest that of the 14 regrafts, 10 were performed within one year of the previously failed keratoplasty. This suggests that time alone is not a principal cause of graft failure in Fuchs' dystrophy.

## Discussion

No conclusive evidence has been presented to demonstrate whether corneal grafts for Fuchs' dystrophy remain clear because of persistence of the donor epithelium or because of repopulation of the graft with endothelium from the recipient. Polack's[6] studies showing persistence of isotopically labeled endothelial cells in rabbit corneal grafts for four years probably indicated that a combination of the two mechanisms is in operation. Our experience with keratoconus patients is similar to that of others, namely, that these grafts seem to have an unlimited lifetime. If one assumes persistence of donor epithelium to be the main factor, one could conclude that grafts in keratoconus should have the same prognosis as in Fuchs' dystrophy (or any other condition) when similar material is selected. In fact, one would be more careful in selecting young, healthy donors for keratoconus than for Fuchs' dystrophy, since the former group of patients has a much longer life expectancy.

To date there has been no direct evidence that donor endothelial cells in human homotransplantation survive in toto and indefinitely. Such evidence in the form of clear grafts from the opposite sex coming to histologic examination or karyographic study is very difficult to obtain but will ultimately be available. Indirect evidence such as the occasional occurrence of very late immune reactions is open to much criticism.

If the primary factor in graft survival were replacement by endothelium from the

* IR = immune graft reaction

† Operative failure = severe edema of graft on first postoperative day.

host, then one might expect a very restricted lifetime of grafts for Fuchs' dystrophy, since the endothelium is usually severely affected by the time a graft is performed. Our data do not seem to support this, since most graft failures were associated with other definite and recognizable causes. If there is a restricted lifetime of these grafts, the follow-up still has not been long enough to detect it.

The idea that there is no possibility of regeneration of endothelial cells from the recipient with Fuchs' dystrophy is open to question. In early cases, some competent cells are still present from which regeneration might conceivably occur, although ultimately these two might become dystrophic. The clinical observation that the results of penetrating keratoplasty in early cases with only central edema are much better than those in which the entire cornea is edematous tends to support this possibility.

On the basis of this material it is concluded that the prognosis of penetrating keratoplasty in Fuchs' dystrophy should be considered good.

## Summary

In 193 penetrating keratoplasties for Fuchs' dystrophy followed six months to 15 years, the incidence of clear grafts was 85%. In 20 grafts observed from eight to 15 years, the incidence of clear grafts was also 85%. A progressive failure rate with time was not present. Various postoperative complications (immune reactions, iridocyclitis, glaucoma, complicated lens extraction, etc.) were associated with the failure of 25 of the 29 cloudy grafts.

# VALIDITY OF MacKAY-MARG APPLANATION TONOMETRY FOLLOWING PENETRATING KERATOPLASTY IN MAN

CHIEL A. WIND, M.D., AND HERBERT E. KAUFMAN, M.D.
*Gainesville, Florida*

Using the Goldmann tonometer, scarred, edematous and irregular corneas produce irregular circles making measurement of intraocular pressure impossible. Similarly, the Schiøtz tonometer was designed for use on corneas of a standard curvature and when used on diseased corneas produces misleading readings.[1] Recent studies[2,3] have indicated that MacKay-Marg electronic applanation tonometer readings of diseased and post surgery corneas are accurate. However, the alarmingly high pressures found in a large proportion of aphakic penetrating keratoplasty patients[3] has caused several experienced clinicians to question the validity of MacKay-Marg readings.

This study assesses the accuracy of the MacKay-Marg electronic applanation tonometer in penetrating keratoplasty patients by comparing its readings with simultaneous measurements made by cannulation of the anterior chamber.

## MATERIALS AND METHODS

Two patients scheduled for penetrating keratoplasty were chosen for this study.

The first, a 67-year-old white man with Fuch's dystrophy, underwent an intracapsular cryosurgical cataract extraction (without chymotrypsin) and an 8 mm penetrating keratoplasty. The corneal graft was sutured with 10-0 nylon running suture. Immediately after securing the transplant to the host (patient was still draped and the operating microscope in place), a 23-gauge needle connected by sterile vinyl tubing to a Sanborn transducer, was inserted into the anterior chamber. The intraocular pressure was varied by injecting a balanced salt solution through the graft wound. Continuous readings were recorded with the Sanborn transducer, and while the cannula remained in the anterior chamber, simultaneous measurement were taken with the MacKay-Marg tonometer. Tonometer readings were interpreted before the manometer readings were known, and then compared with the continuous pressure tracing.

The second patient, a 65-year-old white woman with aphakic bullous keratopathy, underwent an 8 mm penetrating keratoplasty. Using the same method as in the first patient, the intraocular pressure was measured immediately after securing the corneal graft to the host.

These patients had no complications from this procedure and their keratoplasties remained thin and clear.

## RESULTS

Since the keratoplasty wounds were tight and there was no leakage around the cannula, the manometer pressures tended to remain stable at each level between MacKay-Marg measurements.

There was an excellent correlation between the direct intraocular pressure measurements (manometer) and those taken by the MacKay-Marg applanation tonometer (Fig. 1). The 15 measurements covered a pressure range from 5 to 82 mm Hg and gave a slope of 0.956.

## DISCUSSION

Previous clinical studies have shown that while MacKay-Marg readings are accurate in diseased or scarred human corneas and in distorted animal corneas, both Schiøtz and Goldmann readings are inaccurate and mis-

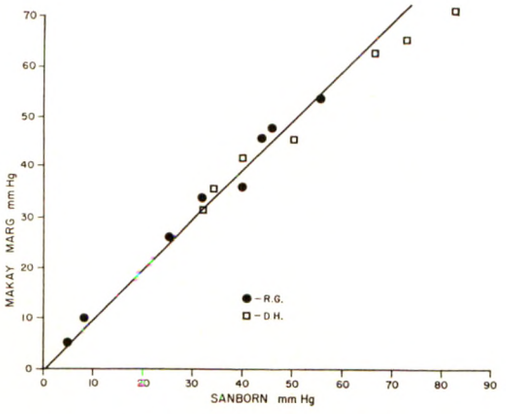

Fig. 1 (Wind and Kaufman). Comparison of intraocular pressure measurements obtained by direct cannulation of the anterior chamber to simultaneous measurements obtained with the MacKay-Marg tonometer.

leading.[1-3] The MacKay-Marg has proven accurate in measuring intraocular pressure in animals following penetrating keratoplasty,[2] and this study verifies that MacKay-Marg tonometry is accurate in patients following penetrating keratoplasty.

Although only two patients were studied, the number of measurements is significant and covers the range encountered clinically. In pressures elevated over 70 mm Hg, a greater discrepancy was noted than at lower pressures. However, even in those high ranges, the pressures correlated well. This study has verified that intraocular pressure measurements in human eyes after keratoplasty are possible, and can be accurate and reproducible. Theoretically, the electronic applanation tonometer readings are not affected by changes in corneal elasticity, since at the point of tracings (where the reading is taken) the corneal bending force is displaced from the plunger onto the probe shoulder.[4]

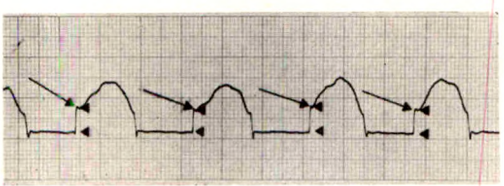

Fig. 2 (Wind and Kaufman). An appropriate reading curve exhibits an initial crest, a central maximum, and a final crest. The small arrows indicate pressure measure points. Note that good readings are serially repetitious and identical in pattern and size.

MacKay-Marg readings are reliable only for good tracings and are interpretable only if repeatable tracings with the proper configuration are obtained (Fig. 2). For example, to obtain accurate readings in eyes with a relatively flat cornea after surgery, great care must be taken to have the probe exactly perpendicular to the globe. If good reproducible readings cannot be obtained, the results cannot be interpreted. Occasionally, especially in early postoperative patients, (usually the first day after surgery), adequate readings cannot be obtained. In general, on diseased and recent postoperative eyes, a certain facility with the MacKay-Marg applanation tonometer is required to obtain interpretable pressure readings.

## Summary

Following penetrating keratoplasty in two patients, intraocular pressure readings with the MacKay-Marg applanation tonometer were compared with simultaneous readings taken by direct cannulation of the anterior chamber (Sanborn transducer manometer).

The readings correlated extremely well and verified the validity and importance of MacKay-Marg measurements in these and other cases where accurate Schiøtz or Goldmann readings are impossible.

# ULTRAMICROSCOPIC ALTERATIONS IN CORNEAL EPITHELIUM IN CORNEAL GRAFTS

ATSUSHI KANAI, M.D., AND FRANK M. POLACK, M.D.
*Gainesville, Florida*

Previous studies[1-3] have described the histologic alterations of the experimental corneal graft reaction as seen with the light microscope. It has been established that rejection of donor tissue starts after a sensitization period of about two weeks.[2] Also, the cellular elements participating in the rejection phenomena are predominantly, if not exclusively, lymphocytes and plasma cells.[2-6] Rejection of experimental penetrating (full thickness) corneal grafts may become evident first in the endothelial layer, in the epithelium, or in the whole graft at once.

The purpose of this paper is to report ultramicroscopic epithelial changes of corneal grafts during the rejection phenomena. Light microscopic alterations of the isolated epithelial layer have been previously described by others.[5]

From the Department of Ophthalmology, College of Medicine, University of Florida, Gainesville, Florida. This study was supported in part by Grants EY-00446, EY-00415, and EY-00033 from the National Eye Foundation.

Reprint requests to Frank M. Polack, M.D., Department of Ophthalmology, College of Medicine, University of Florida, Gainesville, Florida 32601.

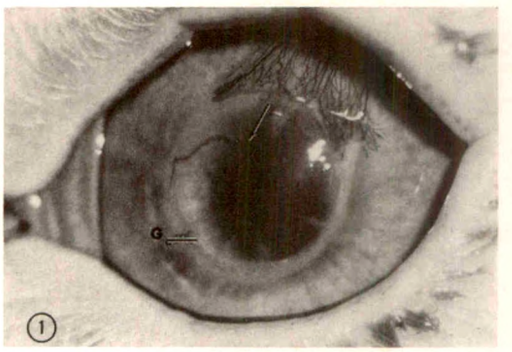

Fig. 1 (Kanai and Polack). Photograph of grafted eye showing rejection of graft epithelium. The methylene blue stained area (arrow) separated the host epithelium from the rejecting graft epithelium. Rejection moved in the direction indicated by the arrow. Beginning or endothelial-stromal rejection is present near the scar.

## MATERIALS AND METHODS

Adult albino rabbits (4 kg) were used throughout this experiment. Penetrating keratoplasties (5 mm) were performed between pairs of rabbits and, one week later, subcutaneous skin grafts (3 × 3 cm) were exchanged between the same pairs which exhibited clear corneal transplants.

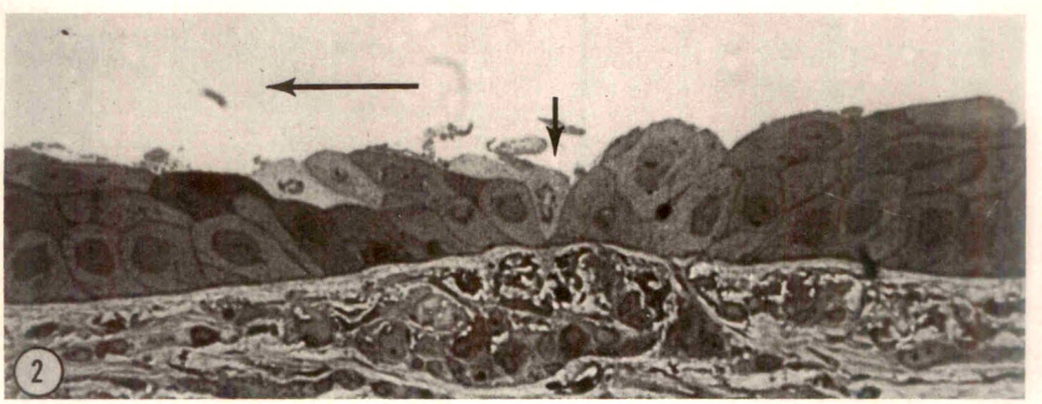

Fig. 2 (Kanai and Polack). Cross-section of epithelium in area of active rejection. Rejection line is indicated by the vertical arrow. Horizontal arrow shows direction of rejection. Note altered cell morphology, cell residues in superficial layers and leukocytes with epithelium. Some leukocytes and fibroblasts are present in subepithelial layer (toluidine blue, ×400).

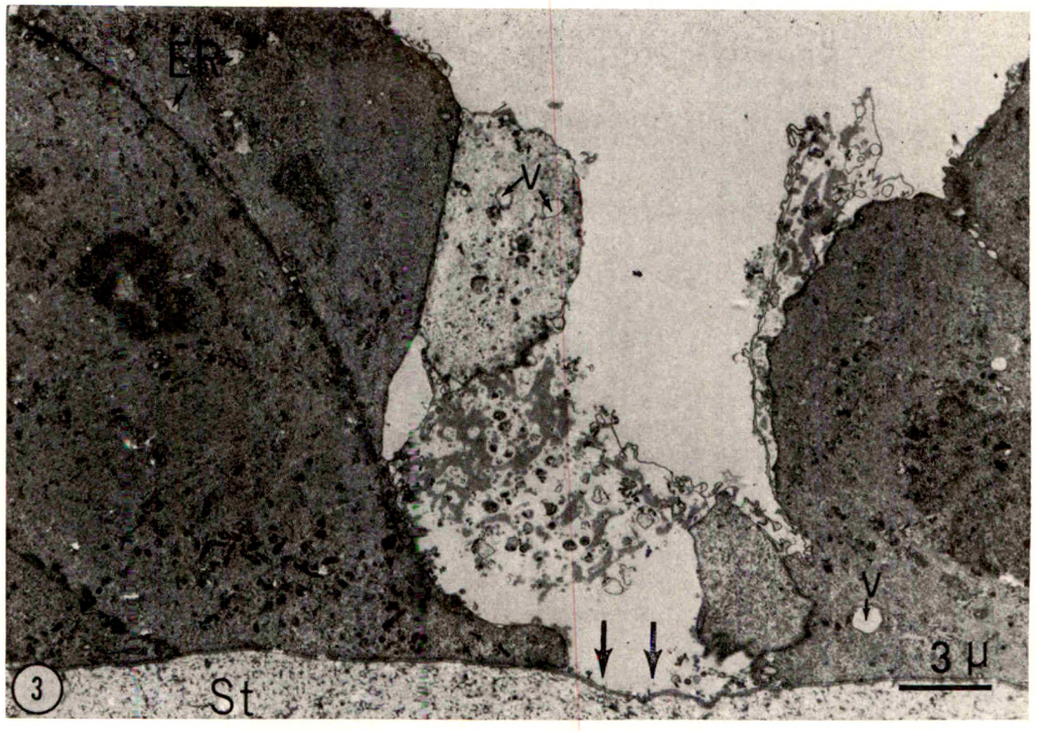

Fig. 3 (Kanai and Polack). Electron micrograph showing destroyed epithelial cells in area of rejection line. Cell residues and cell membranes remain (arrows). Remaining cells show dilated endoplasmic reticulum (ER) and vacuoles (V). Stroma (ST) (×4200).

Grafted eyes were frequently examined for evidence of epithelial rejection which, when present, appeared as a faint, hazy line that stained with topical methylene blue (1%). The stained line, or rejection line, always started at the edge of the graft and, in four to seven days, migrated across the transplant (Fig. 1). This defect was the only visible area of graft alteration in six eyes studied; two other rabbits also showed evidence of endothelial and stromal rejection at the time of enucleation.

Specimens for electron microscopy were obtained at the stage shown in Figure 1. The tissue was properly marked to identify host and donor epithelium on either side of the rejection line. With the animal under pentobarbital anesthesia, 1% osmium tetroxide was dropped onto the corneal epithelium and the eye was promptly enucleated. The cornea was excised and immersed in the osmium fixative for one hour. Subsequently, it was cut in smaller pieces under the dissecting microscope, care being taken not to damage the epithelium, and then again fixed for one hour.

Fixed corneas were dehydrated in alcohols of increasing concentrations and embedded in Epon. These sections were studied with a Hitachi-11 electron microscope. Thick sec-

tions were stained with toluidine blue for light microscopy.

## Results

Light microscopic examination of thick (1 μ) sections showed epithelial cells on either side of the rejection line angled away from it (Fig. 2). Basal cells around the rejection line were flattened, rectangular, or triangular in shape. The rejecting cells stained weakly with toluidine blue, whereas the host cells or nonrejecting epithelial cells stained more intensely. In the center portion of the rejection line, epithelial cells demonstrated rupture of their plasma membranes and disorganization of their cytoplasmic structure. In some sections, only the remaining plasma membrane attached to the basement membrane could be observed (Fig. 3), while in others showing simultaneous stromal rejection, the epithelial basement membrane was fragmented and invaded by macrophages (Fig. 4).

Moderate distention of intercellular spaces were seen at all levels of the epithelium. The cytoplasmic (cellular) interdigitations were altered at the site of contact with lympho-

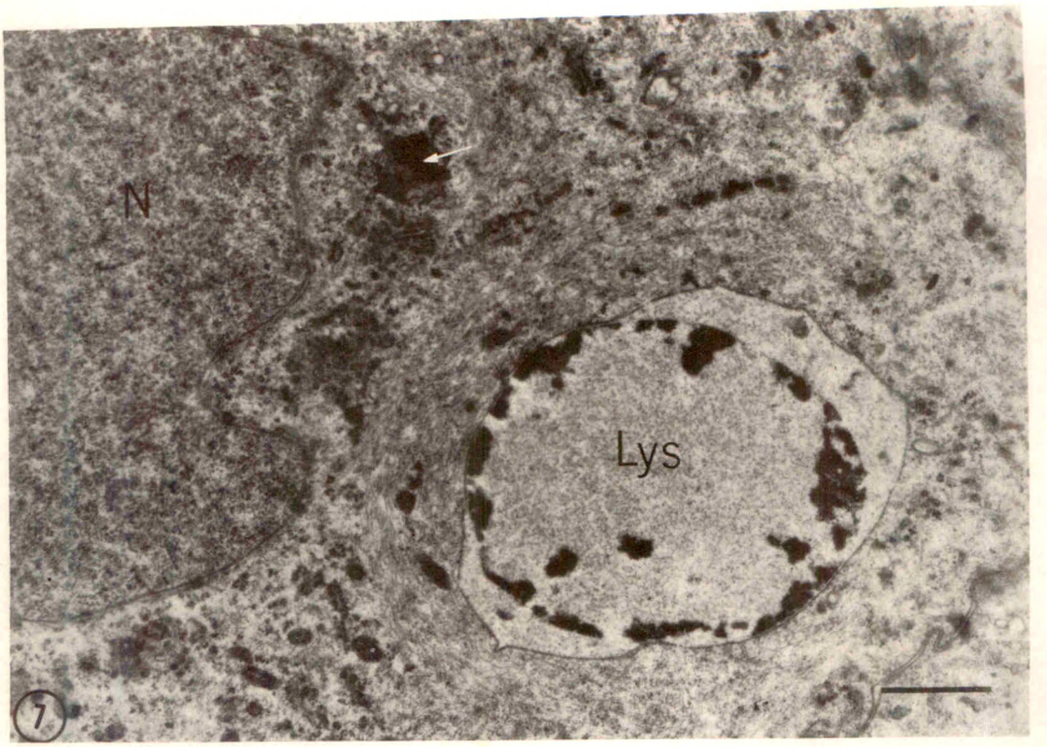

Fig. 7 (Kanai and Polack). Rejecting epithelial cell contains lysosomes (Lys) and a high density crystalline material (arrow). Nucleus (N) (×14700).

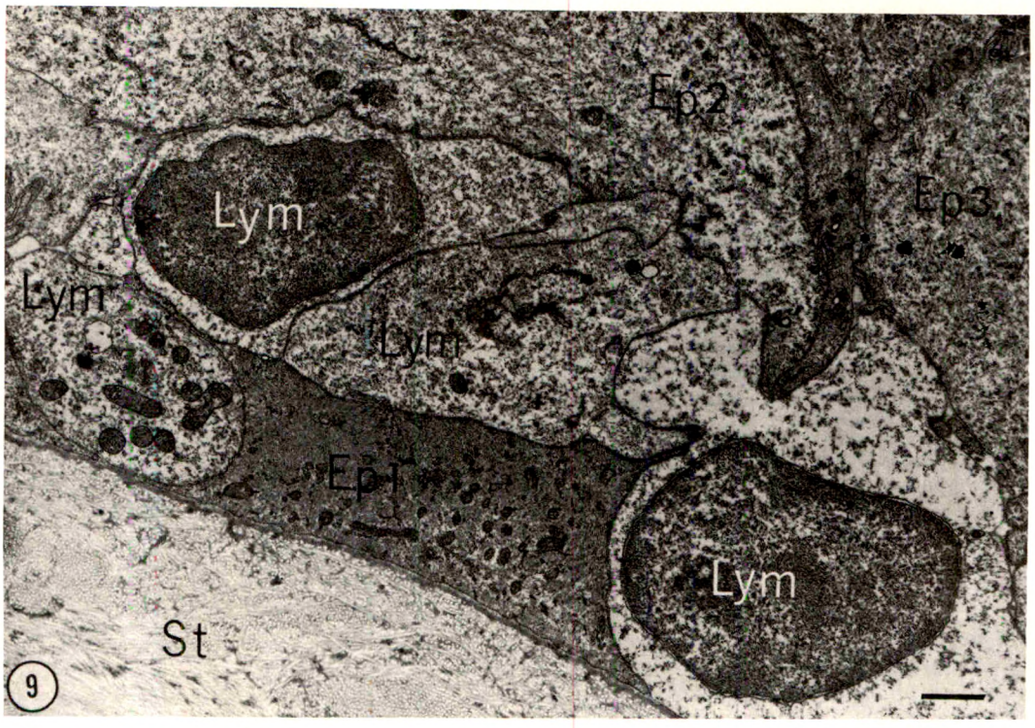

Fig. 9 (Kanai and Polack). Electron micrograph showing lymphocytes (Lym) and epithelial cells (Ep) of various densities. Lymphocyte on the right shows scanty RNP particles without other organelles. The cytoplasm of epithelial cell (Ep 1) is denser than that of other epithelial cells (Ep 2 and 3). Stroma (ST) (×8000).

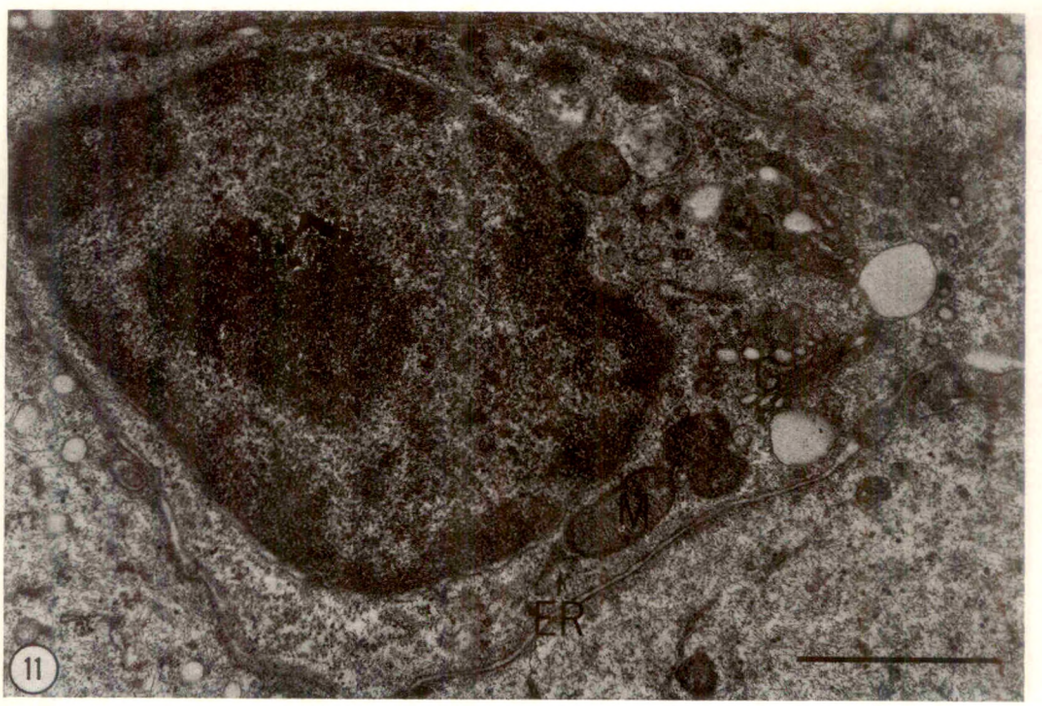
cytes, resulting in a smooth cell boundary without desmosomes (Fig. 5).

Mitochondria were round or oval and evenly distributed throughout the cytoplasm. The endoplasmic reticulum was scanty, usually located around the nucleus, and occasionally showed moderate dilation. RNP particles (ribosomes) were observed around the nucleus or near the cell membrane; the Golgi complex located near the nucleus showed vesicles.

Several epithelial cells in contact with lymphocytes showed cytoplasmic vacuoles and lysosomes (Figs. 6 and 7). High-density crystalline substances without a limiting membrane were also seen in the cytoplasm and were located within the Golgi complex area (Figs. 7 and 8).



Lymphocytes were observed within the rejected epithelial cell layer (Fig. 9) or, at times, on the basement membrane; they were smaller than epithelial cells, round, oval, or pear-shaped, with round or oval nuclei and condensed chromatin (Figs. 5 and 10). Typical, small or middle-sized lymphocytes contained large mitochondria, sparse endoplasmic reticulum, a Golgi complex, and free RNP particles (Fig. 10). Others had few mitochondria, distended endoplasmic reticulum, vesicles or vacuoles in the area of the Golgi complex, and scanty scattered RNP particles (Figs. 9 and 11). No plasma cells

were found in the area of rejecting epithelium.

## Comment

Our studies demonstrate epithelial cells of penetrating homografts undergoing rejection. Cell damage occurred in areas invaded by lymphocytes and was characterized by disorganization of their cytoplasm, changes in density, vacuolation, disappearance of organelles, and rupture and detachment of basal epithelial cells from the basement membrane. These alterations are similar to those described in electron microscopic studies of rejected endothelial cells of experimental homografts.[6] Morphologic changes in lymphocytes were also present, but these could not be related to the various stages of epithelial cell rejection with which they were associated.

The area of active rejection was confined to a band 80 to 100μ wide, seen as a line of haziness in the epithelium or staining with methylene blue. This line of rejecting cells was typified by its migratory character across the graft[5] in a similar fashion as endothelial-cell rejection advanced in rejecting homografts.[3]

Rejection of epithelium from a corneal graft may seem an unlikely phenomenon several weeks after transplantation, if one accepts the fact that corneal epithelial cells have a high turnover rate.[7] However, persistence of grafted epithelial cells for over two weeks was demonstrated by Khodadoust and Silverstein[5] in tritium-labeled donor corneas, and possibly for months by the method of rejection of lamellar grafts they described. The demonstration of a rejection phenomena with its characteristic clinical and histologic picture is good evidence that the cellular changes present are caused by an immunologic phenomena.

## Summary

Penetrating corneal allografts were performed in albino rabbits, and rejection was induced by a skin graft from the same donor; 12 to 14 days later, rejection of corneal graft epithelium developed. Electron microscopic studies showed epithelial cells with cytoplasmic changes, loss of organelles, vacuolation, and rupture of cell membrane. Lymphocytes of varied morphology were present in the area of cell rejection.

# NEW PACHYMETER TO MEASURE CORNEAL THICKNESS

HERNANDO CARDONA, M.D., AND A. GERARD DEVOE, M.D.
*New York, New York*

Measurement of the corneal thickness is of clinical importance in several conditions, including keratoconus when periodic determinations of the apical thickness is a practical method of establishing the degree of thinning of the corneal tissues. In cases of corneal edema it serves to correlate the loss of vision and the edematous condition of the cornea. The thickness of the cornea should also be established in eyes affected with bullous keratopathy to determine if it exceeds 1.2 mm, in which case the prognosis is favorable for either a keratoplasty or a prosthokeratoplasty.

To this end, we have developed a new pachymeter* which makes possible the determination of the thickness of a clear cornea with an accuracy of within .02 mm. A totally opaque cornea cannot be measured.

The calibration of this new pachymeter is based on a refraction index of 1.376, the same as that of the normal cornea. This represents an entirely new approach. A search of the literature has revealed no other model of pachymeter calibrated on the normal corneal refraction index of 1.376.

Gunnar von Bahr,[1] basing his pachymeter on principles similar to those used by Blix to construct his ophthalmometer, mounted two planes of plate glass, one in front of the condensing lens and the other in front of the microscope of the slit lamp. When these plates were rotated, the reflection of the ray on the endothelium could be displaced and made to coincide with the reflection of the ray on the epithelium. The thickness of the cornea was calculated from the angle of revolution, the thickness and index of refraction of the glass plate and the corneal radius.

Maurice and Giardini[2] modified this method. They used a single one-fourth inch thick persplex plate in the illuminating beam from the slit lamp traversed by a horizontal cut covered by a thin strip of colored celluloid. Their apparatus can be adjusted so a white reflection from the posterior surface and a colored reflection from the anterior surface of the cornea are seen in the microscope at the same time. These reflections are aligned by rotating the persplex plate and the angle of rotation gives the corneal thickness.

In 1932, Goldman[3] described a new ocular to measure the transparent media of the anterior pole of the globe. It is mounted inside the right tube of the microscope of the old Haag-Streit slit lamp. The angle is formed by the beam of light set at 60° from the microscope and a system of gears is adapted to provide the reading.

## DESCRIPTION OF NEW PACHYMETER

Basically, the instrument consists of a double mirror (Fig. 1, see A and B). One mirror is movable, replacing the usual mirror in the Haag-Streit 900 slit lamp. Thus, separate images are obtained from the epithelial and endothelial surfaces. These surfaces can be measured separately by means of a calibrated gearing system.

The beam emitted by the slit lamp strikes the cornea surface (Fig. 2) at B and reaches C (the endothelial surface), which is viewed with the microscope through point A. The corneal thickness is determined when the beam from the upper slit lamp mirror strikes the corneal surface at point A (Fig. 2).

* This instrument is manufactured by H & I Instrumentation, 293 Carlton Terrace, Teaneck, New Jersey 07666.

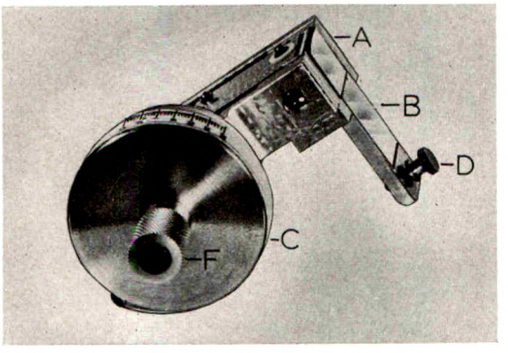

Fig 1 (Cardona and DeVoe). The instrument consists of two arms united at an angle of 90°. One side is the slide rest, which fits into the mirror housing of the lamp. This arm has two front surface mirrors, one fixed superiorly (A) and mounted on two crossed axes, and the other fixed inferiorly (B). The other arm is a 50 mm lever which multiplies the reading ×40. The calibrated dial (C) which synchronizes the two corneal images at "0" position adjustment is at one end. The fixation screw (D) fastens the pachymeter rigidly to the slit lamp.

A special method was used to calibrate this instrument. It eliminates the logarithmic error in calibration obtained with a plastic lens (1.495). The figure obtained with this calibration method very closely approximates the thickness of the human cornea.

When the corneal refraction index surpasses 1.376, a new calibration can easily be performed for research purposes by adjusting the refraction index of the variable thickness chamber to the value desired.

This calibration was chosen for practical purposes. A base curvature of 7.75 and a refraction index of 1.376 were selected as average values for the present calibration. The instrument was checked and the equivalent values are shown in Table 1.

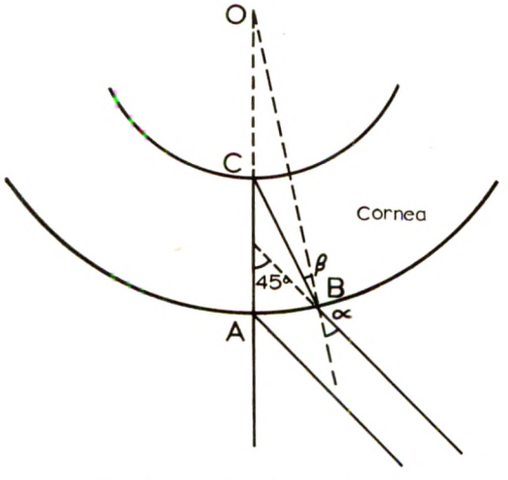

Fig. 2 (Cardona and DeVoe). Diagram showing the pattern of the beam and the physical bases used in corneal thickness determination. The formula is: A + (Cos − Sine) $n^2$ − $sine^2$ + (Cos + Sine) Sine.

### Measurement of corneal thickness

A total of 204 healthy corneas from 102 patients of different races, age, and sex were measured. Two zones were selected, the central and peripheral, because they afforded great precision. No appreciable changes were noted with varying refractive errors except two eyes with high myopia (−9.50 to 16.00). In these cases the central corneal thickness was 0.535 mm, or approximately .024 mm below our average finding of 0.651 mm. The average corneal thickness at the periphery was 0.745+ mm.

## Summary

A new simple instrument to measure the thickness of the cornea is designed for use with the Haag-Streit 900 slit lamp. Its calibration is entirely based on a chamber filled with a solution which has 1.376 index of refraction similar to the human cornea.

TABLE 1

EQUIVALENT VALUES (IN MM)

| Plexiglass Thickness in mm (N-1.49) | Human Cornea (N-1.375) | | Equivalent Thickness of Human Cornea |
|---|---|---|---|
| | Inside Radius | Outside Radius | |
| 0.25 | 8.00 | 8.25 | 0.22 |
| 0.50 | 7.75 | 8.25 | 0.45 |
| 0.75 | 7.50 | 8.25 | 0.68 |
| 1.00 | 7.25 | 8.25 | 0.90 |
| 1.25 | 7.00 | 8.25 | 1.13 |
| 1.50 | 6.75 | 8.25 | 1.35 |
| 1.75 | 6.50 | 8.25 | 1.58 |
| 2.00 | 6.25 | 8.25 | 1.80 |
| 2.25 | 6.00 | 8.25 | 2.03 |
| 2.50 | 5.75 | 8.25 | 2.25 |
| 2.75 | 5.50 | 8.25 | 2.48 |
| 3.00 | 5.25 | 8.25 | 2.70 |

This instrument is primarily used to study the thickness of the corneal before insertion of a keratoprosthesis. The corneas must measure at least 1 mm in thickness. If the cornea is thin, a graft is advisable in order to increase the amount of collagen support as a safety measure.

ACKNOWLEDGMENT

We thank Dr. S. Mishima who kindly reviewed the mathematical portions of this manuscript.

# CONJUNCTIVAL AND CORNEAL CALCIFIC DEPOSITS IN UREMIC PATIENTS

LAURENCE S. HARRIS, M.D., KENNETH COHN, M.D., HIDENAO TOYOFUKU, M.D., EDMUND LONERGAN, M.D., AND MILES A. GALIN, M.D.

*New York, New York*

Deposition of calcium crystals in the limbus and conjunctiva of patients with otherwise normal eyes has long been recognized to occur with hypercalcemia.[1-3] Recently, however, conjunctival metastatic calcification has been reported in uremic patients with low or normal serum calcium.[4,5] It has been felt that the sine qua non for this phenomenon is an elevated serum calcium and phosphorus product, usually in the neighborhood of 70 mg%.[4,5]

The present study was undertaken to analyze further the calcium and phosphorus concentrations necessary to induce limbal and conjunctival calcification and to determine the effect of chronic hemodialysis on these deposits.

## MATERIALS AND METHODS

A total of 18 consecutive patients between the ages of 21 and 65 years, who were undergoing hemodialysis for periods of from two to 33 months, were studied. All had previously undergone extensive medical evaluation and laboratory testing in the Renal Service of the New York Medical College. Each patient was given a complete ocular examination, including visual acuity, refraction, biomicroscopy, applanation tonometry, and ophthalmoscopy. In addition, slit lamp photography of the conjunctiva and cornea was performed and repeated at periodic intervals.

## RESULTS

The age and sex distributions of the 18 patients included in this study are found in Table 1, which also includes their diagnoses and known duration of disease.

Biomicroscopy was essential for the detection of the conjunctival microcrystals in all cases examined, but certain limbal deposits were grossly visible. All deposits were invariably located in the palpebral fissure. Conjunctival deposits were found immediately beneath the conjunctival epithelium, which was elevated over these areas. Small crystals tended to be white in color, but

* AGN = acute glomerulonephritis, CGN = chronic glomerulonephritis.

larger depositions were flat and colorless. The deposits were superficial to the episcleral vessels and did not move with blinking.

Most commonly, limbal calcification formed a half-moon-like arc concentric with the limbus. In all instances, these deposits extended from sclera onto cornea without an intervening area of clear cornea. Of the 18 patients studied, calcium crystals were present bilaterally at the corneoscleral limbus in nine patients and unilaterally in three. Conjunctival crystals were noted bilaterally in seven patients and unilaterally in three (Table 2). Four patients had solely conjunctival, and three solely limbal, calcification. In only two cases of this series were the "red eyes of renal failure" seen. In both of these patients, bacteriologic cultures were negative. Clinically, these patients manifested only conjunctival vascular congestion with mild chemosis. Follicles were not present, nor was there a significant degree of follicular hypertrophy of the tarsal conjunctiva.

The results of laboratory evaluations are listed in Table 3. From this data, it is apparent that serum calcium levels were low or normal in all patients having calcific deposits, whereas the phosphorus level was somewhat elevated to yield mean abnormal calcium-phosphorus products. However, no strict correlations were noted between calcium, phosphorus, or calcium-phosphorus products and the presence of calcific deposits in either the limbus or conjunctiva (Table 3). Furthermore, despite the fact that the calcium-phosphorus product was often reduced and held within normal range by

chronic hemodialysis, no change in the limbal or conjunctival calcification resulted during the one-year period of this study.

In both patients with "red eyes," rather heavy deposits were noted in both limbal and conjunctival locii (Table 3).

## Discussion

Limbal and conjunctival deposition of calcium salts is a frequent occurrence in advanced, acute and chronic renal failure.[1-5] Although there are exceptions, as shown in this study, the calcium-phosphorus product is usually in the neighborhood of 70 mg% in such patients. These findings are not usually noted with frequency in normal subjects or those in whom renal disease is less severe.[4,5]

Histologically, the site of this calcium deposition has been shown to be subepithelial and epithelial.[5] It is felt that these crystals consist of a calcium-phosphate salt, probably hydroxyapatite, as in crystals found in metastatic calcification in other locii.[5]

Limbal calcific deposits in these patients occasionally resembled Vogt's white limbus girdle (Fig. 1), but the limbus girdle is rarely seen in young patients and the deposits are usually not quite this large and coarse. The limbus girdle is most often yellowish-white, whereas the lesions described in the current study are chalk-white in appearance.[6]

Initially, Berlyne and Shaw[4,5] postulated that the "red eyes of renal failure" occurred in those patients with deposits consisting of small crystals. It was felt that in those patients who had a shorter duration of renal failure the crystal size was an important factor in determining the presence or absence of ocular irritation. In our study, however, "red eyes" were noted in two patients with rather dense, conjunctival and corneal deposits involving large crystals (Fig. 2).

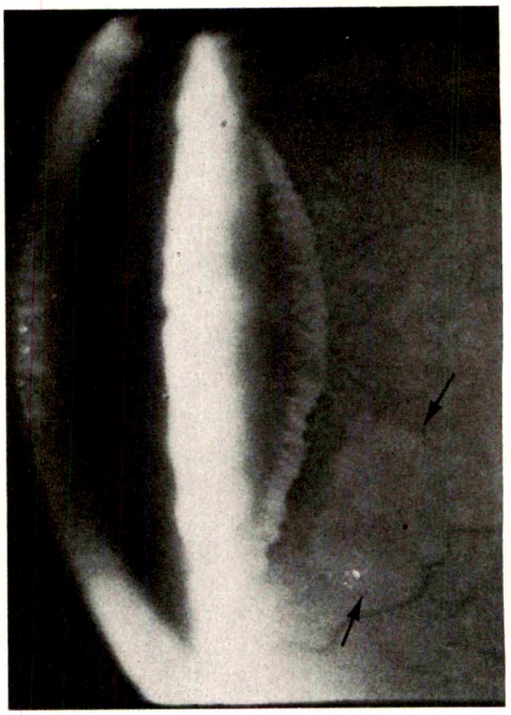

Fig. 2 (Harris and associates). A large, conjunctival, calcific deposit in a 50-year-old man (Patient 6). Extensive limbal crystalline material is also evident.

Moreover, the duration of disease in both of these patients was more than two years. These findings would tend to argue against crystal size as being an important determinant factor in the "red eye" syndrome.

Disappearance of ocular calcific deposits has recently been described to have occurred within several days of renal transplantation, despite persistence of elevated calcium-phosphorus products in some patients.[7] In the current study, calcific deposits were noted in patients undergoing routine, chronic hemodialysis for periods in excess of one year. No change could be detected resulting from or attributable to hemodialysis during this period.

The mechanism of deposition of calcium crystals remains unknown. It has been suggested in the past that the interpalpebral region is a site of crystal deposition in the presence of elevated calcium because of loss of carbon dioxide from the exposed conjunctiva. The decreased P $CO_2$ would be associated with a rise in pH, so that in the presence of an elevated calcium-phosphorus product, calcium-phosphate salts might precipitate.[1]

Fifteen of the 18 consecutive severely uremic patients in this series had biomicroscopically definable crystals. However, the three patients without calcific deposits had distinctly abnormal calcium-phosphorus products and were chemically as uremic as the remainder of the patients in this series who did have calcific deposits. Conversely, three patients with normal calcium-phosphorus products had minimal calcific deposits. It would appear that the ophthalmologist can use this observation to make the diagnosis of advanced renal failure in the overwhelming majority of cases.

## Summary

Examination of a consecutive group of 18 severely uremic patients disclosed an incidence of over 80% corneal or conjunctival calcific deposits, or both, in the presence of low or normal serum calcium levels. Serum phosphorus was elevated in all patients. The prerequisite for this phenomenon would appear to be an elevated serum calcium-phosphorus product in the neighborhood of 70. However, the three patients in this study who had no deposits were in no way distinguishable from other patients in this series with calcific findings on the basis of blood chemistry values or duration of disease.

The vast majority of these patients were asymptomatic and unaware of the calcific deposits. Limbal calcifications in uremic patients are distinguishable from Vogt's white limbus girdle by their presence in young patients and by the considerably larger and coarser crystal size, as well as the absence of a clear area of cornea at the limbus. Chronic hemodialysis appeared to have no influence on the distribution, size, or appearance of these crystals.

# CRYOTHERAPY OF STROMAL HERPES SIMPLEX KERATITIS IN RABBITS

PETER D'ALENA, M.D., MASAO OKUMOTO, M.A. AND BROOKS CRAWFORD, M.D.
*San Francisco, California*

In 1965, Krwawicz[1] found cryotherapy to be of benefit in the treatment of epithelial and stromal herpes simplex keratitis in humans. Corwin and associates[2] found cryotherapy of superficial herpes simplex keratitis in rabbits to be of little value. It is well known that virologists have used freezing as a means of preserving viruses.[3] However, there are conditions under which the herpes virus is adversely affected by freezing.[4]

Since application of cold to the cornea produced little or no damage to that structure, it was felt that experimental studies of cryotherapy on stromal herpes might be of interest.

## METHOD

Both eyes of adult New Zealand White rabbits were given 5 mg of prednisone subconjunctivally one day prior to virus inoculation. On the day of inoculation, after topical anesthesia (proparacaine HCl), the center of each cornea received 10 horizontal and 10 vertical scratches with an edge of a Lindner spatula. An attempt was made to make the scratches only through the epithelium. Three drops of PH strain of herpes simplex virus passed in mouse brain with an $LD_{50}$ of $10^{-5}/0.03$ ml were placed onto each cornea. Every rabbit eye thus treated showed a keratitis the next day.

Fourteen days following virus inoculation, all eyes showed a disciform keratitis. Though not all rabbits showed exactly similar lesions, there was a remarkable similarity

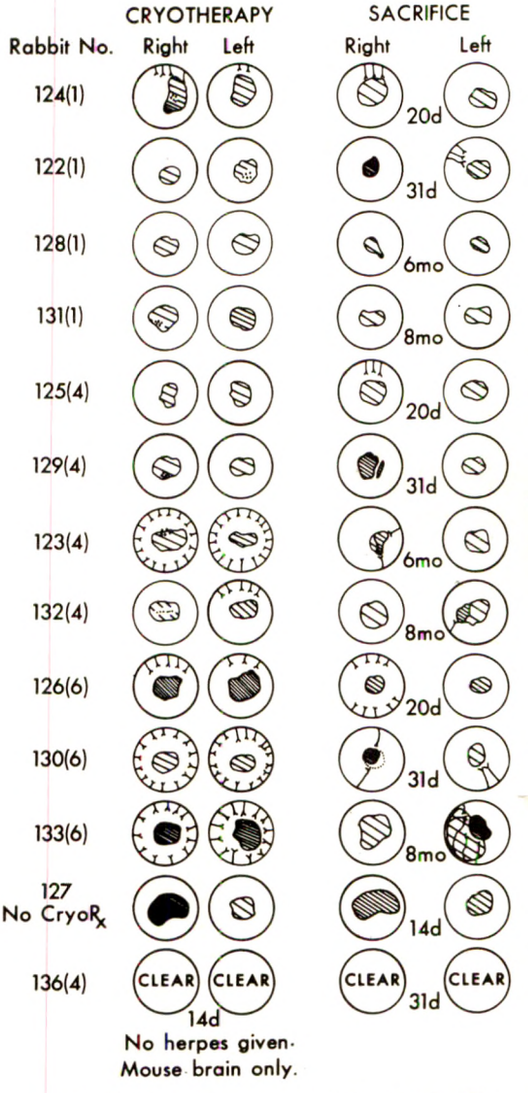

Fig. 1 (D'Alena, Okumoto, and Crawford). Clinical appearance of eyes in rabbits. Days (d) indicated are those after herpes inoculation. Numbers in parenthesis show the number of times the cryoprobe was applied to the right eye. The density of the crosshatching indicates the density of the cornea lesion. Stippling indicates fluorescein staining of the cornea. The Y-shaped areas show the extent of the corneal vascularization.

in the extent of the keratitis in each eye of the same rabbit. At that time, the right eye of each rabbit was arbitrarily selected for cryotherapy, the left eye serving as control. Four identical cryoapplicators were made from a solid copper bar, tapered to a cone with a 3 mm ball on its tip. A tapered handle was made of polyethylene. A test tube containing the probe was placed in a small thermos of liquid nitrogen for at least five minutes. This allowed the temperature of the probes to be about −80°C. Each of the four probes was similarly treated and used in rotation, so that each probe attained about the

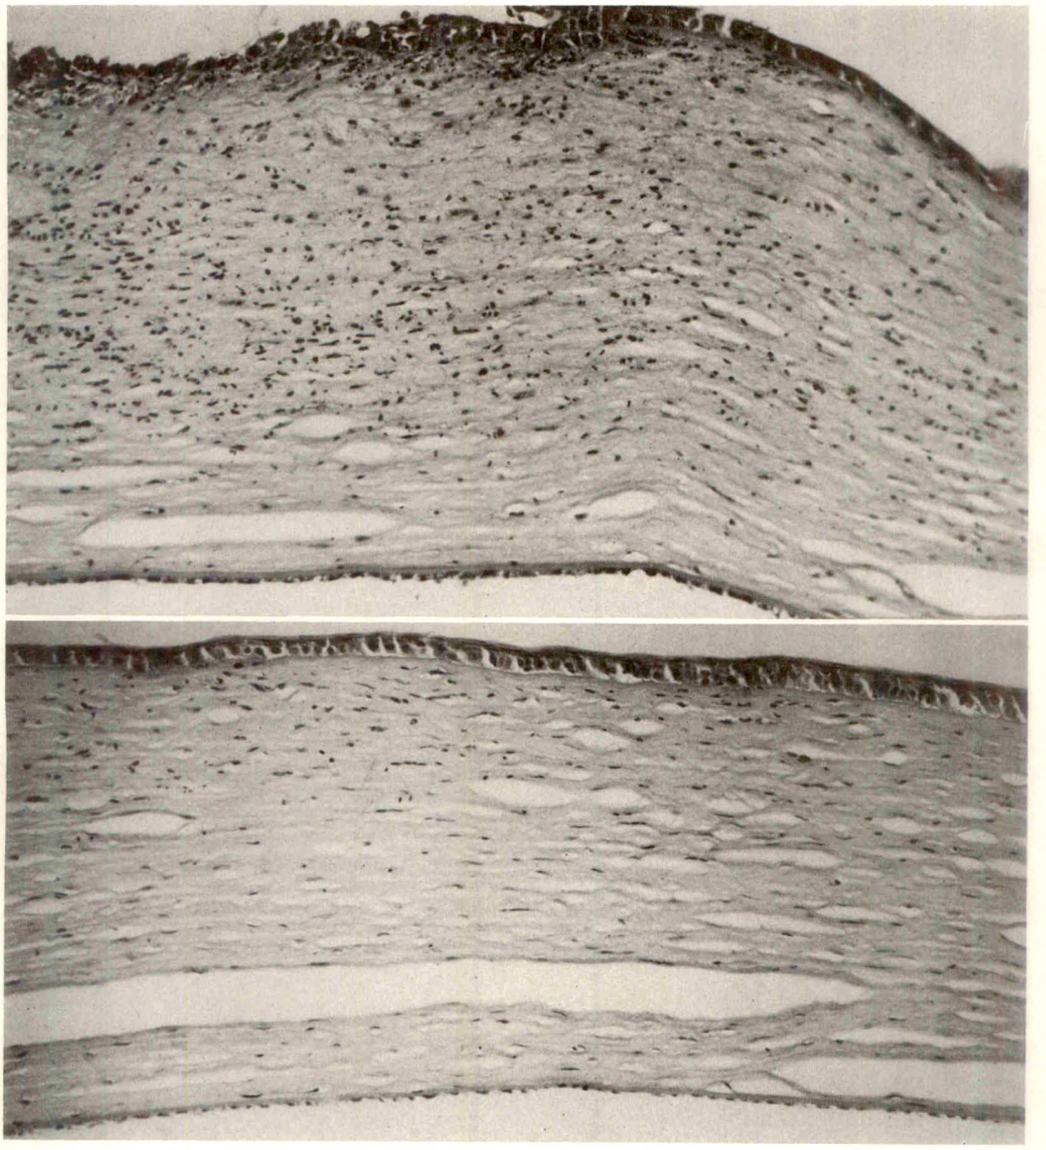

Fig. 2 (D'Alena, Okumoto, and Crawford). Rabbit No. 127. The right (top) and left (bottom) corneas 14 days following herpes inoculation. At this time the right eye would have been treated with the cryoprobe. Variability between the two eyes is evident. This rabbit showed the greatest variability between the two eyes of any rabbit in the series (hematoxylin and eosin, ×100).

same temperature. On the day of cryotherapy, each rabbit eyelid was swabbed with a moist cotton applicator and the material streaked on sheep blood agar before application of the probes.

The rabbits were divided into three groups. Group A had the cryoapplicator applied to the center of the right cornea for five seconds only. This application was sufficient to produce an obvious ice ball within the cornea. Group B had four applications of five seconds duration. Group C had six applications of five seconds' duration. The multiple applications were applied in a circle, overlapping the center of the cornea. There were five rabbits in each group except the last where there were four. One rabbit of each group was treated with mouse brain suspension alone, instead of herpes virus, and then received cryotherapy.

The eyes were examined with slit lamp and then photographed when indicated. The clinical severity of the disease was judged on the basis of evidence of pannus, exudate,

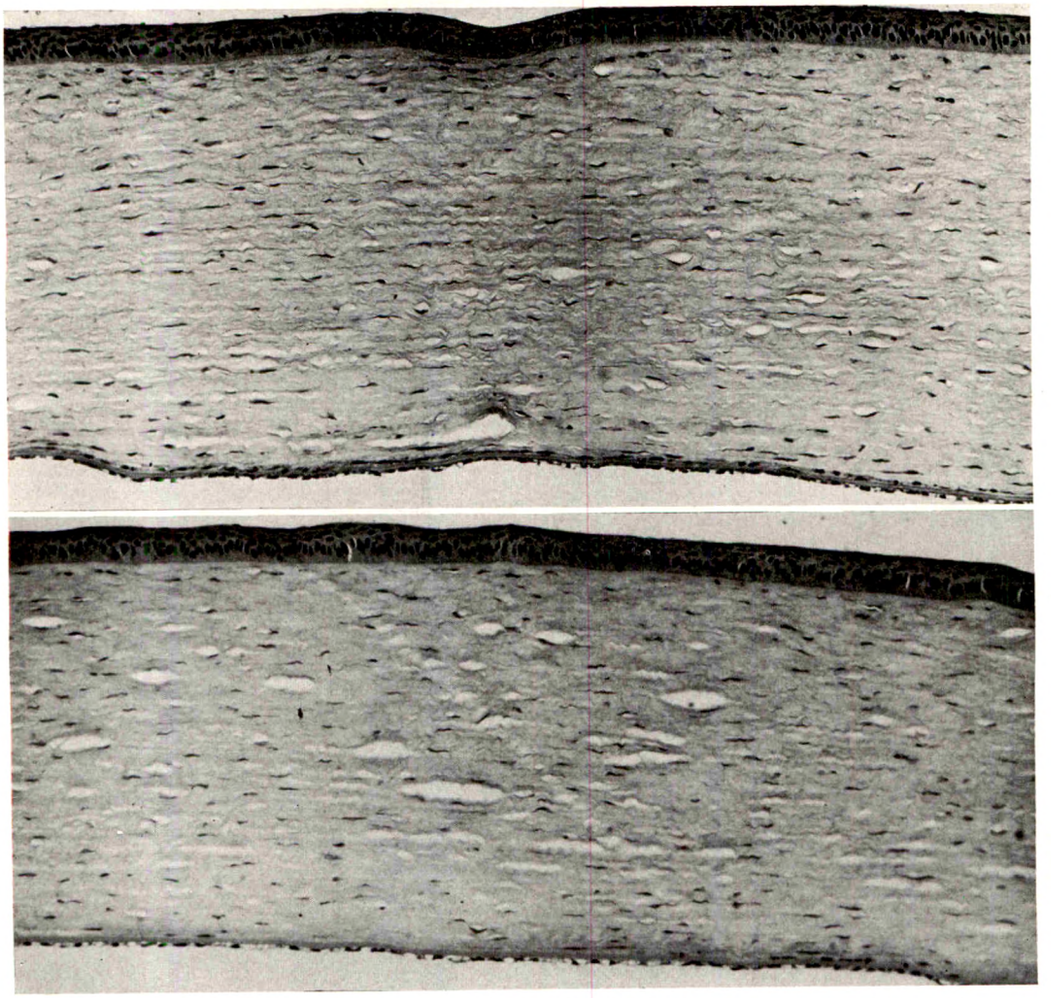

Fig. 3 (D'Alena, Okumoto, and Crawford). Rabbit No. 136. This rabbit was inoculated with mouse brain suspension alone, instead of herpes virus. The right eye (top) was then treated with four applications of cryotherapy. The rabbit was sacrificed 31 days following inoculation (17 days after cryotherapy). Essentially no difference between the right (top) and left (bottom) corneas is evident (hematoxylin and eosin, ×100).

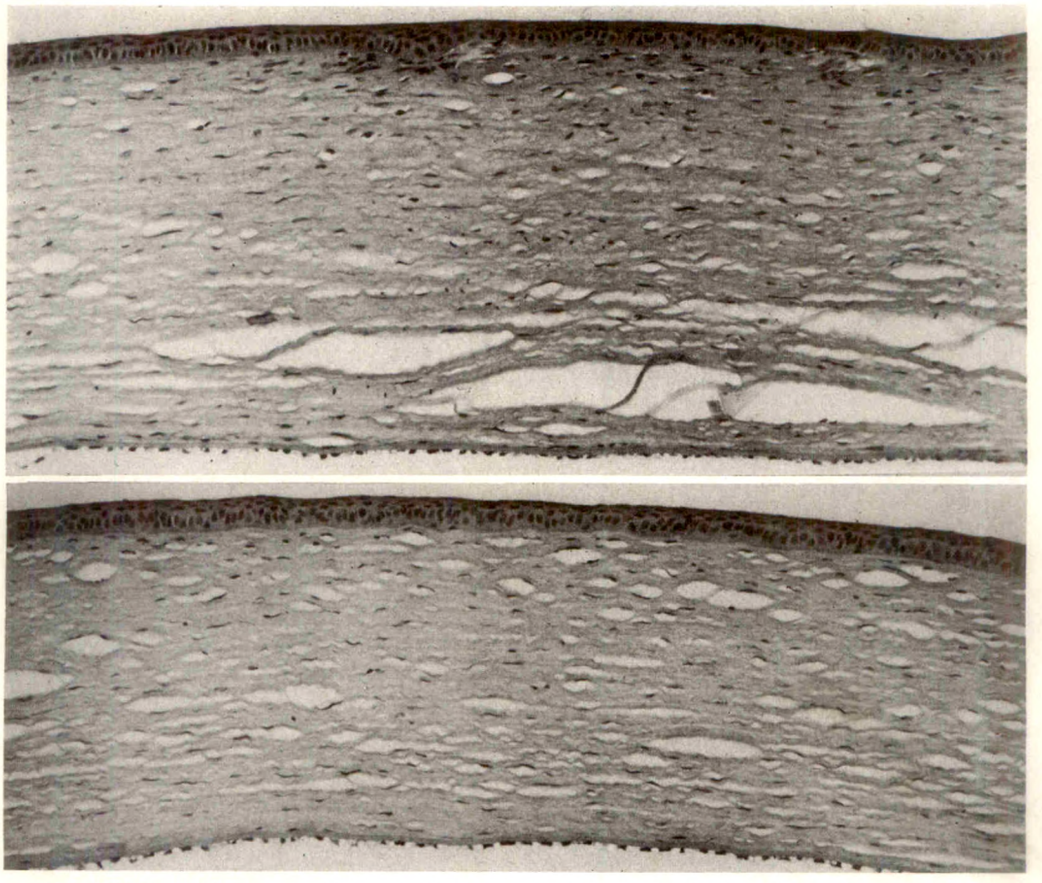

Fig. 4 (D'Alena, Okumoto, and Crawford). Rabbit No. 129. Right (top) and left (bottom) corneas of a rabbit sacrificed 31 days after herpes inoculation (17 days after four applications of cryotherapy of the right eye). Focal epithelial hyperplasia and more stromal inflammation is seen in the right cornea than in the left (hematoxylin and eosin, ×100).

corneal staining with fluorescein, extent of corneal edema, iris congestion, and presence of cells and flare as seen by the slit lamp. The animals were sacrificed at various intervals up to eight months following herpes inoculation at which time the eyes were sectioned and stained with hematoxylin and eosin.

## Results

The clinical findings showed that cryotherapy did not alter the course of the disease. In the treated eye of one rabbit that received four applications, two small superficial lenticular opacities were noted three weeks following cryotherapy. These opacities later became subepithelial and persisted until the rabbit was sacrificed seven and one-half months following cryotherapy (eight months after herpes inoculation).

In some rabbits, one eye was worse than the other prior to the cryogenic treatment. These differences were considered when the histological sections were reviewed and the clinical results evaluated.

Figure 1 summarizes the clinical results of the study. Cryotherapy produced a minimal amount of cells and flare in the anterior chamber even though the iris became moderately injected. From Figure 1 it is seen that six of 11 treated eyes were worse than its control eye; three eyes appeared better than

TABLE 1

SUMMARY OF HISTOLOGIC FINDINGS

| Rabbit No. | Rabbit Eye | |
|---|---|---|
| | Right | Left |
| 124 | 2 (iritis) | 1 |
| 122 | 2 | 4 |
| 128 | 1 | 1 |
| 131 | 1 | 1 |
| 125 | 2 | 1 |
| 129 | 2 | 1 |
| 123 | 3 | 2 |
| 132 | 1 | 2 |
| 126 | 2 | 4 (cyclitis) |
| 130 | 4 | 3 |
| 133 | 1 | 2 |
| 127 | 4 | 3 |
| 136 | 0 | 0 |

the control, and two pairs of eyes appeared approximately equal in the extent of corneal changes. Rabbit No. 127 was sacrificed 14 days following herpes inoculation, the day on which treatment was given to the rabbits (Fig. 2).

The rabbits that were inoculated with mouse brain suspension alone, showed no corneal lesions two weeks after cryotherapy. Rabbit No. 136 (Fig. 3) was treated in this manner.

Figure 4 (rabbit No. 129) shows the results of a rabbit treated with cryotherapy.

The histologic findings confirmed in general the clinical results.

Table 1 summarizes the histologic results of the study. The slides were read by one of us (B.C.) without knowledge of the clinical results. The eyes were grade 0 to 4 depending on the amount of inflammatory cellular reaction, vascularization, and scarring.

## CONCLUSIONS

Except for slight variations, cryotherapy, performed by the method outlined for this experiment, did not alter the course of stromal herpes simplex keratitis in the rabbit.

## SUMMARY

Both eyes of adult rabbits were given 5 mg of prednisone subconjunctivally one day prior to inoculation of the eyes with PH strain of herpes simplex. Fourteen days following virus inoculation, all eyes showed a disciform keratitis. At this time, the right eye was treated with a cryoprobe at a temperature of about −80°C. Three different intensities of freezing were used. Except for slight variations, cryogenics did not alter the course of experimental stromal herpes simplex keratitis followed over an eight-month period.

## ACKNOWLEDGMENT

The cryoprobes used in this study were designed and manufactured under the supervision of George Hilton, M.D.

# MENISCUS-INDUCED THINNING OF TEAR FILMS

JAMES E. McDONALD, M.D., AND STEPHEN BRUBAKER, M.D.
*Chicago, Illinois*

Although studies of the physical chemistry of the tear film have emphasized its importance and characteristics,[1-9] much remains to be clarified, and little clinical application of this knowledge has yet been made. The purpose of this report is (1) to describe some in vitro phenomena of fluid films in the region of the menisci; (2) to show clinical examples of these in the tear film of normal and diseased eyes, and (3) to discuss the implications of these phenomena in tear film renewal.

## MATERIALS AND METHODS

Measured volumes of fluid (water, sodium fluorescein aqueous solutions, or milk) were placed on a glass surface which had been cleaned with a detergent solution and rinsed off with distilled water. After the fluid stopped flowing, the thickness of the fluid layer was measured by dusting talc on the surface and measuring the height above the surface under a microscope. The curvature of the edge was optically analyzed by noting the direction of a reflected beam of light from the surface, when a small light was moved above the edge. The direction of a beam that was refracted by the fluid before and after reflection at the glass surface was also studied.

The menisci raised by various wetted substances (paper clip, wire, dry spaghetti, toothpick, coins, contact lenses, etc.) were similarly analyzed by microscopic measurements and observation of the reflected and refracted beams of light.

The fluids were made to cover a larger area by gravity (tilting the glass) or by mechanically spreading the surface with any wettable object (glass slide, etc.). Measurements and optical studies were made of the spread film. Menisci in these stretched films were studied microscopically and optically, and profile curvatures were made of the menisci and the adjacent thinned area of the film. Optical sections of these surface curves were made with a slit lamp and photographed. Interaction of menisci of different height and curvature were studied. Movies and still photographs were made to document these phenomena in vitro and also in rabbit and human eyes.

## LABORATORY RESULTS

When 1 ml of water, milk or aqueous sodium fluorescein was placed on a horizontal glass surface, it spread so that its depth was between about 1.0 and 1.8 mm and its area was about 10 to 5.5 $cm^2$. If the fluids were set on the glass forceably, the area covered was greater and the depth comparably reduced.

At the edge of the fluid, reflections from a point source of hand-held light moved in the same direction ("with" movement) but more slowly, indicating the virtual image from a convex mirror surface. When starting with the image near the center of the fluid and moving the light towards the edge, the virtual image began to slow down almost a full centimeter from the edge, indicating the beginning of the convex curvature, even at this great distance from the edge (Fig. 1). The slowing of this virtual image became more noticeable on approaching the edge, indicating an increasingly stronger convex mirror toward the edge.

Transmitted light passing through a solution of fluorescein and reflected off the glass

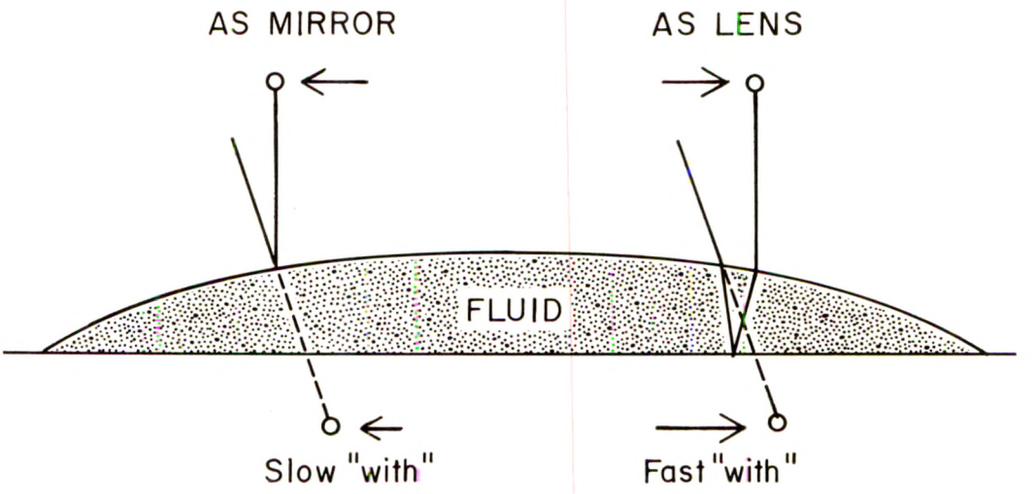

Fig. 1 (McDonald and Brubaker). Curvature analysis by moving a light above a solution of sodium fluorescein. The fluid acts as a convex mirror and reflects a slow "with" movement. It acts as a lens and transmits the greenish refracted ray to give a fast "with" movement.

looks green in contrast to the white color of the surface reflections. At the edge of the fluid the curved fluid lens forms a real image in air and therefore gives an "against" movement. Moving from the center, the transmitted green light starts to speed up

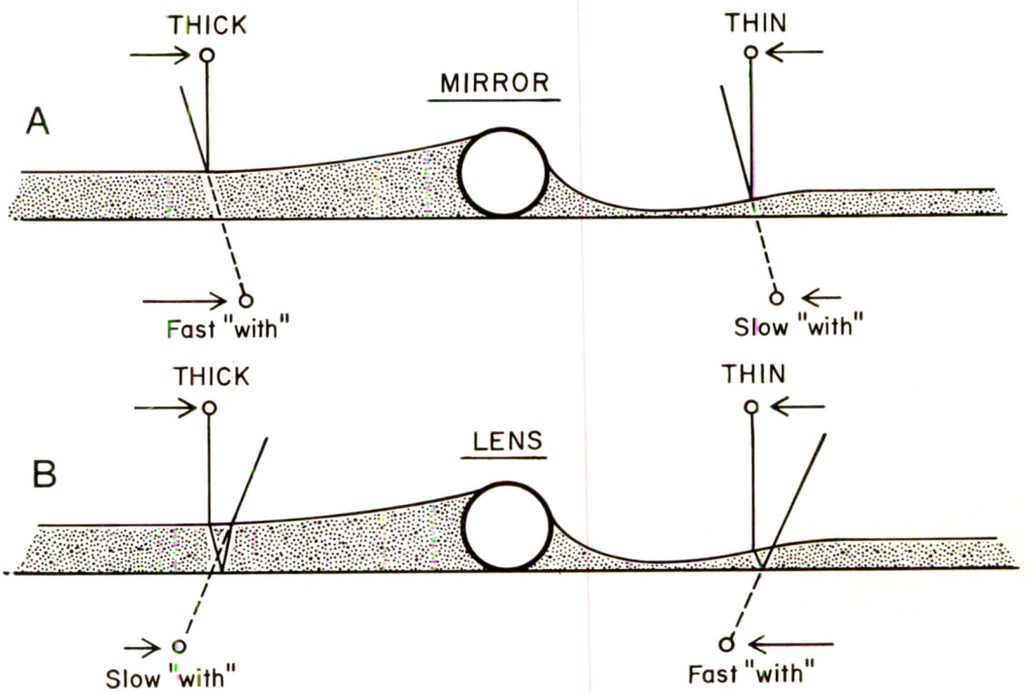

Fig. 2 (McDonald and Brubaker). Optical studies on thick films on the left show a rising surface by both the reflected and the refracted rays. Thin films on the right indicate an initial depression of the surface before rising into the meniscus.

("with" movement) as the gently curved surface acts first as a weak magnifying glass giving a virtual image behind the glass. As the curvature increases toward the edge, the image is converted to a real image in the air in front of the surface and has an "against" movement. The separation of the white reflected ray from the green transmitted ray at a point about 1 cm from the edge gives a sensitive means of detecting and analyzing variations in surface curvature.

Menisci raised from the surface of these relatively thick bodies of fluid lend themselves to study in a similar manner. As the light in front of the surface mirror is moved toward a meniscus, its virtual image begins to speed up in a "with" direction (Fig. 2, top left) at less than a centimeter away from the apex, and then as the light is continued in the same direction, the image converts into a real image with an "against" movement, as the surface mirror becomes more strongly concave. The transmitted ray, acting as a negative fluid lens, slows down in a "with" direction (Fig. 2, bottom left). The slowing increases as the apex is approached.

These studies indicate that the meniscus in a thick film (including the meniscus formed by bodies floating on deep volumes of fluid) gradually rises from the surface with the curvature gradually increasing in amount as the apex is reached. There is apparently no initial depression in the surface before the meniscus rises.

When such volumes of fluid were made to cover an area on the glass that was four to

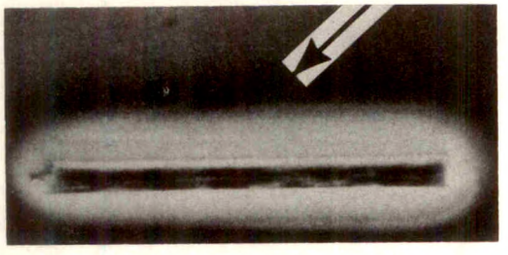

Fig. 3 (McDonald and Brubaker). Piece of uncooked spaghetti in a thin film of milk raises a meniscus which is surrounded by an area of thinning (arrow).

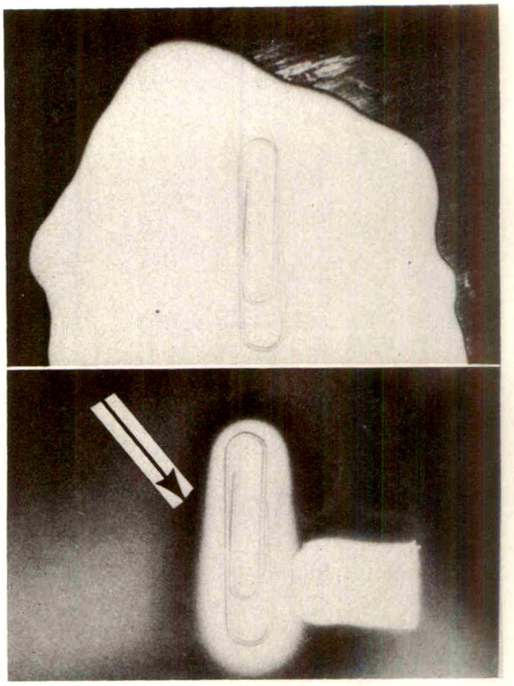

Fig. 4 (McDonald and Brubaker). Top: Paper clip in a thick film of milk shows no meniscus-induced thinning. Bottom: When glass is tilted to make the film thinner, a meniscus-induced thinning occurs. The white rectangular area is the light reflex.

10 times or more than the original area (and the film thickness then measured was 0.1 mm. or less) they acted differently. In these cases the meniscus that was formed was always surrounded by an area of thinning (Fig. 3). This could be seen grossly, but was made more noticeable when milk was put on dark glass, or when a solution of fluorescein was examined under ultraviolet light. This meniscus-related area of thinning could be made to disappear by fluid flow in from the side, provided that the fluid film was made deep enough to permit easy flow of fluid in from the edge. If the meniscus-induced thinning was not present, it could be induced by tilting the glass to make the film even thinner by gravity, or by spreading the film out to a greater area (Fig. 4). For example, no meniscus-induced thinning was noted at about 125μ but it was present when film thick-

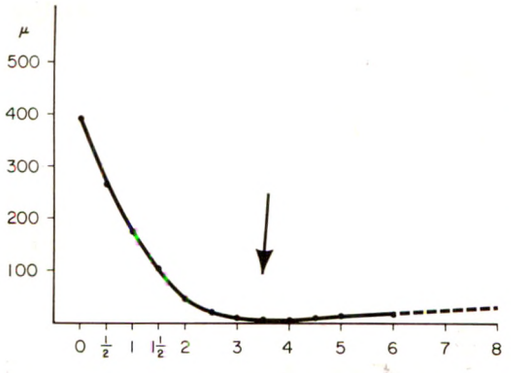

Fig. 5 (McDonald and Brubaker). Results of measuring the film thinning through a microscope. Abscissa is in mm.

ness was reduced to 110μ and was very prominent at 75μ.

Thinning of the film adjacent to the meniscus was confirmed by optical behavior or reflected and transmitted rays. As one approached the region of the meniscus, the reflected ray first showed a retarding "with" motion (Fig. 2, top right), and the transmitted refracted ray showed an advancing "with" motion (Fig. 2, bottom right). These findings confirm an initial depression in the surface in a concave manner before the meniscus rises above the surface toward its apex. Microscopic measurements (Fig. 5) and photographs confirmed the presence of this thinning of the film in the region of the meniscus.

Movement of the object causing the meniscus also moved the meniscus with its thinned area. This thinned region remained thin, unless the object was moved into a relatively deep part of the fluid. Microscopic examination of the thinned area in milk showed the rapid movement of globules of milk from outside of the meniscus through the thinned area into the meniscus. When two menisci of different size touched each other, they tended to become the same size (Fig. 6). The meniscus with less fluid would take from that of more fluid until they were in equilibrium.

The area of thinning adjacent to the meniscus was regularly the site of film fracture. Whenever the stretched film fractured, it almost invariably fractured first in this thinned region, followed by retraction of the film along the line of thinning. It was obvious that the film was weakest in the thinned part.

The intensity of the meniscus-induced thinning depended on the thickness of the surrounding film. If the thinned area could be easily filled in by laminar flow, as in a thick film, the thinned area disappeared by this mechanism. If the surrounding laminar flow was impeded by viscosity or thinness of the adjacent film, the thinned area maintained itself, and then frequently fractured there.

## Clinical observations

Both human and rabbit eyes regularly showed the same phenomena in the precor-

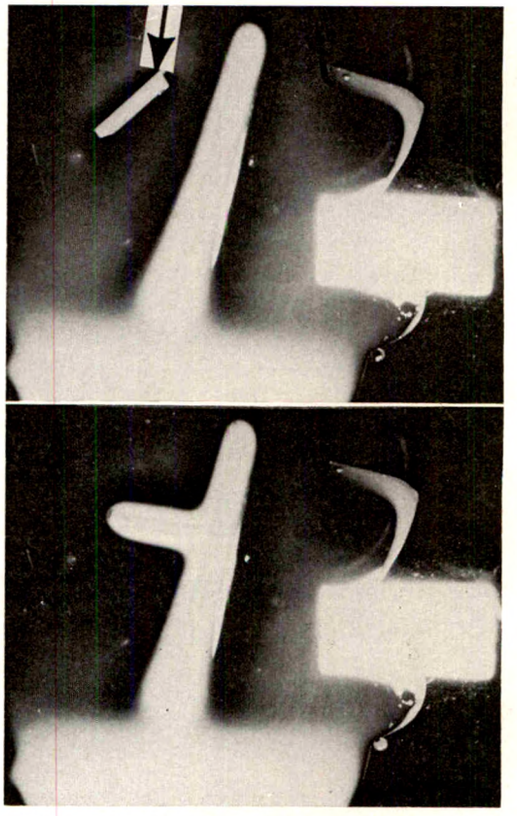

Fig. 6 (McDonald and Brubaker). Uncooked spaghetti in milk film which is stretched by gravity. Top: Meniscus of smaller piece (arrow) is small, acutely curved, and "thirsty." Bottom: Menisci equalize themselves on contact.

neal tear film that are described above in the in vitro experiments.

The lacrimal meniscus is best studied for these phenomena by placing fluorescein in the eyes and observing the region of the lower eyelid with the cobalt blue filter under high power. One notes the concavity of the meniscus and that the surface layer is rather rigid. Immediately above the meniscus on the cornea is the line of thinning manifested by a dark line of less fluorescein (Fig. 7). When the lower eyelid is pushed up, the meniscus and the thinned area above it also move up. A similar thinning is noted in association with the meniscus of the upper eyelid. When the two eyelids are made to come together, the two thinned areas merge (Fig. 8).

Menisci with their adjacent thinning are also noted surrounding bubbles in the tear film (Fig. 9), and also surrounding pieces of mucus (Fig. 10) or pus, which elevate the surface and may be trapped in the film. Contact lenses are surrounded by a meniscus with an area of thinning (Fig. 11). As these objects are moved, the meniscus and the induced thinned region move also.

It is a regular observation that when tear-film fracture occurs in an eye under observation, it occurs in an area of meniscus-induced thinning, similar to that occurring in vitro. When the film fractures in the thinned area, the film rapidly retracts from the initial fracture site along the line of thinning. As has been previously described,[1,4] the dried area resists wetting and causes a hich contact angle to form before the resistance is finally overcome by pushing up the lower eyelid. When the fluorescein-stained meniscus finally wets such a dried cornea, it leaves a delicate linear superficial stain corresponding to the dried line. Such areas of superficial staining were seen to develop naturally

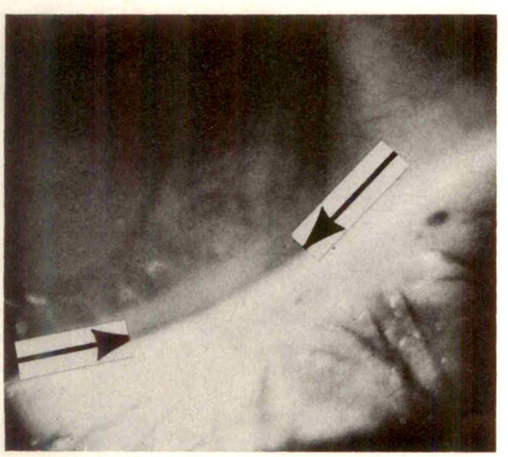

Fig. 7 (McDonald and Brubaker). Line of meniscus-induced thinning (arrow) is seen just above the meniscus in this fluorescein-stained tear film.

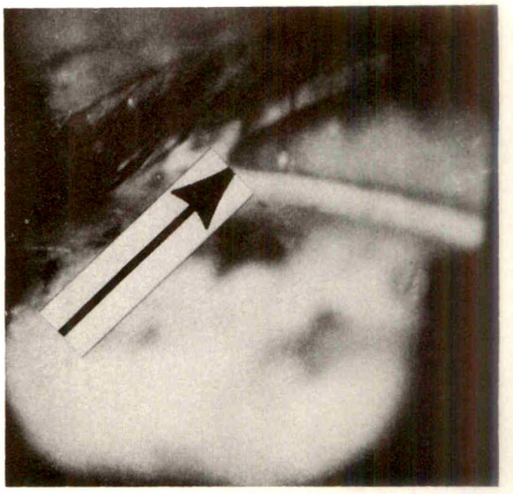

Fig. 8 (McDonald and Brubaker). Meniscus-induced thinning of the upper and lower eyelid seem to reinforce each other to produce extensive thinning.

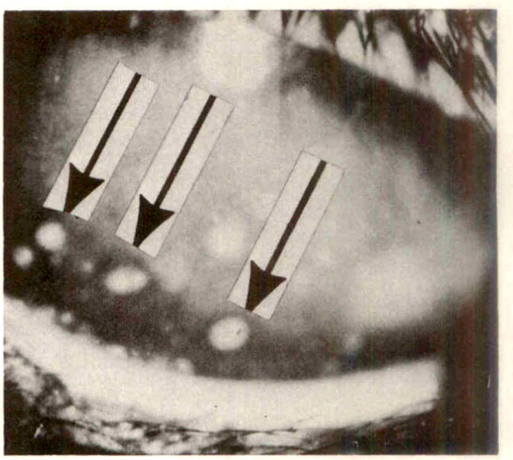

Fig. 9 (McDonald and Brubaker). Bubbles in a rabbit tear film show minisci which are surrounded by rings of thinning (arrow).

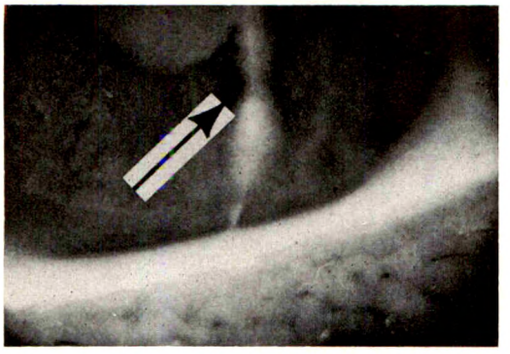

Fig. 10 (McDonald and Brubaker). Mucus on the cornea raises a meniscus which is surrounded by an area of thinning (arrow) in the fluorescein-stained film.

just above the lower eyelid meniscus without any necessity of the eyelid being pushed up.

The circular thinned film surrounding the meniscus of a contact lens acts similarly. It is in this thinned film that fracture of the film usually occurs in a contact lens wearer. The superficial staining frequently seen from three to five o'clock and from seven to nine o'clock in contact lens wearers was seen to develop by film fracture in the thinned film adjacent to the meniscus.

In a fluorescein-stained tear film observed with the blue light of the slit lamp, the thin area acts like a subsurface vacuum cleaner. If the lower eyelid is raised, the fluorescein-stained aqueous phase of the tear film shoots rapidly through the thinned area into the meniscus, just as the fat particles were seen to speed through this area into the meniscus in vitro. The surface oil layer remains immobile. From the direction of movement one can conclude that the hydrostatic pressure is lower in the thinned region than in the tear film, and that it is even lower in the meniscus. This sucking phenomenon of the thinned film is even more striking in conjunctivitis, when cellular debris dramatizes the rapid flow.

If the lower eyelid is then lowered, the tear film remains thinned over a wide area until it thickens by interlaminar flow from the thicker parts of the film, or is made even again by a rapid blink of the upper eyelid. The effect of gravity is negligible, as evidenced by the fact that the same phenomenon can be seen on the upper eyelid meniscus.

When the meniscus and its thinned film from the lower eyelid touch the meniscus of a contact lens, it frequently drains much of the volume of fluid from the contact lens both from its meniscus and the fluid under it.

## Discussion

The concept that negative pressure sucks fluid from stretched film faster than it can be replaced and thereby induces thinning of a film appears logical. It is compatible with present ideas on capillarity and foam and bubble drainage.[10] The more acutely curved (the shorter the radius of curvature) a meniscus is, the greater is the reduction in pressure inside the fluid as compared to the gas or nearby fluid. The simple situation relating to the reduction of pressure in the meniscus of a capillary tube is shown in the following equation of capillarity:

$$\Delta P = \gamma \ (1/r_1 + 1/r_2)$$

In this equation, $\Delta P$ equals the reduction of pressure inside the fluid, $\gamma$ equals the surface tension, $r_1$ equals the radius of curvature of the meniscus, and $r_2$ equals the radius of curvature in the meniscus in a plane at right angles to the plane of $r_1$. In a capillary tube,

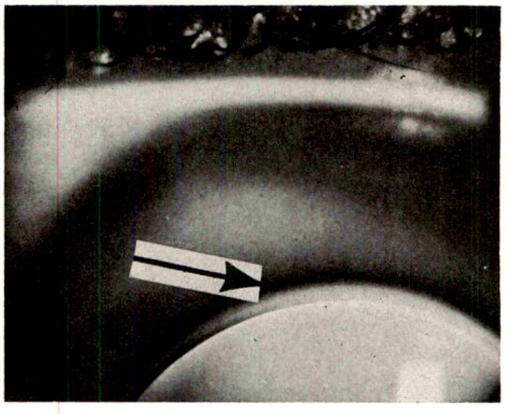

Fig. 11 (McDonald and Brubaker). Contact lenses are always surrounded by a meniscus, which in turn is surrounded by a ring of tear-film thinning (arrow).

if the meniscus is assumed to be hemispherical, $r_1$ and $r_2$ are equal, and the equation reduces to $\Delta P = 2\ \gamma/r$. Using this equation, Ehlers[1] calculated a $\Delta P$ of about 4.5 mm of water between the fluid in the precorneal film and the meniscus. He concluded that this pressure difference will "suck fluid from the film and bring about a speedier reduction in the thickness of this film." We believe that he wrongly concludes that this pressure will "hardly have any effect on the interlaminar flow."

When both radii of curvature are drawn from the same side of the film (as in a capillary tube), $r_1$ and $r_2$ are positive, and both curvatures contribute to the suction effect. In the case of the eyelids, the curvature of the tear film meniscus in the vertical axis ($r_1$) is not helped by any contribution of curvature in the horizontal plane. In this case, $r_2$ becomes very large and $1/r_2$ is almost nothing. In the case of the meniscus of a contact lens, $r_1$ contributes to the suction, but $r_2$ in the plane of the lens is drawn from the other side of the meniscus, and is therefore negative. This second curvature subtracts from the suction effect of the primary curve. Any meniscus so drawn around the periphery of an object should therefore have less suction than one of the same primary curvature located on a straight or concave line. For this reason an eyelid meniscus of a given curvature can drain a contact lens meniscus of the same curvature as well as the weaker menisci around the periphery of curved objects.

This mechanism seems a most likely explanation for the normal renewal of the aqueous phase of the tear film (Fig. 12). The low-pressure menisci of the upper and lower eyelids suck the subsurface fluid into themselves. The thinning is a manifestation of this sucking, because the tear film cannot replenish the aspirated fluid fast enough by interlaminar flow. As the eyelids move across the cornea, this wave of low pressure in the thinned areas and menisci of the eyelids acts like a subsurface vacuum cleaner, since the film is too thin to depend on gravitational forces for renewal. This mechanism

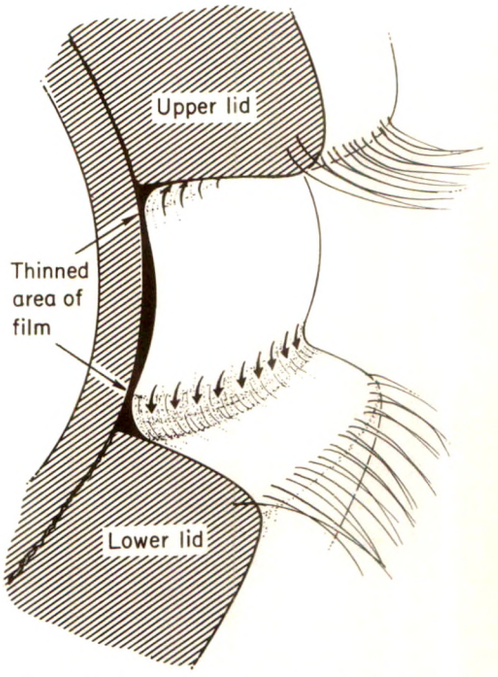

Fig. 12 (McDonald and Brubaker). Negative pressure in the meniscus thins the adjacent tear film. The blinking of the eyelids acts as a subsurface vacuum cleaner resulting in renewal of the aqueous phase of the tears.

is compatible with the fact that the surface oil layer does not participate in this fluid movement.

It is interesting that a "thirsty" meniscus (small radius of curvature) will take fluid from one with a larger radius of curvature in vitro and in vivo. This may act as a servomechanism. When the meniscus gets larger and less curved, it gets less "thirsty." When the eyelid's meniscus gets drained by the puncta and canaliculi, it becomes more curved and commences to "vacuum" under the surface more strongly.

In many patients, especially the elderly, one frequently sees a delicate linear horizontal staining just above the lower limbus. Observations on these eyes suggest that tear film fracture in the thin area of the lower eyelid meniscus may be the underlying cause of this condition.

The commonly observed staining in the inferior nasal and temporal quadrants near, but not under, contact lenses may be due to

tear film fracture induced by the additive effects of the thinning associated with the contact lens meniscus and the lower eyelid meniscus. Film fracture in these areas also may be partly due to the upper eyelid being kept away from the epithelium, resulting in poor wettability of the cornea, possibly due to a surface deficiency of phospholipids[1] or mucus.[7] This explanation seems more likely than the explanation that this staining is a manifestation of too loose or too tight a fit of the contact lenses.

It may be that burning and superficial staining of conjunctivitis may be due to tear film weakness, associated with the meniscus of mucus or debris in the tear film. Indeed, anything which causes a meniscus, such as a high pterygium, a successful filtering bleb, swollen limbal tissue after muscle surgery, might by this mechanism contribute to tear film fragility and staining and even dellen sometimes seen in these conditions.

## Summary

There is a thinning of fluid films adjacent to concave menisci both in vitro and in the tear film. Films fracture preferentially in these thin areas.

Menisci of the eyelids, of contact lens, of bubbles and mucus or debris in the tear film, or of adjacent perilimbal elevations such as filtering blebs, all have an adjacent area of thinning where film fracture and resultant staining often occur.

This sucking action of the eyelid menisci seems to be a basic mechanism for subsurface tear renewal.

# LYMPHATIC DRAINAGE FROM VASCULARIZED RABBIT CORNEA

GILBERT SMOLIN, M.D., AND ROBERT A. HYNDIUK, M.D.
*San Francisco, California*

Although it is generally acknowledged that the nonvascularized cornea does not have cell-lined lymphatic vessels, the presence of lymphatics in the vascularized cornea seems to be indicated by the experimental work of Collin,[1] Busacca,[2] Mann and associates,[3] Aoki,[4] and Katayama.[5] In corneal transplantation, vascularization of the host cornea is associated with a high incidence of graft rejection. To evaluate the role of the lymphatics in this unfortunate phenomenon, it is important to determine the nature of the lymphatic drainage in vascularized corneas. This preliminary objective may serve as a basis for future studies of the role of sensitized regional lymph nodes in the graft rejection phenomenon. This we have attempted to do in rabbit corneas by the intrallamellar injection of India ink.

## MATERIALS AND METHODS

The experimental animals were seven pigmented adult male rabbits, each weighing five pounds. Vascularization was induced in the corneas of rabbits 1-4 by gentle swabbing with a cotton-tipped applicator soaked in 20% sodium hydroxide solution. Corneal edema and vascularization developed rapidly, then quieted down and stabilized in from two to three weeks.

At this point we injected the right eye of rabbit No. 1 with bovine gamma globulin (BGG). The BGG was dissolved in physiologic saline solution and filtered through a millipore filter; the concentration of the final solution was 30 mg/ml. Intravitreal inoculation of approximately 0.05 ml (1.5 mg) of this solution (with a 27-gauge needle attached to a 0.25-ml tuberculin syringe) was followed by subconjunctival injection of 1 ml of India ink (previously boiled, diluted, and filtered) in the same eye. Five days later the animal was killed, and the preauricular and cervical lymph nodes were excised from the surrounding tissue.

Both eyes of rabbits 2-7 (three with vascularized corneas and three with nonvascularized corneas) then received similar intrav-

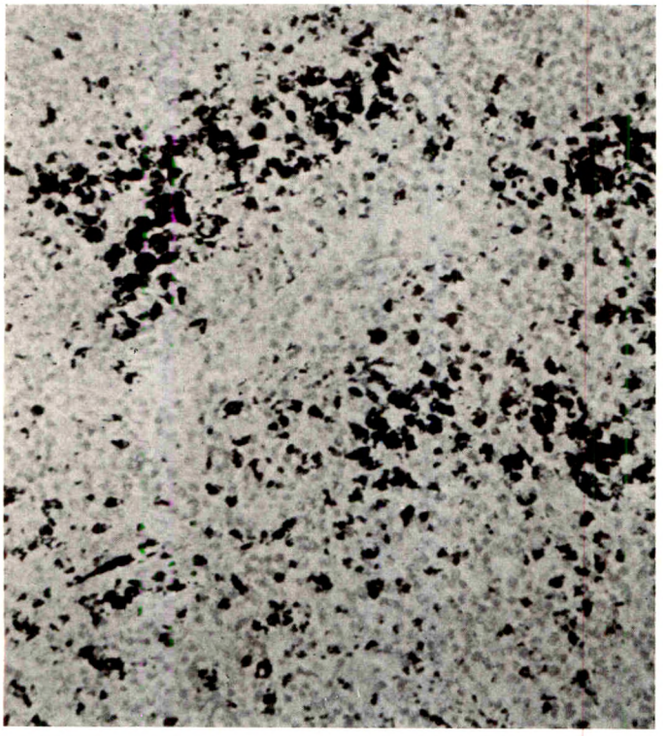

Fig. 2 (Smolin and Hyndiuk). India ink particles in regional lymph node (×200).

itreal inoculations of BGG. This was followed by intralamellar injections of India ink in the right eyes only, as follows: A fixation forceps was used to grasp the limbal conjunctiva at the 11 o'clock position, and 0.05 ml of India ink was injected through a 30-gauge needle into the corneal mid-stroma. The animals were killed five days later. The "draining" lymph nodes and corneas were first photographed in situ and then excised for histologic study.

## Results

The preauricular and cervical lymph nodes of rabbits 1-7 were enlarged. This was attributed to the animals' reaction to the BGG inoculation. Gross examination of the nodes of rabbit No. 1 revealed a black coloration (Fig. 1), and histologic examination revealed an abundance of India ink particles (Fig. 2).

In the nonvascularized corneas of rabbits 5-7, the depot of India ink remained at the site of inoculation (Fig. 3). The isolated lymph nodes were enlarged, but no black coloration would be seen either grossly or on histologic examination of stained or unstained sections (Fig. 4). Histologic examination of the nonvascularized corneas was also negative: There were no cell-lined channels filled with India ink (Fig. 5).

In the vascularized corneas of rabbits 2-4, there was immediate dispersion of the India ink in a linear, branch-like configuration. This pattern was still in evidence on day five

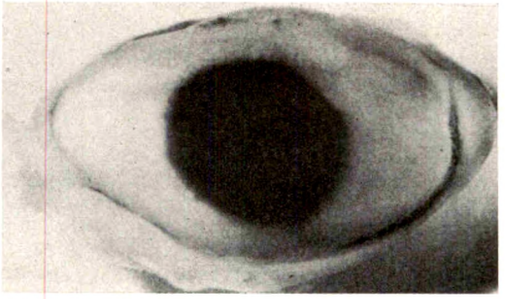

Fig. 3 (Smolin and Hyndiuk). Rabbit cornea with depot of India ink (×2).

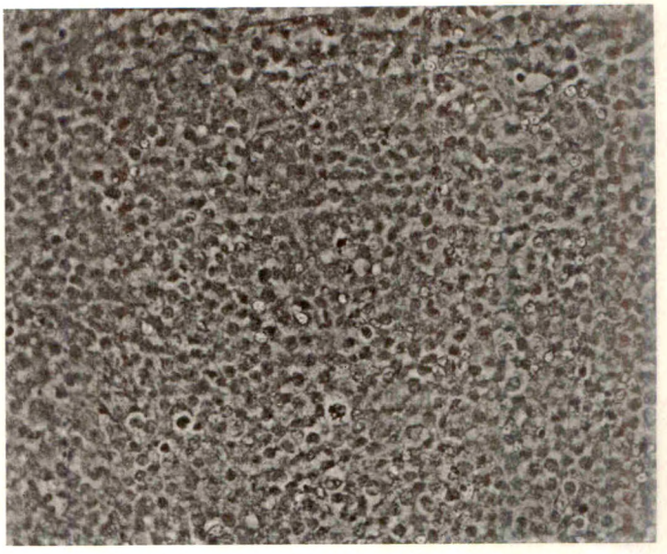

Fig. 4 (Smolin and Hyndiuk). Negative-phase photomicrograph. Regional lymph node showing no evidence of India ink (×400).

when the animals were killed (Fig. 6). When the enlarged lymph nodes were excised and examined grossly, none of them looked discolored. When unstained sections were examined histologically, India ink was absent from the lymph nodes on the left side, but present in small quantities in those on the right side (Fig. 7). Histologic examination of the vascularized corneas revealed channels infrequently filled with India ink and devoid of red blood cells (Fig. 8)

## Discussion

Preauricular and cervical lymph nodes were usually difficult to identify in the rabbit. The intravitreal inoculation of BGG enlarged the nodes and thus facilitated their identification and removal. BGG was injected intravitreally into the left eye of rabbits 2-7 as a control, in order to show that it had no influence on the lymphatic drainage from the cornea. India ink was selected because of the satisfactory way in which it out-

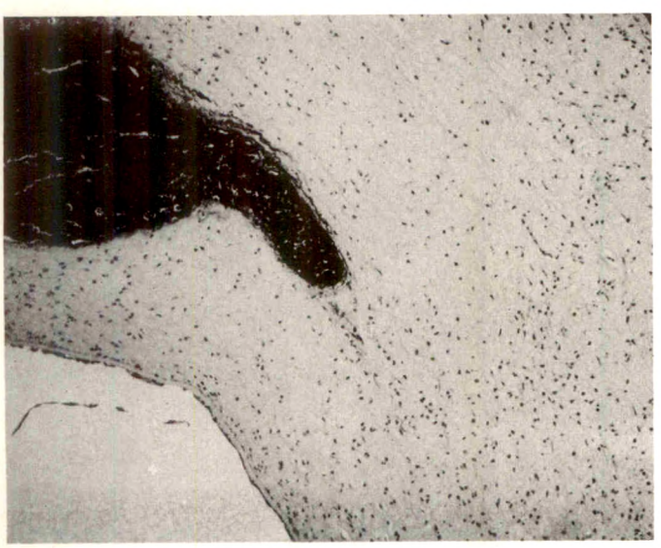

Fig. 5 (Smolin and Hyndiuk). Rabbit cornea with depot of India ink (×100).

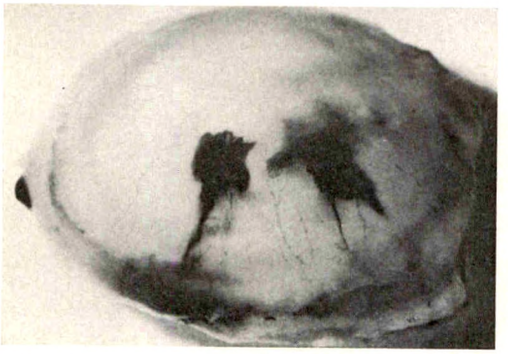

Fig. 6 (Smolin and Hyndiuk). Spread of India ink in rabbit cornea (×2).

lines lymphatic vessels.[4] Mandarin Ink,[1] Patient Blue V,[1] Evans blue,[6] and other dyes have also been used effectively for this purpose in the past.

The passage of India ink to lymph nodes on the right side and not on the left indicates that spread of the dye was localized. These results are consistent with those obtained by Collin[6] in his experiments with rats.

In the nonvascularized corneas India ink was not present in detectable amounts at the limbus or in the lymph nodes. This was consistent with the belief that although cell-lined lymphatic vessels are not present in nonvascularized corneas, they may be present in vascularized corneas and may play a significant role in the passages of large-sized particles from the cornea, as for example, India ink.

In Polack's[7] opinion, corneal antigens can diffuse through the cornea toward the limbal vasculature, and neither blood vessels nor lymphatic vessels in the cornea are necessary for sensitization of the host. We believe that this concept is at least partially correct. Corneal antigens may diffuse toward the limbus in the manner suggested, but we feel that corneal lymphatics, when present, play the major role in the transfer. The obvious application of this concept is in keratoplasty. We know that marked vascularization of the recipient cornea is a serious threat to the survival of the grafted cornea. If lymphatic vessels were transporting soluble corneal antigens to the regional lymph nodes as they can transport India ink, then local treatment of the graft might alter the afferent arc of the sensitization process associated with transplantation, and rejection might be prevented. According to Lambert's[8] experimental evidence, the lymphatic system is important in the spread of tissue antigens, and others[9-12] have shown that continuous local treatment of the graft site may alter the rejection phenomenon. However, periodic local treatment seems to have no effect.[13]

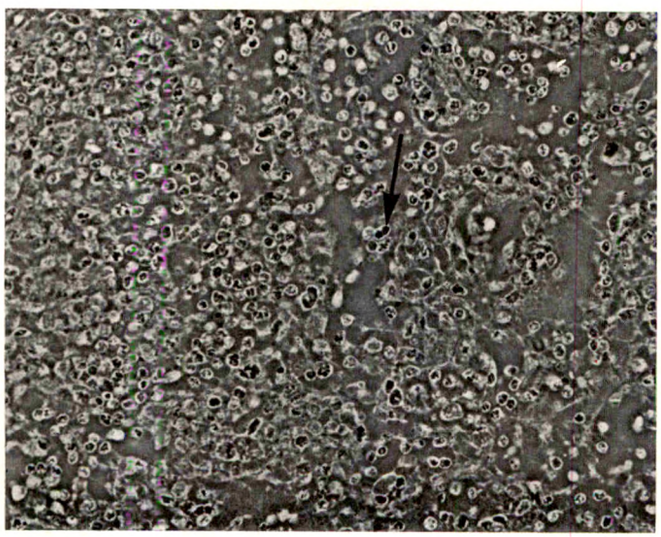

Fig. 7 (Smolin and Hyndiuk). Negative-phase photomicrograph. Regional lymph node with small amount of India ink (×400).

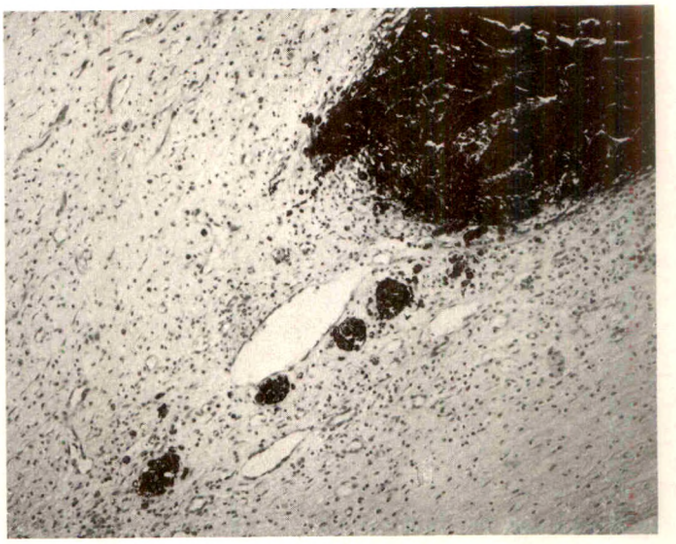

Fig. 8 (Smolin and Hyndiuk). Rabbit cornea with channels filled with India ink (×100).

## Summary

Intralamellar injection of India ink into vascularized rabbit corneas was followed by rapid spread of the material to the limbus and ipsilateral regional lymph nodes. In nonvascularized corneas no such spread occurred.

# SPECTACLE GLASS INJURIES TO THE EYE

ARTHUR H. KEENEY, M.D., AND BERT R. ESTLOW, M.D.
*Philadelphia, Pennsylvania*

The common place familiarity of spectacles tends to lessen our concern for them as a source of lacerations or burns.[1] The immediate demands of the surgical repair of an injured eye tend to preempt our attention away from the cause of the injury. Unfortunately, neither coding systems nor the vast majority of patient records identify causative mechanisms or the source of glass when trauma or foreign-body injury is noted on hospital charts. Further, it may be difficult, either on the basis of history or examination, to differentiate spectacle glass fragments from windshield, bottle, window, or other glass sources. Thus, on the basis of literature review, Duke-Elder[2] contended that the incidence of ocular injury from spectacles was relatively rare. This, however, is contradicted by personal experience and surveys of trauma initiated by the National Society for the Prevention of Blindness.[3,4]

In the enormous literature on ocular trauma, causative details are often ignored. At other times, when glass is named as the cause of injury,[5] the source of the glass is not identified. Frequently, cases of spectacle glass foreign bodies[6] are found only on critical reading of reports such as those by Laibson[7] (one in five, Thorpe[8] (one in five), Roper-Hall[9] (in a primarily industrial study, one in 555), McDonald and Ashodian[10] (one goggle in four), Sornson and Brown[11] (six in 270), Kaufman[12] (nine "regular spectacle glass" in 1107 industrial injuries), or Burke[13] (two cases in discussion). In 1958, Dickinson[14] reported 36 cases of spectacle glass injury. Occasional reports deal with unique aspects of an individual spectacle glass injury,[15,16] or detection of spectacle glass foreign bodies.[17]

This report of 42 injured patients (Table 1) covers personal and institutional experience from May, 1964, through November, 1970. This is an underestimation of total experience because the mechanism of injury or the type of glass are impossible to determine in some cases. Several additional cases have been brought to our attention by others who knew of our interest in this subject.

In this series, there were 37 males and five females, or a male/female ratio of seven to one. Ages ranged from eight to 72 years, with the highest incidence in the second decade of life, and fairly even distribution throughout all other of the first five decades. Causes of these spectacle glass injuries varied widely (Table 2), but only six injuries could be considered occupational. Refractive errors extend upward to +6.00 D, but the majority are in the moderately myopic range of −1.00 to −3.00 D. A total of 57 surgical procedures have thus far been performed on these injured eyes and a few more may yet be necessary. Despite extensive ophthalmic care, 12 eyes are now legally blind and three more may meet this fate in time—or a total of one-third of this series.

Three of these patients were treated entirely as outpatients; three more had unusually long military hospitalizations of 90, 90, and 150 days. In the remaining 36 cases, average length of hospitalization was nearly 11 days—or approximately 390 days of hospital and medical care expense that need not have been incurred.

In each of these patients, it appears that ocular damage could have been prevented by heat-tempered, impact-resistant, glass lenses, or even more certainly by allyl resin lenses.[18,19] Laboratory study a decade ago[20] suggested that high-density or heavy, small

foreign bodies (1 to 2 mm in diameter) traveling at high velocities (1200 to 1800 feet per second) might more easily penetrate tempered than nontempered glass. Such lens behavior under these unique circumstances seemed possibly related to slightly increased brittleness of heat-tempered glass in comparison to greater elasticity in nontempered glass. All such studies have shown greater impact resistance (per mm of thickness) in allyl resin lenses than in heat-tempered or conventional crown glass for both small, high-velocity missiles and larger, low-velocity missiles.[21] Decades of substantial industrial experience,

however, have documented the great value of heat-tempered glass in saving thousands of eyes.

Less frequently, spectacle glass injuries result when the lens is dislodged but unbroken. Eyelid or adnexal lacerations may be produced by posterior dislocation of an intact (safety or non-safety) lens from the eyepiece of a spectacle frame not affording a posterior retaining lip. In one patient in this series, a boy of 13 years, a baseball dislodged the right spectacle lens, which, in turn, caused a one-inch laceration beneath center of the right brow. The lens was not broken ($+2.00 - 4.50 \times 5 = 20/20$). The boy developed an infected hematoma with tenderness and swelling and a temperature of 104°F. After incision and evacuation under ketamine, healing, with the assistance of antibiotics, was uneventful. No bulbar damage was incurred.

Good safety frame design now includes a posterior lip on the eyepieces extending about 0.1 mm more centrally than does the anterior lip.[1] This requires that the lens be inserted from the front of the frame and makes it essentially impossible for a blow to dislocate the lens into the eye or adnexa.

Every frame should be made of nonflammable or fire-retardant materials, as are all industrial frames in this nation. Several foreign countries, however, still export frames made of highly flammable cellulose nitrate, which was outlawed both by the motion picture film industry and the Optical Manufacturers Association of this country many years ago.

Occasionally, opinion has been expressed that conventional crown spectacles offer more protection to the eye than no glasses at all. This may be true in the limited case of liquid splash accidents, but certainly, these 42 cases clearly indicate that the added protection of impact resistance should be an appropriate part of every spectacle prescription.

Fragile conventional crown glass and inadequately supporting frames should no longer be placed in hazardous proximity to the eye. Every pair of spectacles should be a protective armor to the irreplaceable human eye.

TABLE 2

CAUSE OF INJURY IN 42 CASES OF SPECTACLE GLASS INJURIES

| Cause | No. Patients |
|---|---|
| Assault (fist blows, 6) | 9 |
| Thrown rocks | 5 |
| BB pellets | 4 |
| Sports (volley ball, baseball, golf ball, golf club) | 4 |
| Falls | 2 |
| Nails | 2 |
| Wood, flying | 2 |
| Tree branch | 1 |
| Auto crash | 2 |
| Miscellaneous (broom handle, champagne cork, bow, pliers, plastic bomb, jack handle) | 6 |
| Occupational (all low velocity) | 6 |
| Unknown | 2 |

## SUMMARY

Forty-two patients are reported who sustained significant to blinding ocular injuries from spectacle glass fragments. Fifty-seven procedures have been required in treatment of these 42 patients, and a few additional operations may be anticipated. Only six of the total cases could be considered industrial. Males predominate by a ratio of 7 to 1. Both physicians' records and hospital charts generally fail to show causative details in ocular injuries. Also it is frequently impossible to differentiate glass fragments as deriving from spectacles versus windshields or bottles. Most of these injuries were preventable by the use of impact-resistant lenses and appropriately supporting posterior lip frames.

# EYE INJURIES IN NIGERIA

## A Review of 433 Cases

Oyin Olurin, M.B.
*Ibadan, Nigeria*

The incidence of blindness resulting from trauma has a worldwide variation. In some countries accidental trauma is the commonest cause of bilateral blindness,[1-3] while in other countries trauma rarely causes blindness in both eyes.[4-7] There are no comparable figures for Nigeria. The University College Hospital, Ibadan, serves a cross section of the Nigerian population. Nigeria is predominantly an agricultural country. The aim of this paper is to report on the causes of traumatic blindness in this community and to show how local situations affect ocular morbidity from trauma.

### Material and Method

In the period between 1963 and June 1970, there were 470 patients with traumatic blindness seen in the University College Hospital, Ibadan. Included in this number are 26 of 1000 consecutive patients blind in both eyes and 444 patients out of 2000 with uniocular blindness. Each patient was seen by an ophthalmologist and half of them were personally examined at subsequent visits. Thirty-seven patients were excluded from the series for inadequate information. All patients had sustained injuries resulting in reduction of visual acuity to counting fingers at three feet or less at first visit. Eye injuries have been classified by a number of authors[8-10] but for this paper, a simplified classification has been used.

The interval between injury and consultation varied considerably but only 20% of the patients were seen within one week of eye injury. This long interval between injury and consultation was due to difficulty in getting expert medical attention in time or failure of the patient to make use of available facilities. Difficulty in financing long journeys was also a problem. Of the 433 patients, 294 had received no previous treatment until they reached University College Hospital; 122 had received first aid at a local dispensary, their nearest general hospital, or at a general medical practitioner's clinic; 17 had received initial surgical treatment elsewhere. A large number had applied traditional remedies and came to the hospital only after several days of unsuccessful treatment at home, or when intractable pain forced them to do so.

### Age and sex distribution

There were 360 male patients (83.75%) and 73 (16.25%) female, a ratio of 5:1 (Fig. 1). This male preponderance is shown in studies from other countries.[1,11] In this study, however, the preponderance of males was only partly due to the greater number of male patients attending the eye clinic. Some activities that are causes of traumatic blindness are quite often limited to the male. The 30-month civil war during this period further increased the number of injured males; traumatic blindness was due to military activity in 79 men in this study. Ages ranged from five to 70 years. The largest number of injuries (146) occurred in the 20-30 year age group (33%); most of these patients were men and more than half (79) were soldiers. The next largest number of patients (110) were in the 10-20 year age group (Fig. 3). The incidence of eye injury fell rapidly after 40 years of age, with only a handful of patients in the 60-70 year age group. Detailed analysis of the age and sex distribution is shown in Figures 1 and 2.

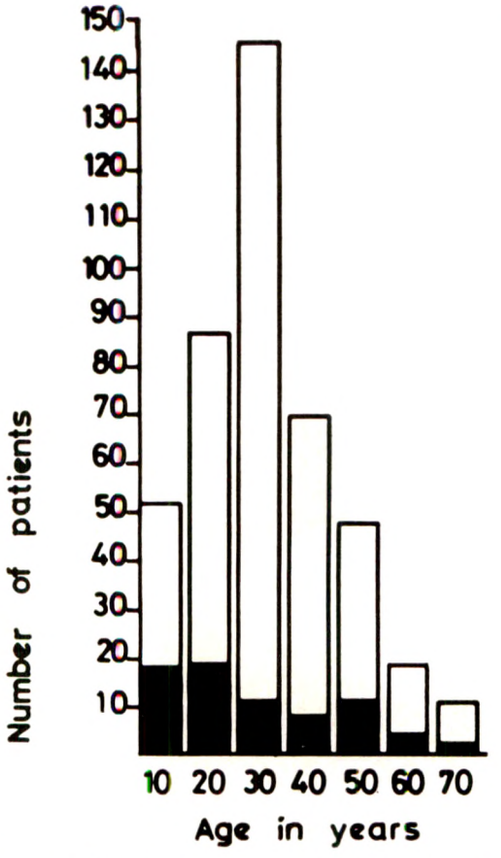

Fig. 1 (Olurin). Age and sex distribution in 433 patients. Key: white = males, black = females.

## Occupation

Patients were divided into 10 different occupational groups: (1) The category of "school children" included all young persons under the age of 20 years except those apprenticed at trades; (2) farmers; (3) industrial workers, including trade apprentices; (4) clerical office personnel; (5) executives and senior professionals; (6) housewives; (7) tradesmen; (8) soldiers; (9) old age pensioners; and (10) unemployed adults. The incidence of injury in each occupational group is shown in Table 1. The highest incidence was among soldiers (27.5%). Injuries in school-age children accounted for 25.4% of the total, and a more detailed study of the causes of injury in children is examined below. Farmers accounted for 24.5% of those injured. The country is still largely agricultural, and farming methods are not mechanized. The older methods of manual digging, hoeing and felling of trees make the farmer susceptable to some of the more serious types of eye injuries. A similarly high incidence of eye injury amongst farm workers was found in agricultural Ceylon,[12] where farming conditions are probably similar.

Industrial accidents accounted for 52 patients (12%), most of whom were employed in small-scale industries which abound in the country. Twenty-nine (6.7%) housewives sustained severe eye injuries mostly in the home. Activities that are probably peculiar to our way of life were responsible in 17 of these women: Nine were blinded by chips of palm kernels which they cracked manually in order to extract the seeds; eight were blinded while splitting firewood, often the job of the housewife in this country.

## Types and complications of injuries

Injuries were classified as perforations, contusions, or "others." Complications arising from each type of injury were as follows.

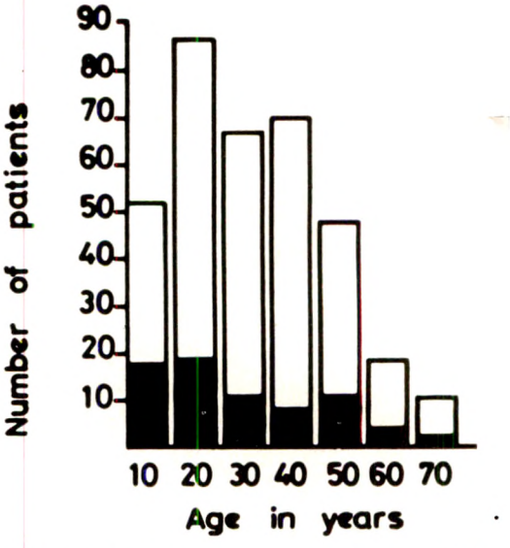

Fig. 2 (Olurin). Age and sex distribution in 354 patients (soldiers excluded). Key: white = males, black = females.

*Perforating injuries*—Perforation of the globe occurred in 242 patients (56%). On the whole, complications from these injuries were more severe than those following contusion injuries. Many perforating injuries were caused by gunshots and bomb blasts in soldiers, and these eyes were often shattered beyond repair, with surgery consisting principally of debridement and repair of the socket. Severe perforating injuries were also caused by wood (wood-splitting and twigs) during work on the farm. Such injuries were often complicated by large iris prolapses through lacerated cornea, traumatic cataracts, or sometimes loss of vitreous and the lens or both. Many farm injuries were complicated by severe endophthalmitis even when the injury itself did not seem severe.

*Contusion injuries*—These occurred in 162 patients (37.4%). The commonest complication was intraocular hemorrhage, which occurred in 65 patients. Vision was often lost from secondary intractable glaucoma, organization of blood in the anterior chamber, or blood staining of the cornea. Traumatic cataracts occurred in 60 patients with contusion injuries; subluxation of cataractous lenses occurred in 12 patients.

*Other injuries*—Endophthalmitis occurred in 27 patients. Ten of these cases were due to nonperforating injuries with hypopyon, which, with neglect, often proceeded to panophthalmitis. In 9 patients soil got in their eyes while digging or hoeing, and in these, infected corneal ulcers caused maceration and necrosis of the cornea. Four patients were blinded by burns, three by chemicals and one by fire. A detailed list of injuries and complications is shown in Table 2.

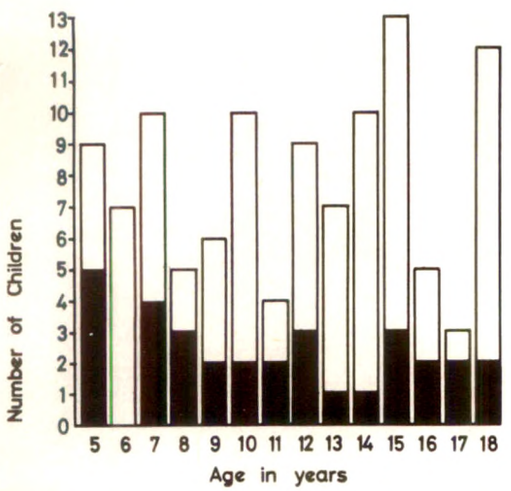

Fig. 3 (Olurin). Age and sex distribution in 110 children blinded by trauma. Key: white = males, black = females.

TABLE 1

INCIDENCE OF EYE INJURY BY OCCUPATIONAL GROUPS IN 433 PATIENTS

| Occupation | No. Patients | Percentage |
|---|---|---|
| School children | 110 | 25.4 |
| Farmers | 106 | 24.5 |
| Industrial workers | 52 | 12.0 |
| Medium grade office workers | 13 | 3.0 |
| Executives and professionals | 18 | 4.1 |
| Housewives | 29 | 6.7 |
| Tradesmen | 18 | 4.1 |
| Soldiers | 80 | 27.5 |
| Old age pensioners | 1 | 0.2 |
| Unemployed | 6 | 1.4 |
| Total | 433 | 100.0 |

*Occupational injuries*—These activities accounted for 212 injuries (49%), including those occurring during military service (Table 3). The total number of injuries sustained during occupational activities other than military service was 133 (30.6%). Household activities caused eye injuries in 98 (22.5%) patients. Play or sport accounted for injuries in 80 (18.5%) patients.

By far, the commonest agents were twigs, sticks, and pieces of wood, causing 182 (41.9%) severe eye injuries. Guns and explosives came next, causing 82 eye injuries —79 of these were in soldiers.

*Disability*—The rate of permanent disability was high. In this part of the country, people do not often come to the hospital for minor eye injuries, thus most of the injuries seen in the eye clinic are severe. There was no light perception in the injured eyes of 187

TABLE 2

TYPES OF EYE INJURIES AND COMPLICATIONS IN 433 PATIENTS

| Complications | Total No. | Percentage | Diagnosis | | |
|---|---|---|---|---|---|
| | | | Contusion Injuries | Penetrating Injuries | Others (Burns, Ulcers, etc.) |
| Intraocular hemorrhage | 65 | 15.0 | 65 | — | — |
| Traumatic cataracts | 94 | 21.7 | 60 | 34 | — |
| Secondary glaucoma | 45 | 10.25 | 37 | 8 | — |
| Ruptured globe | 8 | 1.7 | 8 | — | — |
| Luxation or subluxation of the lens | 12 | 2.8 | 12 | — | — |
| Retinal detachment | 3 | 0.7 | 3 | — | — |
| Endophthalmitis | 27 | 6.3 | — | 17 | 10 |
| Corneal necrosis, anterior staphyloma | 12 | 2.8 | — | 4 | 8 |
| Iris prolapse | 150 | 35.0 | — | 142 | 8 |
| Traumatic uveitis | 6 | 1.4 | 6 | — | — |
| Sympathetic ophthalmia | 2 | 0.46 | — | 2 | — |

patients when they were first seen. Many traumatic cataracts were associated with almost total occlusion of the pupil from secondary uveitis. In patients who had traumatic cataracts extracted, unilateral aphakia rendered the patient uniocular for most activities. Restoration of useful vision was therefore seen only in about 8% of the patients. Enucleation was the obvious treatment of choice in about 40% of the patients, but half of these refused the operation, preferring discomfort in a totally blind and a potentially

TABLE 3

ACTIVITY WHEN INJURED AND AGENTS CAUSING EYE INJURY IN 433 CASES

| | Male | Female | Total | Percentage |
|---|---|---|---|---|
| Activity: | | | | |
| Occupational | 122 | 11 | 133 | 30.0 |
| Military | 79 | — | 79 | 18.5 |
| Household | 60 | 38 | 98 | 22.5 |
| Play or Sport | 66 | 14 | 80 | 18.5 |
| Traffic or transport | 17 | 2 | 19 | 4.4 |
| Acts of violence and falls | 10 | 5 | 15 | 3.5 |
| Accidents in schoolroom | 6 | 3 | 9 | 2.0 |
| Total | 360 | 73 | 433 | 100.0 |
| Causes of accidents: | | | | |
| Twigs, sticks, pieces of wood, tree branches, grass blades | 159 | 40 | 199 | 44.9 |
| Cutlass or knife | 6 | 4 | 10 | 2.4 |
| Guns and explosives | 80 | 2 | 82 | 18.9 |
| Motor traffic accidents | 17 | 2 | 19 | 4.3 |
| Palm kernel chips | 6 | 9 | 15 | 3.5 |
| Injury by fingernail, hand, fist | 10 | 5 | 15 | 3.5 |
| Gravel | 8 | 1 | 9 | 2.1 |
| Tools and working materials | 21 | 2 | 23 | 5.4 |
| Other | 53 | 8 | 61 | 14.0 |
| Total | 360 | 73 | 433 | 100.0 |

dangerous eye. Twenty-six patients (20 males) were rendered blind in both eyes as a result of their injury (Table 4), but 10 of these were already blind in one eye from some earlier cause. Two patients lost second eyes from sympathetic ophthalmia. Seven patients were blinded by occupational injuries, seven were soldiers engaged in military activity, and six were blinded as a result of activities at home. Three of the totally blinded patients were children.

*Injury in school children*—There were 110 children studied in this group (Table 5). There were 78 boys and 32 girls, or a ratio of 2.4:1 (Fig. 3).

A large variety of agents caused eye injuries in these children, but these agents were different from those of other countries. In England, for example, Lambah[13] found that arrows, catapulted missiles, fireworks, and air gun pellets were responsible for the majority of eye injuries in the group he studied. They were rare causes of eye injury in our group. This is due to the difference in types of play and toys used in the two groups. Possibly, the pattern here will change with increased industrialization. There was no striking difference in the incidence of blindness in the different age groups. Injuries at play had the greatest incidence, accounting for 70 of 110 children. This included play at school and outside, but not inside, the home. There were 29 injuries in the home, three due to traffic accidents, and eight sustained in the classroom. Five classroom injuries were inflicted by a teacher's cane, one by a pen nib, one by a needle that penetrated the cornea, and one was caused by a blow delivered with a writing slate. Most boys were injured at play, whereas injuries in the home were relatively more common in girls. Perforating injuries were the commonest types of injury in children, occurring in 59 patients. Contusion injuries occurred in 41 children: falls, five; motor traffic accidents, three; chemical burns, one; and gravel, one. The types of complication and high rate of disability was similar to that seen in the adult group. Three children lost the sight of both eyes, one of them from sympathetic ophthalmia. This last child was the first patient in this clinic to have such a complication. The history was that of a neglected corneoscleral rupture by a door handle, with prolapse of uveal tissue, two months before consultation. There was a lower half corneociliary staphyloma and active uveitis in the uninjured eye on the first visit. Despite treatment with corticosteroids, the boy, aged 12, rapidly became blind. The only other occurrence of sympathetic ophthalmia in the series was in a 22-year-old soldier who refused enucleation after a retained intraocular foreign body in a blind, painful eye. Sympathetic ophthalmia is said to have a higher incidence amongst young persons.[14]

## Comments

Eye injuries are of major socioeconomic importance, particularly from the preventive view. The activity of the individual plays an important part in the cause of injury, hence causes of eye injuries in children differ from those in adults. The largest number of eye injuries in children are sustained at play; in this study they accounted for 70 of 110 (63.6%) cases. Many could have been prevented—such injuries include those from firearms, knives, cutlasses, and many of the injuries in the classroom and the home. Leisure activities, which featured prominently as causes of eye injury in adults in other studies,[1,11] were infrequent in this study, accounting for only 10 of 323 (3%) eye injuries. This perhaps reflects the mode of life in this community, where few adults engage in active sports, games, or active hobbies. Occupational activities (excluding military activities) accounted for 30% of ocular injuries in the study as a whole, and 40% of eye injuries in adults alone. Most of these were agricultural injuries. It is tempting to assume that with better agricultural methods such injuries would not occur, but even in Sweden with modern farming methods, Lindstedt[15] remarked on the high incidence

TABLE 4

BLINDNESS IN BOTH EYES DUE TO EYE INJURY
(26 patients)

| No. | Age | Sex | Occupation | Type of Activity | Cause of Injury | Type of Injury | Complication | Eyes Lost From Injury | Cause of Loss of First Eye |

of eye injury in branches of forestry and farming. Household activities caused eye injuries in 60 of 433 patients (22.5%); this was almost equally as common in males as females, and many could have been prevented.

The high rate of disability is due to a number of factors. The study is limited to the severer forms of eye injuries, because the majority of minor injuries are seen elsewhere. Often, the damage to the eye at time of injury was so severe that useful vision could not have been achieved whatever the treatment. Nevertheless, the long delay in seeking help was a contributing factor, especially in patients who developed secondary infection, or secondary glaucoma from hemorrhage and the like. All perforating injuries were severe and many involved tears and prolapse of uveal tissue, with incarceration for long periods. Some eyes remained inflammed for many weeks or even months. The low incidence of sympathetic ophthalmia is notable (2 out of 433 patients). In two other studies,[6,11] sympathetic ophthalmia was responsible for blindness in 2.8% and even 6.7%, although both authors stated that it rarely occurred after 1950. It is difficult to say whether or not the low incidence in the present study is due to racial immunity,[14] or whether the high rate of infection protected the patients in this series against sympathetic ophthalmia.

TABLE 5

CAUSES OF EYE INJURY IN 110 CHILDREN

| | Total No. | Percentage |
|---|---|---|
| Activity when injured: | | |
| Play activity | 70 (57 boys) | 63.6 |

Although there have been no previous detailed reports on the causes and types of eye injuries in Nigeria, it is likely that the picture will be similar in all parts of this country except for the larger and newly industrialized towns. Eye injury in children will probably continue to be due to similar etiologic factors, but as the country gradually becomes more industrialized, it will be helpful to compare this study with future ones.

## SUMMARY

This report from the eye clinic of the University College Hospital, Ibadan, Nigeria, reviews 433 cases of severe eye injury seen between 1963 and 1970. It yields data in regard to the character, incidence, and causes of severe eye injury, and compares the results with studies from other countries. Eye injury in 110 children, accounting for a quarter of the series, has been studied separately and compared with injury in adults.

OPHTHALMIC MINIATURE

Great men have a curious way of appearing in complementary pairs. This has happened so often in history that I don't think it can have been invented by symmetrically minded historians, but must represent some need to keep human faculties in balance. However that may be, there is no doubt that the two great musicians of the early eighteenth century, Bach and Handel, fall into this pattern of contrasting and complementary personalities. They were born in the same year—1685; they both went blind from copying musical scores and were operated on, unsuccessfully, by the same surgeon. But otherwise they were opposites.

# ATYPICAL MYCOBACTERIA AND UVEITIS

JANET C. WEBER, PH.D., AND T. F. SCHLAEGEL, JR., M.D.
*Indianapolis, Indiana*

AND

JOHN S. CHAPMAN, M.D.
*Dallas, Texas*

As part of a long-term study of the causes of uveitis, the responses of the sera of uveitis patients to the antigens from 12 strains of atypical mycobacteria were studied. Atypical mycobacteria, once thought harmless, are now known to produce granulomatous lesions.

Sera from uveitis patients are found to react with mycobacterial antigens more frequently than sera from any other group studied except patients with sarcoidosis.[1] The purpose of this paper is to attempt an explanation for this reactivity.

## MATERIALS AND METHOD

Undiluted sera from 364 patients with all types of uveitis and from 191 blood donors were subjected to agar diffusion against antigens from 12 strains of atypical mycobacterial.[1] The sera from the blood donors were supplied by the Indiana University Medical Center Blood Bank. The donors were unselected, and the only information given was age, sex, and that they met the usual criteria required for blood donation. The reactivity of a serum was measured by the number of precipitation lines formed in the agar between the serum and the antigen.

The atypical mycobacteria have been divided into four groups: the photochromogens, the scotochromogens, the nonchromogens, and the rapid growers. We were concerned only with the first three groups. The numbers following the P's in Table 1 refer to strains obtained from Runyon. PC, SC, and NC are mixtures. T6D6 is a wild strain isolated from muddy soil. The uveitis patients also received the battery of skin tests previously reported.[2]

TABLE 1

SEROLOGIC REACTIVITY TO GROUPS OF ATYPICAL MYCOBACTERIA BY UVEITIS PATIENTS AND BLOOD DONORS

| Antigens | Percent of Patients Reacting | |
|---|---|---|
| | Uveitis Patients (364) | Blood Donors (191) |
| Photochromogens (Group 1) PC, P1, P8 | 9.61 | 21.99 |
| Scotochromogens (Group 2) SC, P6, P15, T6D6 | 48.35 | 14.14 |
| Nonchromogens (Group 3) NC, P44, P2, P17, P39 | 53.02 | 19.90 |

## RESULTS

Table 1 shows that uveitis patients differ ($p < 0.001$) from blood donors in their reactivity to the three Runyon groups of atypical myobacteria. Since atypical mycobacteria are widespread and tend to have antigens in common, they were considered in groups. A reaction to one or more members of a group was considered a reaction to the group. Some patients and donors showed reactions to more than one group and are included in the figures for each group to which they showed reactivity.

The significance of a single precipitation

TABLE 2

SEROLOGIC REACTIVITY TO ATYPICAL MYCOBACTERIA IN VARIOUS UVEITIS DIAGNOSTIC CATEGORIES

| Diagnostic Category | Percent of Patients Reacting | | | Total Cases |
|---|---|---|---|---|
| | Group 1* | Group 2* | Group 3* | |
| Histoplasmosis | 8.91 | 50.49 | 58.42 | 101 |
| Toxoplasmosis | 14.06 | 46.88 | 51.56 | 64 |
| Peripheral uveitis | 11.54 | 26.92 | 30.77 | 26 |
| Unknown etiology | 5.00 | 55.00 | 52.00 | 100 |
| All others | 12.33 | 45.20 | 56.16 | 73 |

* Group 1: PC, P1, P8 (photochromogens); Group 2: SC, P6, P15, T6D6 (scotochromogens); Group 3: NC, P44, P2, P17, P39 (nonchromogens).

line in the case of the mycobacteria is a matter of controversy. Some workers[1] believe that such a line is due to a nonspecific lipopolysaccaride. Others[3,4] feel that any line of precipitation must be accounted for. Since antigens from atypical mycobacteria are not pure, since the strains overlap, and since only two groups of patients (those with sarcoidosis and uveitis) show a preponderance of two or more lines of reactivity, we chose to define a reactor as an individual who showed two or more lines of reactivity as opposed to one or less lines of reactivity.

TABLE 3

FACTORS ANALYZED

1. Characteristics of the patients:
   - Age
   - Sex
   - Race
   - Place of residence (urban or rural)
2. Characteristics of the uveitis:
   - Type of inflammation (granulomatous or nongranulomatous)
   - Course of the disease (acute, chronic, or recurrent)
   - Severity of the disease (mild, moderate, or severe)
   - Site of the inflammation (anterior, posterior, or both)
   - Type of lesion (iritis, cyclitis, iridocyclitis, retinitis, choroiditis, chorioretinitis, papillitis, pars planitis, focal, disseminated or diffuse lesions)
   - Presence or absence of macular involvement
   - Presence or absence of prior trauma
3. Reactivity to any of 18 different skin tests
   - Sedimentation rate
   - Serum electrophoresis
   - Differential white blood cell count

The percentage of patients showing positive tests to atypical mycobacteria may be seen in Table 2. They are grouped by diagnostic category. Reactivity to more than one group was common. This was particularly true of Group 2 and Group 3.

No relationships could be found between reactivity to one or more atypical mycobacteria and any combination of factors (Table 3). In other words, we could not find a patient/disease pattern that could be linked with positive reactions to any of the positive mycobacteria.

We, therefore, investigated the possibility that the reactivity of uveitis patients to atypical mycobacteria might be due to the immunologic characteristics of the patients rather than to their disease process. Since we had already studied the immunologic characteristics of uveitis patients with respect to skin testing,[2] we decided to compare the skin test reactivity of these patients with their serum agar diffusion reactivity to atypical mycobacteria.

The measure of reactivity was a ratio. In the numerator was the number of tests positive, and in the denominator, the number of tests done. The number of skin tests done varied from 10 to 18. The number of agar diffusion tests was 10 or 12. We applied the Freeman-Tukey Angular Transformation to the ratios in order to obtain values suitable for statistical analysis.[2] This transformation is the method of choice for dealing with ratios, since it gives due weight to the denominators, which the use of percentages does

TABLE 4

AGE, DIAGNOSIS, AND PERCENTAGE REACTING TO SKIN AND AGAR DIFFUSION TESTS

| Age | | Histoplasmosis | | Toxoplasmosis | | Unknown Etiology | | Peripheral Uveitis | |

* Unweighted means.

not. For easier comparisons, however, values have been transformed into percentages in Table 4. Each cell contains the mean percent of positive reactors. It includes the positive reactors for the skin tests and the agar diffusion tests against atypical mycobacteria. Only those diagnostic categories were included which gave reasonable cell frequencies. This limited our study to the major types of uveitis seen. Age is included as a dimension since it has been found that skin test reactivity does vary with age.[2] The values were subjected to an analysis of variance. In regard to skin test reactivity both diagnosis and age were significantly different (Table 5) which confirms our previous report.[2]

The analysis for the agar diffusion results revealed that the diagnostic categories differed significantly, but there was no significant change with age of the patients (Table 6). The reason for this may be that whereas the

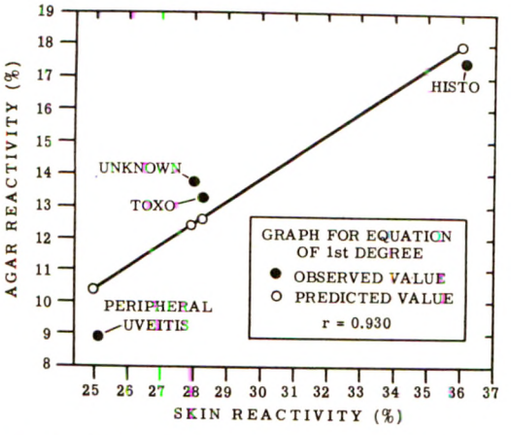

Fig. 1 (Weber, Schlaegel, and Chapman). Graph for equation of first degree.

reactivity to skin tests of all types falls off with age, the reaction to agar diffusion does not.

Linear regression analysis applied to the unweighted means (last row of Table 4) shows (Fig. 1) the relationship between the two measures of immunologic reactivity in the uveitis diagnostic groups. The positive correlation between the two measures ($r = 0.930$) is significant at the 5% level.

## Discussion

Patients with presumed histoplasmic choroiditis react to many antigens besides histoplasmosis—both by skin testing and by agar diffusion. Patients with peripheral uveitis react to very few antigens by either method. Those with toxoplasmosis and uveitis of unknown etiology are intermediate in reactivity on both measures (Fig. 1).

Another possible explanation for the presence of antibodies against atypical mycobacteria in patients with uveitis could be that these organisms may act somewhat in the nature of Freund's adjuvant with respect to some other antigen. Acid-fast organisms, either with or without an oil, may maintain some type of tissue contact which alters the initial reaction from one of simple inflammation to one of cellular hypersensitivity. Thus, in uveitis patients it is possible that atypical mycobacteria might potentiate other types of antigens.

## Summary

Undiluted sera from 364 uveitis patients of all types and 191 unselected blood donors were subjected to agar diffusion against antigens from 12 strains of atypical mycobacteria. The sera of uveitis patients were significantly more reactive to the scotochromogens and nonchromogens and less reactive to the photochromogens ($p < 0.001$) than were the sera of blood donors.

No patient-disease pattern could be linked with positive reactions to any of the atypical mycobacteria.

Comparison of the reactivity of the uveitis patients to a battery of 10 to 18 skin test antigens and the reactivity of their sera to the atypical mycobacteria showed: (1) Patients with presumed histoplasmic choroiditis are highly reactive to both types of antigens; (2) patients with peripheral uveitis react to very few antigens of either type; (3) patients with toxoplasmosis or uveitis of unknown etiology are intermediate in both types of reactivity.

The reactivity of uveitis patients to atypical mycobacteria appears to be a reflection of their immunologic characteristics rather than their disease process. This leads us to postulate that the atypical mycobacteria are rarely, if ever, a direct cause of clinical uveitis.

# DIAGNOSIS OF CRYPTOCOCCAL UVEITIS WITH HYPERTONIC MEDIA

MICHAEL H. GRIECO, M.D., AND DENNIS B. FREILICH, M.D.
*New York, New York*

AND

DONALD B. LOURIA, M.D.
*Newark, New Jersey*

Eye symptoms have been reported ot occur in 44 per cent of patients with cryptococcal meningitis including blurred vision, retrobulbar pain, diplopia and photophobia.[1] Such symptoms are most often due to extraocular causes and reflect elevated cerebrospinal fluid pressure or extraocular muscle paresis. Less often symptoms are due to intraocular infection with Cryptococcus neoformans; occasionally the infection may extend directly along the subarachnoid space into the optic nerve, producing optic neuritis,[2] uveitis, and keratitis,[3] Involvement of the orbit from contiguous skin lesions is rare.[4–6]

The purposes of this report are to present an additional case of probable cryptococcal uveitis and to emphasize the value of the latex slide agglutination test for detecting cryptococcal antigen and the use of hypertonic sucrose media for cultural identification.

## CASE REPORT

A 58-year-old charter boat operator from Montauk, Long Island, developed spots in the visual field of his right eye and retro-orbital pain in February, 1967. He was subsequently noted to have right anterior and posterior uveitis and was managed over a five-month period with triamcinolone in doses varying from 8 to 32 mg daily. During therapy he developed progressive loss of right eye vision and physical findings of severe right chorioretinitis. He was admitted to South Hampton Hospital, Long Island, July 3, 1967, with fever and three days of vertigo with a tendency to fall to the right. While hospitalized it was discovered that a tuberculin test was positive and that the cerebrospinal fluid was abnormal (sugar, 26 mg%; total protein, 268 mg%; white count, 244 $mm^3$ with 114 PMNs and 130 lymphocytes; serology, negative).

July 18, 1967, he was admitted to St. Luke's Hospital Center because of continuing fever. Ophthalmic examination revealed a total retinal detachment in the right eye with severe inflammatory reaction in the vitreous and what appeared to be active inflammatory foci in the retina. There was a 3+ flare and cells in the anterior chamber; a small pupil in this eye was bound down by posterior synechiae. The corrected vision was 20/20 in the left eye and there was absent right light perception. Intraocular pressure was RE: 8 mm Hg, and LE: 14 mm Hg. The vertigo had resolved and the neurologic examination was within normal limits. The hemoglobin was 14.9 g% and the white blood count 18,000 $mm^3$ with a normal differential count. Urine analysis was normal. The serum alkaline phosphatase was 11 King-Armstrong units and a two-hour postprandial sugar was 135 mg%. Protein electrophoresis revealed a gamma globulin level of 790 mg%. A brain scan ($^{99}Tc$) and echoencephalogram were essentially normal. Chest x-ray examination revealed normal lung fields. On July 27, 1967, signs of an abdominal right lower quadrant infection appeared and laparotomy revealed a right lower quadrant appendiceal abscess which improved following surgical drainage and treatment with antibiotics. Retrospectively it appeared likely that the entire febrile course might have been related to the appendiceal abscess.

Six cerebrospinal fluid examinations during this admission were performed. Cultures for Mycobacterium tuberculosis and Cryptococcus neoformans were repeatedly negative. Attempted isolation of fungi included culture at 25° and 37°C on four media: Sabourand-glucose, blood, Littman oxgall and brain-heart infusion agar. Cryptococcal antigen and antibody studies were performed by Dr. Morris Gordon of the New York State Department of Health: The presence of 1:4 spinal fluid and 1:2 serum cryptococcal antigen titers suggested a cryptococcal infection. In view of a positive PPD reaction, intermediate strength, and the failure to isolate a fungus, the patient was discharged on August 31, 1967, on antituberculosis therapy.

The cerebrospinal fluid abnormalities remained essentially unchanged after three months. The spinal fluid of July 26 cultured in hypertonic sucrose media (M/0.3 sucrose in brain-heart infusion broth, enriched with 10% horse serum) to explore the possible presence of microbial L forms showed tiny colonies of two types when subcultured on blood agar,

From the Allergy and Infectious Disease Division, Department of Medicine and the Department of Ophthalmology, St. Luke's Hospital Center, New York City, The Department of Ophthalmology, The Mount Sinai School of Medicine, and the Department of Public Health and Preventive Medicine, The New Jersey College of Medicine and Dentistry.

one appearing microscopically like cells of Candida and the other appearing diphtheroid-like. Both were considered contaminants and were placed in the refrigerator. Two months later the colonies were again examined. The small colonies containing Candida-like cells all now showed typical encapsulated cryptococci. The diphtheroid-like colonies were unchanged; 10 of these were transferred to blood agar on different days; each of these, on subculture, appeared as large mucoid colonies consisting of typical encapsulated cryptococci. Subsequently, this isolate was definitely identified as mouse-virulent C. neoformans. It appeared likely that the uveitis was due to an infection with this agent, although mycologic studies of the eye were not performed. Amphotericin B therapy was initiated on November 7 with increasing intravenous doses administered daily together with 25 mg of hydrocortisone in an infusion over three hours for a total dose of 2.0 gm. Spinal fluid cultures on February 9 and 24, and September 23, 1968, were negative on hypertonic sucrose media. His right eye became quiet and comfortable but remained without light perception. Visualization of the posterior segment was not possible due to cataract lens changes and vitreous opacification.

## Comments

Review of the literature reveals at least 13 previously reported cases of probable cryptococcal uveitis since 1948.[1,7-17]

Of the previously reported cases, in nine there was histologic evidence of cryptococcal involvement of the uveal tract. In three cases, the eyes were not examined histopathologically[1,13,15] and in the case reported by Weiss and associates[7] pathologic examination revealed only granulomatous inflammation.

Two additional unreported cases of cryptococcal uveitis are on file in the registry of Ophthalmic Pathology.[16] In addition, one of us (D.B.F.) has recently seen a 65-year-old Caucasian woman who presented with acute right hemiplegia followed in several weeks by anterior and posterior uveitis as well as retinal detachment. Subsequent autopsy revealed C. neoformans meningoencephalitis but the eye was not examined.

## Pathogenesis

The intraocular structures may be involved either by direct extension from the central nervous system along the meningeal sheaths of the optic nerve of via the blood stream from a localized or disseminated cryptococcal infection. An important observation is that in each of the seven cases in which culture results are reported, C. neoformans was cultured from the spinal fluid. This, cryptococcal uveitis is frequently accompanied by meningeal involvement indicating that eye involvement usually results from spread along the optic nerve. Whether the ocular involvement starts in the retina or choroid, or in some cases, as simultaneous involvement of both structures, is difficult to establish. Since C. neoformans has a marked affinity for the brain and meninges, perhaps the sensory retina may also be extraordinarily susceptible to cryptococcal invasion. Cryptococcosis often complicates malignant lymphoma, and three of 13 patients had a reticuloendothelial malignancy, an incidence of 23%. An additional patient was a premature infant and another was in her third trimester of pregnancy. Eleven of the 13 previous patients have been males. There was no evidence to suggest augmentation of infection by antibiotics, corticosteroids or antimetabolites.

## Diagnosis

The patient presented here, without underlying disease, developed cryptococcal uveitis associated with transient dizziness but without physical findings of focal neurologic involvement. A routine cerebrospinal fluid examination revealed increased lymphocytes and protein and decreased glucose and choloride but the etiologic agent escaped isolation by routine culture.

Examination of the cerebrospinal fluid reported in eight of these patients was consistently abnormal. This indicates that cerebrospinal fluid examination is essential to the diagnosis of cryptococcal uveitis and should be considered in the evaluation of any patient with persistent uveitis of undetermined etiology, especially if progressive deterioration occurs despite corticosteroid therapy. Of the 14 reported cases, this is the ninth to be diagnosed during life. The diagnosis was suggested in this patient by progressive uveitis

despite triamcinolone therapy, abnormal spinal fluid, and the presence of cryptococcal antigen in the serum and CSF and later verified by hypertonic sucrose media culture.

Delayed reactions to cryptococcin skin test antigen frequently occur in patients with active cryptococcosis, with treated, inactive cryptococcosis, or with exposure to cryptococci in the environment, but the test may be positive in apparently normal persons. Epidemologic data are thus far fragmentary, and the skin test cannot yet be utilized to suggest the diagnosis of active cryptococcal infection.[18-20] The determination of cerebrospinal fluid alcohol concentration is unlikely to be helpful since strains of C. neoformans vary markedly in alcohol production.[21]

A significant development was the description of a complement-fixation test to detect circulating cryptococcal polysaccharide.[22] More recently Gordon and Vedder[23] found that a latex slide agglutination test for cryptococcal antigen was sensitive and specific as a diagnostic tool. Studies for cryptococcal antigen are most effective when used in conjunction with whole yeast cell agglutination tests for cryptococcal antibody since there appears to be an inverse relationship between the two. Of 14 cases in which specimens of body fluid, usually both serum and CSF, were obtained during the period of positive cryptococcal cultures, antigen was demonstrated in 11, antibody in two, and neither in one. Both the latex slide agglutination test for cryptococcal antigen and the whole-cell agglutination test for cryptococcal antibodies appear to be highly specific. Similar results have been reported by Bindschadler and Bennett[24] in 75 patients with cryptococcosis using an indirect fluorescent test for serum anticryptococcal antibody and a complement fixation test for serum and cerebrospinal fluid cryptococcal antigen. Although the CF test for antigen has been specific for cryptococcosis, a few false-positive tests for antibody were found. The presence of cryptococcal antigen in the spinal fluid and serum of the patients reported here definitely helped to lead to the correct diagnosis. The spontaneous decrease in titer prior to the institution of amphotericin B therapy is worthy of note but remains unexplained.

It has been previously emphasized that cryptococci may be isolated with difficulty from some patients with cryptococcal meningitis and that it is important in these cases to plant a large volume of spinal fluid on each of several small flasks of agar. Use of a flask of agar permits a long incubation period without undue evaporation of water from the medium.[25] The recovery of an aberrant form of C. neoformans from cerebrospinal fluid has been reported once previously, but no details of the other patient has been reported.[26] The value of cultivating for wall deficient microbial variants by using hypertonic media which protect the organisms from osmotic stress has also been shown to be useful in another yeast infection. In three instances, wall defective forms of Candida have been recovered from human blood.[27-28] Watanakunakorn and associates[27] grew Candida parapsilosis from blood in hypertonic media at a time when routine cultures were negative. Rosner[28] recovered L forms from the blood of a patient with endocarditis; after multiple subcultures these organisms reverted to a strain of Candida tropicalis. An extensive discussion of clinical infections associated with the isolation of aberrant forms of bacteria and fungi including a presentation of the bacteriologic findings in this case was recently published.[29]

Since chemotherapy with amphotericin B is available for the therapy of infections due to C. neoformans, it is important to consider this etiology in the evaluation of patients with uveitis of undetermined etiology, particularly if the disease progresses despite corticosteroid therapy. The majority of cases will be detected by cerebrospinal fluid examination and examination of the fluid and serum for cryptococcal antigen. In the presence of abnormal cerebrospinal fluid findings and a negative culture, diagnosis may be established by culture on hypertonic sucrose media.

## Summary

A probable case of cryptococcal uveitis is reported. The frequent occurrence of meningeal involvement is indicated by abnormal cerebrospinal fluid findings and cultural isolation of Cryptococcus neoformans in all patients in which these studies have been presented. The value of cultivating for wall-deficient microbial variants by using hypertonic media had been previously demonstrated in candidiasis and is further supported by the recovery of aberrant forms of C. neoformans in the cerebrospinal fluid of this patient. The usefulness of the latex slide agglutination test for detecting cryptococcal antigen is again emphasized.

Since chemotherapy with amphotericin B is available for the therapy of infections due to this organism, it is important to consider it in the evaluation of patients with uveitis of undetermined etiology, especially when corticosteroid therapy is ineffective.

# OCULAR TOXIN OF THE PNEUMOCOCCUS

MARY K. JOHNSON, PH.D., AND JAMES H. ALLEN, M.D.
*New Orleans, Louisiana*

Although the pneumococcus often is cited as an example of an organism which produces disease purely by means of its invasiveness, there are in the literature numerous suggestions of toxic activity on the part of this organism. These include reports by Shumway and Polack[1] of spherocytic anemia in rabbits infected with pneumococci or treated with concentrates of hemolysin; a report by Halbert and associates[2] of lethal and dermonecrotic effects of the purified hemolysin upon injection into the mouse; a report by Dick and Gemmell[3] of a variety of toxic effects produced following intraperitoneal injection of pneumococci; and a report by Blackman and associates[4] of acute nephritis produced by means of a pneumococcal autolystate. The extensive damage to corneal tissue and the hypopyon which characterize pneumococcal infection of the cornea suggested to us that toxic factors might play a role also in the pathogenesis of pneumococcal ulcer. This paper reports an experimental investigation of this possibility.

## MATERIALS AND METHODS

*Preparation and treatment of extract*—The organism used was an encapsulated Type XXI strain of Diplococcus pneumoniae isolated from a corneal ulcer and maintained in the lyophilized state. Pathogenicity of this strain for the rabbit eye was demonstrated by production of keratitis following intracorneal injection of about $10^6$ viable organisms. In agreement with the results of many other investigators, we found that instillation of viable bacteria ($10^9$) onto the conjunctiva of the rabbit did not produce conjunctivitis.

The bacteria were cultivated in filtered trypticase soy broth with 1 g per liter of $CaCO_3$ and harvested by centrifugation in the late exponential or early stationary phase of growth. The cells were washed with phosphate-buffered saline and stored at −60° C. Cell-free extracts (containing 3-5 mg protein/ml) were prepared in the Mickle cell disintegrator or by use of the French pressure cell, followed by centrifugation to remove whole cells and debris. When necessary, sterilization of the extract was accomplished by Millipore filtration.

Concentration of extracellular proteins in the culture fluid was effected after removal of cells by addition of ammonium sulfate to 90% saturation, stirring for several hours or overnight, redissolving the precipitate, and dialyzing against distilled water or buffer.

Protein content of these preparations was determined by the method of Lowry.[5]

For extraction of lipoidal material, the crude cell-free extract was lyophilized (a procedure which does not destroy toxicity) and then extracted five times with chloroform-methanol (2:1, v/v). After evaporation of the solvent, the extracted material was emulsified in phosphate-buffered saline. Separation of polysaccharide components of the extract was effected by addition of two volumes of ethanol, followed by centrifugation. The water-soluble portion of the precipitated material was diluted with phosphate-buffered saline before testing. Pneumococcal capsular polysaccharide was isolated from trypticase soy culture medium by the method described by Kabat.[6]

In treatment of the extract with deoxyribonuclease, 1 ml was incubated for 30 minutes at 0° C. with 0.05 mg salmon sperm de-

From the Departments of Ophthalmology and Microbiology, Tulane University School of Medicine, New Orleans. This investigation was supported by USPHS Grant 1 RO1 EY 00424 from the National Eye Institute, National Institutes of Health, Bethesda, Maryland, and by a grant from Research to Prevent Blindness, Inc.

oxyribonuclease (Calbiochem, A grade). Treatment with trypsin was accomplished by incubation of 1 ml of extract at 37° C. for 60 minutes with 0.5 mg enzyme (Worthington, TRL 6JA).

*Animal experiments*—Tests for toxic activity of the extracts were made on the eyes of adult albino rabbits. Variability in the response of different animals to the same preparation made it necessary to use one eye of each rabbit as a control on the level of response of that individual. Conjunctival instillation was accomplished by dropping the sterile preparation into the eye at a rate of 1 drop (approximately 0.05 ml) every 20 minutes. Intracorneal injection was effected with a 30-gauge needle after instillation of local anesthetic (Ophthaine).

*Enzyme assays*—Enzyme assays were performed as follows: hyaluronidase and chondroitinase by the method of Nakada and associates.[7] Keratanase was assayed by incubating 1 ml of extract with 2 ml 0.05 M buffer (acetate, pH 4.0, citrate, pH 5.5, or Tris-HCl, pH 7.8) and 2 mg keratosulfate for periods up to 12 hours, followed by measurement of release of reducing sugar by the method of Nelson[8] and amino sugar by a modification of the Elson-Morgan reaction described by Ashwell and associates[9] for 2-acet-amido hexoses. Both β-galactosidase[10] and β-acetylglucosaminidase[11] were assayed by the methods described by Hughes and Jeanloz. Lipase was assayed by the method of Lawrence and associates.[12] Proteinase was assayed by incubation of 0.5 ml crude extract with 0.5 ml 0.2 M buffer (acetate, pH 5.3 or Tris-HCl 7.5 or pH 8.8) and 0.5 ml of 2% diazocasein for 60 minutes at 37° C, followed by the addition of 3.5 ml 5% trichloracetic acid, filtration, addition of 0.5 ml 0.5 M NaOH, and reading of optical density in the Klett colorimeter with the blue filter, or by incubation with 2% gelatin followed by detection of the release of amino acids by the ninhydrin reaction as described by Hirs.[13] Peptidase was measured by incubation of 0.1 ml extract with 0.5 ml of leucyl-glycyl-glycine (2.5 mg/ml) and 0.4 ml Tris-HCl buffer (pH 7.5, 0.1 M), followed by removal of samples at varying time intervals for determination of liberated amino acids by the ninhydrin reaction as described above. Phospholipase C was assayed by the method of Kushner,[14] employing egg yolk saline, purified lecithin, or sphingomyelin. Activity was measured also in the presence of 0.01 M $Ca^{++}$, $Mg^{++}$, or $Co^{++}$.

*Hemolysin assay*—Hemolytic activity was determined with rabbit erythrocytes washed twice with phosphate-buffered saline and suspended in the same medium at a concentration of about 2%. Varying levels of extract were incubated with 1.5 ml erythrocyte suspension plus phosphate-buffered saline to a total volume of 3 ml for 30 minutes at 37° C with frequent gentle shaking. The intact cells were then sedimented by centrifugation and the hemoglobin in the supernatant layer estimated by reading the optical density at 541 mμ on a Bausch and Lomb Spectronic 20 spectrophotimeter. The $HD_{50}$ (amount of extract producing 50% hemolysis) was read from a plot of extract concentration vs optical density in the region from 20 to 75% hemolysis where this relationship is linear.

## Results and discussion

Instillation of sterile crude extract into the rabbit eye produced swelling, redness of the conjunctiva, and a purulent discharge (Fig. 1). The purulent material showed a typical acute inflammatory pattern with polymorphonuclear leukocytes predominating. These symptoms appeared in from 45 minutes to two hours after the first drop was instilled, depending on the strength of the extract and varying also from one rabbit to another. The treated eye appeared normal on the next day except for the presence of considerable quantities of dried purulent material.

When 0.01 to 0.02 ml of sterile extract was injected intracorneally, the response elicited included the above signs plus diffuse

corneal haze, iritis, and circumcorneal injection (Fig. 2). These signs appeared shortly after the injection, were even more severe at 24 hours when an extensive corneal opacity was observed (Fig. 3), and persisted for several days, leaving a small amount of residual scarring at 13 days. The control inoculation of phosphate-buffered saline produced a transient corneal haze, considerably less extensive than that in the test eye, and which was almost entirely clear in a few hours.

The properties of the toxic factor or factors responsible for the production of these effects have been studied by subjecting the extract to a variety of physical and chemical procedures and observing their effect on toxic activity. The results of this study are shown in Table 1.

Exhaustive dialysis (24 hours with a 5000-fold ratio of dialysand to dialysate) against buffer or water did not reduce the toxic activity of the extract as measured by the effect produced upon conjunctival instillation, indicating that the toxicity is due to the presence of a relatively large molecule. The effects produced upon intracorneal inoculation also were not reduced by previous dialysis of the extract. The factor was relatively heatstable, being only partially inactivated after three minutes at 100° C and still showing some capacity to provoke production of purulent discharge after 10 minutes at 100 ° C. The results of testing toxic activity of a chloroform-methanol extract of the preparation indicated that the material is not lipoidal, and the results of the alcohol treatment indicated that it is not a polysaccharide. Also, conjunctival instillation of purified

| Treatment with trypsin | | None |

* Also tested by intracorneal injection.

† D, S, R: production of discharge, swelling, and redness, respectively, upon conjunctival instillation.

capsular polysaccharide produced no response. The precipitability by ammonium sulfate (confirmed also for intracorneal toxic activity) and the susceptibility to trypsin strongly suggest that the toxic material is protein in nature, although its heat stability is unusual for a protein.

A concentrate of ammonium-sulfate-precipitable constituents of the culture medium prepared after removal of cells did not produce a toxic effect. Therefore, we assume that the factor is normally part of the intact pneumococcal cell body. Different methods of cell treatment have been examined in order to study conditions under which the factor might be released from the cell. The results of these experiments are shown in Table 2. No detectable toxin was released from freshly harvested exponential phase cells as evidenced by lack of response to the instillation of unbroken cells. Toxin was relased when the cells were allowed to grow into stationary phase, or when the cells were stored, or when the cells were frozen as judged by the response to instillation of unbroken cells. We conclude that some release of toxin takes place under many types of suboptimal conditions.

In an attempt to determine the nature of the toxic factor, we have studied numerous degradative activities of the pneumococcal extract (Table 3). Hyaluronidase activity was present, as one would expect in a pneumococcus. The level of activity was not very high, however, and was not increased by inclusion of hyaluronate in the growth medium. No chondroitinase activity was detected by this method, even when cells were grown in the presence of chondroitin sulfate. Since most of the corneal mucopolysaccharide is keratan sulfate, exhaustive tests for keratanase activity were conducted. No activity was detected in cell extracts tested at pH 4, 5.5, or 8, even when keratan sulfate was included in the growth medium. Glycosidases which are capable of hydrolyzing

TABLE 2

EFFECT OF VARIOUS METHODS OF CELL TREATMENT ON TOXIC ACTIVITY

| Preparation of Cells | Toxic Activity (as compared to that of crude extract) |

the type of oligosaccharides which would result from keratanase activity (i.e., β-acetylglucosaminidase and β-galactosidase) were found to be present in the cell extract. Lipase activity was detected on a tributyrin substrate. The lipase was not inactiviated by heating for three minutes at 55° C, but was completely inactivated by three minutes at 100° C. Since some toxic activity remains after this heat treatment, it would seem that the lipase probably does not play a major role in production of toxic effects.

Proteolytic activity, as measured by release of amino acids from casein or gelatin, was not detected in cell extracts. Bacteriologic tests for the hydrolysis of gelatin were also negative. However, a high level of peptidase activity was demonstrated on leucyl-glycyl-glycine. This enzymatic activity showed a heat sensitivity which paralleled that of the toxic factor, and thus it may be involved in the production of the toxic effects.

The pneumococcal extract contains an active hemolysin. The hemolysin does not appear to be involved in the production of toxic effects, as it was completely inactivated by heating for three minutes at 55° C, a procedure having no effect on toxic activity. We have attempted to measure phospholipase C activity on numerous substrates, as in some bacteria this enzyme is responsible for hemolytic activity. However, no phospholipase C activity was detected.

At present we are planning to fractionate the cell extract with gel filtration, column chromatography, and electrofocusing techniques and to follow toxic activity and the activity of the degradative enzymes in an attempt to correlate the two.

TABLE 3

DEGRADATIVE ACTIVITIES OF THE CELL EXTRACT

| Extract | Level of Activity | Observations |
|---|---|---|
| Mucopolysaccharases: | | |
| Hyaluronidase | SA* = 2.0 | Not inducible† |
| Chondroitinase | None | Not inducible† |
| Keratanase | None | Not inducible† |
| Other glycosidases: | | |
| β-acetylglucosaminidase | SA = 3.3 | Determinations made with cells grown to late exponential phase; activity lower in older cells |
| β-galactosidase | SA = 20.5 | |
| Lipase | 6 mm zone/2 hr/0.025 mg protein | Completely inactivated by heating three minutes at 100°C |
| Proteinase: | | |
| Diazocasein | None | |
| Gelatin | None | |
| Peptidase | SA = 20.1 | Retains 75% of activity after heating for three minutes at 100°C |
| Hemolysin | 2250 $HD_{50}$ per mg protein | Completely inactivated by heating three minutes at 55°C |
| Phospholipase C | None | |

* S.A. = μM/hour/mg protein.

† Enzyme activity not increased by addition of substrate (0.5%) to growth medium.

## SUMMARY

Extracts of a pneumococcus have been shown to produce a severe inflammatory reaction upon instillation into the rabbit eye. Upon intracorneal injection of the material, extensive corneal opacification was also observed. The toxic factor was shown to be non-dialyzable, trypsin-sensitive, and precipitable by ammonium sulfate, indicating that it is a protein. It is released from the cells upon aging or after freezing and thawing. A high level of hemolysin and various degradative enzyme activities have been demonstrated in the pneumococcal extract, including hyaluronidase, glycosidases, lipase, and exopeptidase. Only the exopeptidase showed a level of heat resistance comparable to that observed for the toxic factor.

## ACKNOWLEDGMENT

The keratosulfate used in this study was supplied by Dr. J. Anthony Cifonelli.

OPHTHALMIC MINIATURE

Mr. Squeers's appearance was not prepossessing. He had but one eye and the popular prejudice runs in favour of two. The eye he had was unquestionably useful but decidedly not ornamental; being of a greenish grey, and in shape resembling the fanlight of a street door. The blank side of his face was much wrinkled and puckered up, which gave him a very sinister appearance, especially when he smiled, at which times his expression bordered closely on the villainous.

# BACTERIAL PROTEASES IN MORAXELLA ANGULAR CONJUNCTIVITIS

O. P. VAN BIJSTERVELD, M.D.
*Utrecht, Holland*

Biochemical activity of Moraxella species associated with infections of the outer eye is generally low and consequently it is not very surprising that early workers such as Petit[1] associated Moraxella proteases with virulence and pathogenicity. Paul,[2] Schmidt,[3] and Scarlett[4] made observations at variance with Petit's view which was largely abandoned.

It is generally accepted, however, that these bacterial enzymes are responsible for the characteristic angular maceration as postulated by Abe.[5] Only relatively recently, Thygeson and Kimura[6] challenged the concept of the overriding importance of Moraxella proteases in the causation of the angular lesion, and thus, in fact, also the hypothesis of Abe[5] on the explanation of the typical localization.

Angular conjunctivitis with strikingly large macerations was observed in two sisters with generalized ichthyosis. The observation was interesting in that from each patient a separate Moraxella species was isolated which differed markedly in proteolytic ability. It appeared that the extent and localization of the maceration was associated with quantity and position of the coherent exudate rather than the proteolytic ability of the strains.

## CASE REPORTS

Two sisters, patients A and B, aged 12 and 16 years, respectively, were referred to the Eye Clinic for treatment of intractable bilateral conjunctivitis. Both patients were inmates of separate wards in an institution for retarded children.

Upon examination, conjunctival hyperemia was found. It was most pronounced in the interpalpebral fissure. Gray coherent mucous exudate was present in quantity at the internal canthi, spreading onto the skin of the commissures. The most striking signs were the unusually large macerations of the skin, extending some 9 mm from the internal canthi. The configuration of the maceration was rather similar to the position of the exudate. The aspect of the inflammatory reaction of both eyes of both sisters was virtually identical.

Each had generalized ichthyosis which had resulted in moderate bilateral ectropion and disciform corneal changes. The normal configuration at the internal eyelid commissures was also altered.

Smears from the exudate revealed Gram-negative diplobacilli. From the discharge of both eyes of patient A, M. liquefaciens was cultured, while from the discharge of both eyes from patient B, a hitherto unrecognized carbohydrate-splitting Moraxella strain was isolated.[7] The strain was catalase-negative, nonhemolytic, produced indole and produced acid from a number of carbohydrates.

## DESCRIPTION OF NEW STRAIN

A short description of the new Moraxella strain follows:

*Micromorphology*—Medium-sized rods with rounded ends in pairs and chains (Fig. 1); Gram-negative; capsulated (Fig. 2); no flagellar motility, but "gliding" motility is present; no endospores.

*Colonies*—Translucent or slightly opaque, 0.15 to 0.5 mm in diameter after 24 hours. Colonies have low hemispheric or low conical elevation, with a tendency to differentiate into a raised center and flattened periphery. No beta hemolysis.

*Relation to oxygen*—Strictly aerobic.

*Temperature*—Optimal growth at 33° to 37°C; no growth initiated at 20°C.

*Growth requirements*—No growth in Koser's citrate medium and Audureau's medium. Very little growth in Hugh and Leifson's medium and peptone media. Growth enhanced by the addition of blood, serum, or ascites.

*Biochemical reactions*—Oxidase-positive, catalase-negative. Nitrate and nitrite were not reduced. Acid from glucose, fructose, mannose, saccharose; some acid was produced from starch, dextrine, and maltose. A trace reaction was found with galactose, trehalose, and xylose. Minimal gelatinase and proteolytic activity. Indole was produced.

From the Koninklijk Nederlands Gasthuis voor Ooglijders, Utrecht, Holland.

Reprint requests to O. P. van Bijsterveld, M.D., Ph.D., Koninklijk Nederlands Gasthuis voor Ooglijders, F.C. Dondersstraat 65, Utrecht, Holland.

Fig. 1 (van Bijsterveld). The new Moraxella strain. Four-hour culture showing the spongy cytoplasm of the cells characteristic of Moraxella species (Bouin-thionin preparation, ×1750).

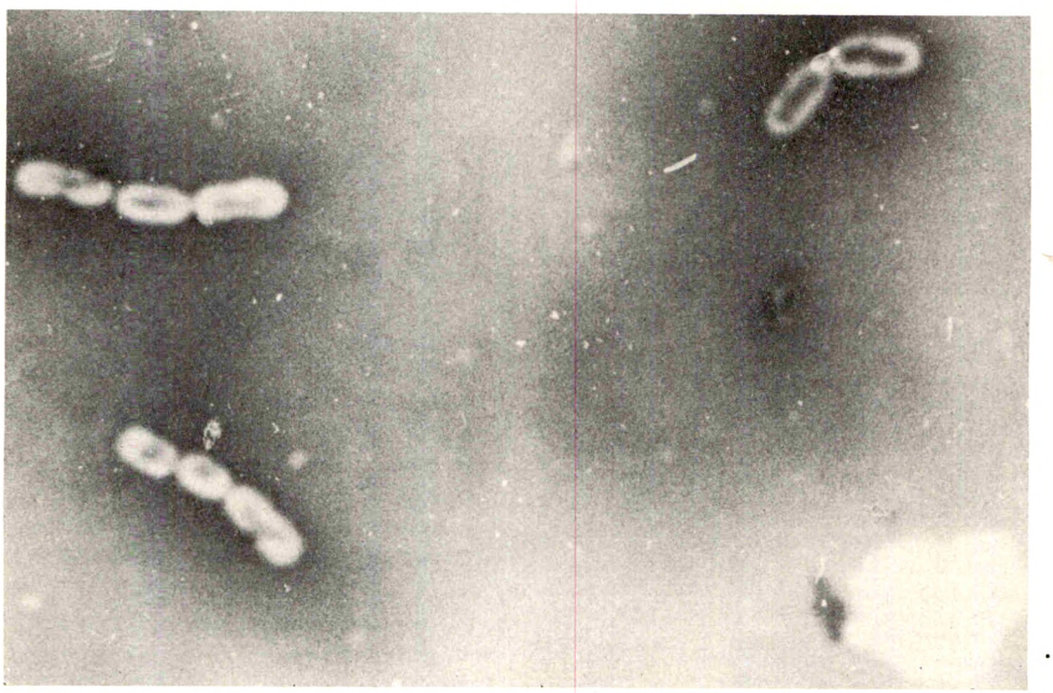

Fig. 2 (van Bijsterveld). Capsules of the new Moraxella strain (white capsule stain, ×4000).

$H_2S$ was not produced. No urease activity was found. The methyl red test was negative. Acetylmethylcarbinol was not produced. The phosphatase test was positive. Oxidative deamination of L-phenylalanine and DL-norleucine. Decarboxylase reactions are negative.

*Antibiotic sensitivity*—Highly sensitive for penicillin, streptomycin, chloramphenicol, oxytetracycline, erythromycin.

*DNA base composition*—Composed of 49 mole% guanine + cytosine (CsCl buoyant density method).

In Table 1 the differential characteristics of the carbohydrate splitting Moraxella species, i.e. M. amylolytica,[8] M. kingii,[9] and the new Moraxella strain are presented. It must be remembered that M. saccharolytica (Flamm, 1956[10]) has been identified as Flavobacterium meningosepticum.[11]

The species isolated from our patients differed markedly in their proteolytic activity. While M. liquefaciens produced powerful proteases, liquefaction of serum by the carbohydrate-splitting Moraxella could be demonstrated with difficulty. Likewise, gelatinase activity was minimal but could be detected by incorporating 3% w/v gelatine in the Moraxella base medium[12] and treatment of the surface of the medium with saturated ammonium sulfate after a suitable time of incubation.

TABLE 1

DIFFERENTIAL CHARACTERISTICS OF THE CARBOHYDRATE-SPLITTING MORAXELLA SPECIES

## DISCUSSION

While relatively little attention has been given to host factors in the causation of Moraxella infection, there has always been much interest in the offensive powers of these conditional pathogens for which the bacterial proteases were thought to be responsible.

Since the isolation of M. lacunata and M. nonliquefaciens from corneal ulcers, the concept of the relation of virulence and pathogenicity to qualitative and quantitative differences in proteolytic enzymes became untenable. The role of bacterial proteases in the causation of angular lesions is still generally accepted. However, Thygeson and Kimura[6] reported the isolation of M. nonliquefaciens from cases of angular conjunctivitis that were clinically in no way different from those associated with proteolytic Moraxella. Also, proteases are very common with microorganisms associated with infections of the outer eye and even with members of the normal conjunctival flora. It is difficult to see why these macerations would not occur more often in conjunctivitis if bacterial proteases alone were responsible.

The localization of the macerations in Moraxella angular conjunctivitis was explained by the unfavorable ratio of the supposedly protective antiproteolytic tear enzymes and bacterial proteases at the canthi. Since tears tend to collect at the angles this explanation seems unlikely to begin with.

We have isolated M. lacunata, M. liquefaciens, M. nonliquefaciens and a carbohydrate-splitting Moraxella species from angular conjunctivitis. Even in the infections caused by the proteolytic species, we did not find a correlation between the amount or type of proteases and size or location of the maceration, which was rather clearly exemplified in two of our two patients with ichthyosis.

One common denominator, however, in all those infections was the typical Moraxella exudate with its predilection to accumulate at the angles. It is the combination of the co-

hering and adhering quality of the exudate and the chronicity of the infection that distinguishes Moraxella infections from mucopurulent infections caused by other organisms.

Ichthyosis had changed the natural barrier of the eyelid folds at the internal canthi in our patients, facilitating the spread of the exudate well onto the skin at the commissures. The configuration of the macerated areas in our patients was rather similar to the extension pattern of the exudate. It seems much more likely that the size and the typical localization of the maceration is conditioned by contact of the skin with the exudate, rich both in bacterial and host metabolic products, including proteases from the inflammatory cells, rather than the interaction of bacterial proteases and protective antiproteolytic enzymes of the tears.

## Summary

Two Moraxella species, M. liquefaciens and a new carbohydrate-splitting Moraxella species that differed markedly in proteolytic activity were isolated from the exudate of two patients, sisters, with angular conjunctivitis characterized by large macerations. Generalized ichthyosis had changed the configurations of the canthi, allowing the exudate to spread onto the skin. The extent of the maceration and its localization appeared closely related to the position of the exudate.

# GNATHOSTOMA SPINIGERUM: AN UNUSUAL CAUSE OF OCULAR NEMATODIASIS IN THE WESTERN HEMISPHERE

ROBERT C. TUDOR, M.D., AND EDWIN BLAIR, M.D.
*Harbor City, California*

According to Sirisamban,[1] the first reported case of ocular gnathostomiasis was recorded in Thailand in 1936. He reported the second case in 1941 and alluded to two others which he had seen but had not reported. Neither of these reports has been previously cited in the Western ophthalmic literature. Six cases (eight reports[2-9]) of ocular gnathostomiasis have been well documented in the Western literature prior to this paper. Two more cases have recently been reported from India.[10]

The present case is reported not only because of its rarity, but also because it is unique in two respects: it is the second to be diagnosed in the western hemisphere, and it has been possible to establish with certainty that a minimum time of three and one-half years elapsed between ingestion of the worm and the appearance of clinical disease.

## CASE REPORT

The patient, a 17-year-old, single, Filipino girl left Bocarra Ilorcas Norte, Luzon, in August, 1966. She visited relatives in Oahu and Maui, Hawaii, on her way to the continental United States. She has lived in Southern California since her arrival in September, 1966. In the Philippines she ate raw fresh-water shrimp prepared in a dish called "udang," fresh water fish called bañgos, and the "walking catfish" (Clarias batrachus).

On the evening of March 21, 1970, a dark spot, which moved, appeared in the visual field of the left eye. The patient awakened the following morning with decreased vision, redness and pain of the left eye. Finding no spontaneous improvement over the subsequent two days, she presented herself with these complaints on March 24, 1970.

Ocular examination revealed the right eye was free of disease and possessed 20/20 vision without correction. Vision in the left eye was counting fingers at three feet. The left eye demonstrated the signs of a severe uveitis: marked conjunctival hyperemia and ciliary flush, a blood-tinged hypopyon occupying the lower one-third of the anterior chamber, plasmoid aqueous superior to the hypopyon, and myriad red and white blood cell keratic precipitates. The pupil was round and regular and 6.0 mm in diameter. It reacted sluggishly and incompletely to direct and consensual light and accommodative stimuli. No synechiae were present. The lens and vitreous were clear. A choroidal and subretinal hemorrhage four disk diameters in width was present one disk diameter superior temporal to the optic nerve head. A retinal tear was present in the area of hemorrhage, and preretinal and vitreous blood, which partially obscured the disk, had come from this source (Fig. 1). We believe the worm entered the eye at this point by boring through the sclera, choroid, and retina from the orbit.[11]

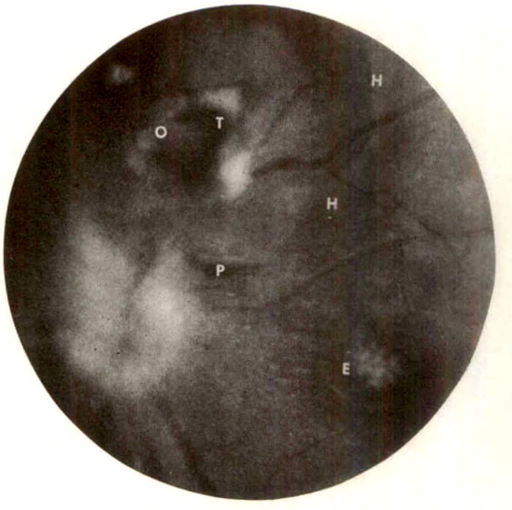

Fig. 1 (Tudor and Blair). Fundus photograph of the left eye taken six days after the onset of the patient's first symptoms. O = operculum of the retinal tear, T. H indicates the perimeter of the choroidal and subretinal hemorrhages. P marks the preretinal hemorrhage. E = macular exudate which developed six days after the onset of symptoms. The appearance of the fundus is otherwise unchanged from the time of the initial examination.

A 1.0% atropine ointment and 10.0% phenylephrine drops were instilled into the patient's eye. She was given prednisolone acetate 1.0% ophthalmic drops to place into the eye at hourly intervals and was instructed to return the following day. At 1 P.M. on

Fig. 2 (Tudor and Blair). The worm in the anterior chamber at surgery. The S-shaped form of the nematode is visible overlying the pupil and the 12 o'clock meridian of the iris.

March 26, the vision remained unchanged. The inflammatory response was markedly decreased and the hypopyon had disappeared almost completely. The plasmoid aqueous persisted. A red, immobile nematode was seen lying in the angle between five and seven o'clock. It floated about the anterior chamber when the patient's posture was changed.

The patient was admitted and a complete history was taken and a physical examination was performed by the patient's internist. No signs or symptoms of systemic disease were found.

By 7 P.M. on March 26, the patient was prepared for surgery and photographs were taken (Fig. 2). The worm was actively moving at this time. The globe was fixated and a keratome incision was made through the cornea at the anterior edge of the temporal limbus. A lacrimal cannula attached to a 5 ml syringe filled with sterile lactated Ringer's solution was introduced into the anterior chamber through the keratome incision, and one end of the actively moving worm was aspirated into the cannula. The entire nematode was withdrawn from the eye. A single 7-0 silk suture was used to close the keratome incision; 2 mg of dexamethasone in 0.5 ml of diluent were injected subconjunctivally over the inferior portion of the globe at the conclusion of surgery. After 1.0% atropine ointment and corticosteroid (Cortisporin) ointment were instilled into the eye, a patch and shield were applied.

The patient's postoperative course was uneventful. The following points were of interest: two highly refractile, fine white strands looking like mucus were noted on the iris near the keratome incision on March 27. These strands disappeared as the inflammatory response in the anterior chamber diminished. We believe them to have been secretions from the parasite. By March 30, the visual acuity was correctable to 20/50. A +4 cellular reaction was present in the anterior chamber at this time. When examined on April 1, the patient complained of decreasing visual acuity, and a yellow exudate was seen in the macular area for the first time. By April 6, the best corrected vision was 20/100, but the yellow macular exudate had completely cleared leaving only a small degree of macular edema. There were +2 cells in the anterior chamber at this time. The patient was continued on prednisolone acetate 1.0% four times daily, and on April 14 the anterior chamber contained only an occasional cell, the vision was 20/50 with −1.25 sph. ⊃ −1.00 cyl. ax. 10, and gliosis had occurred in the area of the choroidal and subretinal hemorrhage. A few folds of the internal limiting membrane of the retina were present.

Complete blood counts performed on March 24 and 26 showed 75 and 85% polymorphonuclear leukocytes and 4 and 2% eosinophils, respectively. The corrected sedimentation rate was 26 mm/hour. These were the only abnormal or borderline laboratory test results. Three stool examinations for ova and parasites were negative and three blood smears were negative for microfilaria. Immunoelectrophoresis and special procedures for the determination of IgE were performed and were normal.

The patient disappeared from follow-up between April 1 and June 25. On June 25 the best corrected vision was 20/20 in the right and counting fingers at one foot in the left eye. Fibrous tissue bands extended from the worm's point of entrance into and

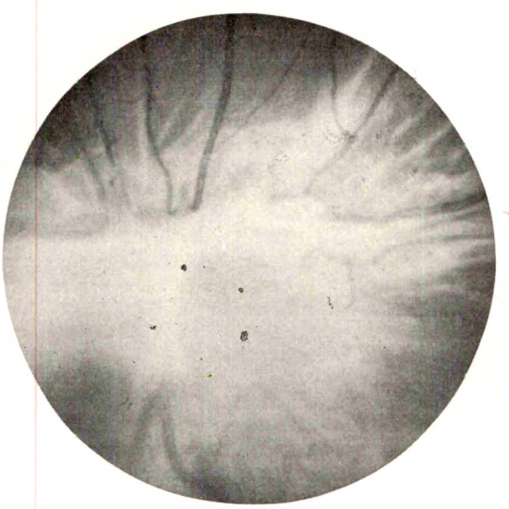

Fig. 3 (Tudor and Blair). Fundus photographs of the left eye three months after the onset of first symptoms. Same field of view as Figure 1. The fibrous bands outlining the course of the worm through the vitreous and the retinal detachment produced by their traction on the retina are clearly seen. The bands originate and terminate at points where the worm contacted the retina.

through the vitreous, outlining the path which the worm had traversed. Contraction of these fibrous bands had produced total detachment of the retina (Fig. 3). We think that excretions of the worm produced this reaction.

## Discussion

The nematode genus, Gnathostoma, was first described and named by Richard Owen in 1836 when he found the worm in a tumor of the stomach wall of a tiger which had died in the London Zoological Gardens.[12] At the present time approximately 20 species of Gnathostoma have been described.[13] Of these species, only three, with certainty, have been found as the cause of human gnathostomiasis: G. spinigerum, G. hispidum, and G. viverrina.[14] These species are found primarily in Southeast Asia and in the Japanese, Philippine, and Indonesian archipelagoes. G. spinigerum is by far the most common cause of human infection and was the worm removed from the eye of our patient.[15]

While alive, the worm was red-orange in color and measured approximately 4.5 mm long by 0.5 mm wide. The color comes from oxyhemoglobin retained in solution in the worm's body fluids.[16] The head bulb had four rows of hooklets. From the most anterior row to the most posterior row the minimum numbers of hooklets in each row, were respectively: 27, 33, 40, and 48. A precise hooklet count was not possible since they could only be counted from lateral view. Spination of the body was prominent over its anterior half but the single, pointed 10μ-long spines became shorter posteriorly until they were ultimately lacking on the posterior fourth of the body. The morphologic characters of the larva are consistent with a diagnosis of G. spinigerum.[13]

Gnathostomes can infect all human soft tissues. As a result, the signs and symptoms of human gnathostomiasis are protean and depend, in the individual case, upon the random migration of the larva through the host tissues. Most commonly, human gnathostomiasis is observed as a cutaneous larva migrans. Rangoon tumor (Burma), Embassy

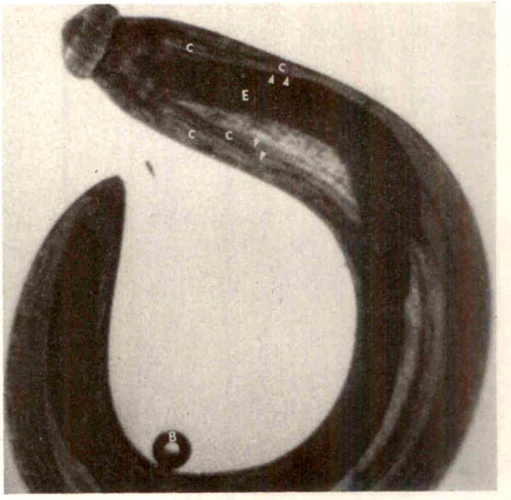

Fig. 4 (Tudor and Blair). Photomicrograph of the third-stage larva in life. Note the well-defined head with its four rows of hooklets and the transverse striations of the body. These striations are composed of single pointed spines which are 10 μ long anteriorly but which diminish in length until they disappear posteriorly. Also note the well-defined divisions of the alimentary tract. Lying alongside the anterior portion of the esophagus, E, are four muscular tubes called the cervical sacs, C, which play an important role in swelling and contraction of the head bulb. The arrows indicate the posterior edges of the cervical sacs. B is an air bubble.

disease, or Yangtze river edema, consulate disease (Nanking), and Shanghai rheumatism are some of the local names used to describe a cutaneous larva migrans which may be caused by gnathostomes.[17,18] Less commonly, disease of the CNS, eyes, lungs and pleura, urinary tract, intestines, mastoid sinuses and uterus has been reported as having been caused by the larvae of gnathostomes.[11,15,19-22] Congenital infection of the newborn is also known to occur.[23]

Since G. spinigerum was reported for the first time in 1889 as a cause of human disease—producing a breast abscess in a Siamese woman—human infection with gnathostomes has been reported with increasing frequency.[24] Subsequently most human cases have been reported from Thailand and Japan, although human gnathostomiasis has also been reported in Malaysia, Burma,

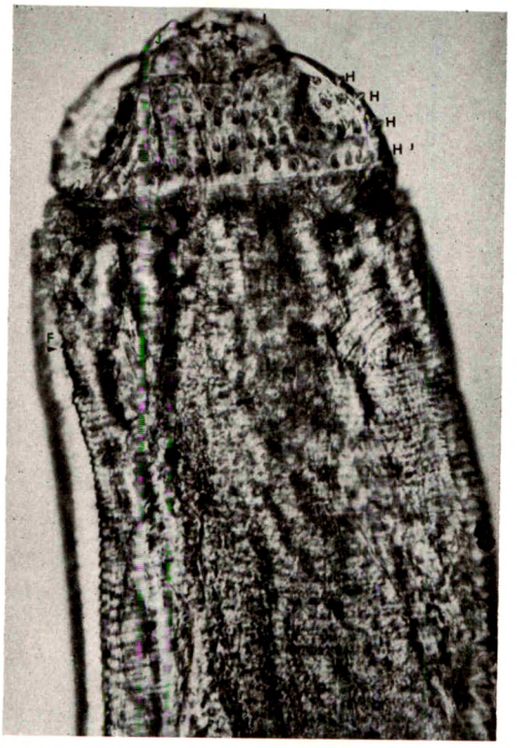

Fig. 5 (Tudor and Blair). Photomicrograph of the head and anterior body of the third-stage larva after fixation in formalin. Numerous artifacts have been created by the shrinkage produced by this fixative; 70% ethanol containing 5% glycerin and warmed to the vapor point is the proper fixative for nematodes. J = the massive labia about the mouth which give the genus its name. H = the four rows of hooklets on the head bulb. The minimum counts for each of the four rows in the pictured specimen were 27, 33, 40, and 48, respectively. F = one of the fine body hooklets seen highlighted against a diffraction image produced by the thickness of the specimen.

Vietnam, China, India, Pakistan, the Philippines, Israel, and North Queensland, Australia. In Thailand the infection is so commonly recognized as not to warrant reporting of individual cases.

The life cycle of the gnathostomes is quite complex. Daengsvang has elucidated the cycle.[15,23,25,26] During the three larval stages, the parasite lives first in fresh water, then successively in two intermediate hosts (copepods and cold-blooded vertebrates), and finally reaches maturity in the definitive host. The adult worms produce eggs which are passed in the host's feces to begin the cycle again.

The known natural definitive hosts of G. spinigerum include wild and domestic felines and dogs. The adult male and female worms cohabit in tumors of the stomach wall and eggs are layed in the lumen of the host's gut via a small opening at the mucosal surface of the tumor. Eggs develop and hatch about one week after entering fresh water. Free-swimming, first-stage larvae emerge and die unless ingested by one of several species of cyclops, a fresh water crustacean (copepod), within two or three days. If ingested, the first-stage larvae penetrate into the body cavity of the copepod, molt twice, and in approximately one week become third-stage larvae (Figs. 4 and 5). Fish, snakes, or frogs eat the copepod and the larvae migrate from the intestinal tract of these animals into their muscles where they become encapsulated. If these infected second intermediate hosts are eaten by another animal capable of serving as a second intermediate host for the worm, the worm re-encapsulates without further development. When the definitive host eats the second intermediate host, the third-stage larvae penetrate the walls of the stomach or duodenum, migrate into the host's liver, muscles, and connective tissues, molt twice and then return to the wall of the stomach where they mature and produce the characteristic nodules.

Man is an abnormal host for gnathostomes. The third-stage larvae undergo their characteristic tissue migration but cannot reach maturity in man. The larvae may wander aimlessly into all parts of the body. As they bore through the tissues they sometimes produce the signs and symptoms of clinical disease—although we have seen how they may also move about without symptoms. They fail to return to the stomach as mature adult worms, and the ova-producing nodules of the upper GI tract do not develop. Thus humans are not considered to be infective even when harboring worms.

The question of the mode of human infection has often been discussed. There are two

possible ways in which the mammalian host can be infected. The most common is by the ingestion of the infected second intermediate host. A rare means of infection can be by the ingestion of infected copepods in drinking water. This has been experimentally demonstrated in pigs and has been suggested to occur in G. procyonis infections.[27,28] However, human infection is more often acquired by eating raw or improperly cooked fish, either through carelessness or through choice. There is no experimental evidence that infection can occur through the skin.

The diagnosis of human gnathostomiasis can be made only by removal and morphologic identification of the larvae. An eosinophilia or elevation of sedimentation rate is more often absent than present in gnathostomiasis.[29]

In every reported case of ocular gnathostomiasis in which the time of onset of symptoms has been mentioned, it has been in the evening. The increased motility of the worm noted by us at surgery may explain this phenomenon.

## Summary

A 17-year-old Philippine girl suddenly developed a severe uveitis of the left eye three and one-half years after leaving Luzon. The uveitis was caused by a third stage larva of Gnathostoma spinigerum which had entered the globe by boring through the sclera, choroid, and retina superior to the optic disk, traversing the vitreous, entering the anterior chamber after penetrating the ciliary body and iris. The larva was successfully removed by aspiration and vision returned to 20/50 four days postoperatively only to be reduced to light perception three months later when fibrous bands that formed along the path traveled by the worm through the vitreous contracted and produced retinal detachment. No systemic signs or symptoms of parasitic infection were apparent in the patient.

This is the second case of ocular gnathostomiasis reported from the Western hemisphere and is interesting because it developed three and one-half years after the patient's last exposure to a source of infection.

*Addendum:* Since this paper was submitted for publication, a report of two human gnathostome infections in native-born Mexicans, who had never left their country, has come to our attention. One of these infections was ocular (diagnosed in 1967 by Dr. E. López-Quiñones of Mexico City) and the other involved the abdominal wall. Species identification was not possible in these two cases. This report antedates ours and accordingly describes the first known cases of human gnathostomiasis in the western hemisphere.[30]

### Acknowledgment

We thank Miss Lilliam Pusavat and Drs. A. Pusavat, C. Villanueva, and K. Tsugawa for their assistance; Mrs. Sybil Schwartz for her diligent librarianship and helpful suggestions; and Lawrence Ash, Ph.D., of the Department of Public Health at UCLA for his identification of the worm, and for editing the manuscript.

# EVALUATION OF 48 CASES OF ORBITAL EXENTERATION

J. Earl Rathbun, M.D., Crowell Beard, M.D., and Marvin H. Quickert, M.D.
*San Francisco, California*

Orbital exenteration is a radical surgical procedure. It must, however, be done when less radical operations, local chemosurgery, or irradiation will not eradicate malignant tumors of the orbit or periorbital tissues. A critical review of the literature reveals little information on results of orbital exenterations. Naquin[1] reported 48 orbital exenterations performed at the Wilmer Ophthalmological Institute; Simons and associates[2] presented follow-up data on 31 patients who had undergone exenteration for malignant orbital and periorbital tumors; and Jones and Reese[3] reported on rhabdomyosarcoma treated with exenteration, irradiation, or both. In order to further assess the value of orbital exenteration and to determine which types of tumors respond best to this radical surgery, all orbital exenterations done on both the private and clinic services at the University of California, San Francisco, were extensively evaluated and are reported here. Each tumor type was examined separately, since each has individual characteristics of growth rate, recurrence, type of spread, and of response to other modalities used in place of or in conjunction with orbital exenteration.

## Clinical data

Between 1940 and the present, 48 orbital exenterations were done within the Department of Ophthalmology of the University of California, San Francisco. Full descriptions of the operative techniques have been reported elsewhere.[4-6] Basically, the orbital contents and periosteum were removed in each case; the amount of eyelid skin excised varied with the location and extent of the tumor. Grossly involved bone was removed by rongeur until bone of normal consistency was encountered. The area of resected bone and the orbital apex were treated with electrocautery. Frontal, ethmoid, and maxillary sinuses were removed as necessary. A split-thickness skin graft from the thigh was used to line the orbital defect in 43 patients; temporalis muscle flaps were used in the remaining five. Radiation therapy, chemosurgery, or the two together were used postoperatively if indicated. Recurrences were treated by operation, or by irradiation and chemosurgery alone or combined.

*Basal cell carcinoma*—Orbital exenterations were done for advanced basal cell carcinoma in 14 patients (Table 1). Frontal, ethmoid, and/or maxillary sinuses were also exenterated in seven of the patients. Eleven of the patients were men; the average age at time of operation was 62 years (range: 23 to 82 years). The known duration of the carcinoma prior to operation ranged from one to 25 years. All but two of the tumors had been treated with surgical, chemical, or radiation therapy prior to exenteration.

Four patients are alive after five years of follow-up without recurrence; one died after more than five tumor-free years. Two patients, aged 38 and 44 years at the time of exenteration, survived five years but died of tumor recurrence seven years and nine years, 10 months, respectively, after exenteration. The latter had had two additional operations for recurrence of bony tumor invasion. Four patients are living without recurrent disease one and one-half to five years after exenteration. Three patients died in less than five years of causes that were not tumor related.

*Squamous cell carcinoma*—Of six cases of advanced squamous cell carcinoma, three originated from the conjunctiva, two from

| 14. 73-F | Left | Basal cell carcinoma inner canthus and orbit, ×1+year | No | Yes | Alive 1 year, tumor-free | Frontal, maxillary and ethmoid sinuses removed |

the eyelid skin, and one from the tear sac (Table 2). The patients' ages ranged from 61 to 77 years.

The three patients with squamous cell carcinoma of the conjunctiva are tumor-free after five months, six and one-half years, and 13 years, respectively. The two patients whose initial lesion was in the eyelid skin died of causes unrelated to their tumor at 21 months and seven years, five months, respectively. The patient whose primary tumor had originated in the tear sac died of accidental causes one year, nine months, postoperatively. None of these patients required any further surgical or radiation therapy.

*Melanoma*—Eight patients underwent

| 28. 38-F | Right | Melanoma of orbit with history of excision of melanoma of arm 7 years before | No | No | Died of metastases, 6 months | |

orbital exenteration for malignant melanoma (Table 3). This originated in the conjunctiva in five patients, the choroid in two patients, and the orbit in one patient in whom the tumor was possibly related to a skin melanoma excised from the arm seven years before. The average age of these patients was 52.5 years (range: 29 to 79 years); seven of the eight were women.

Of the patients with conjunctival melanoma: two died of metastatic tumor at three years, nine months, and four years, ten months, respectively; one died accidentally at 14 months; one is alive after nine years without recurrence; and one died five years, six months, postoperatively, apparently free of melanoma. One patient with advanced orbital involvement from choroidal melanoma died of metastatic disease 10 years later; the remaining patient with choroidal melanoma is alive with cure 19 years after operation. The patient with orbital melanoma died six months postexenteration of metastatic disease.

*Rhabdomyosarcoma*—Five patients, aged one and one-half to six years (average four and one-third years), underwent orbital exenteration for rhabdomyosarcoma, followed by irradiation in three (Table 4). One patient died of cardiac arrest two hours postoperatively. One patient (irradiated) died of tumor at nine months, while two are alive without recurrence at nine and one-half years and 13 years (irradiated). One patient

TABLE 4

DATA FROM 5 PATIENTS UNDERGOING ORBITAL EXENTERATION FOR RHABDOMYOSARCOMA

| Case No., Age, and Sex | Eye Removed | Site of Tumor and Duration Prior to Exenteration | Postexenteration Radiation | Postexenteration Chemosurgery | Results | Comment |
|---|---|---|---|---|---|---|
| 29. 6-M | Left | Rhabdomyosarcoma ×2 weeks | Yes | No | Alive 13 yr, tumor free | — |
| 30. 1½-F | Left | Rhabdomyosarcoma ×6 months | Yes | No | Died 9 months of extensive intracranial involvement | — |
| 31. 5-F | Right | Rhabdomyosarcoma ×6 weeks | No | No | Alive 9½ year, tumor free | — |
| 32. 3-M | Right | Rhabdomyosarcoma ×1 month | No | No | Died 2 hours, postoperatively of cardiac arrest | — |
| 33. 6-M | Left | Rhabdomysarcoma ×3 weeks | Yes | No | Alive 2 years, 10 months, tumor free | Reoperated for recurrence 8½ month postexenteration |

with recurrence discovered nine months after operation is alive two years and 10 months postexenteration, apparently tumor-free after a course of radiation therapy.

*Lacrimal gland tumors*—Of eight orbital lacrimal gland tumors leading to orbital exenteration, five were adenocarcinomas and two were mixed tumors (Table 5). One, on frozen section, was misdiagnosed as adenocarcinoma, while permanent sections showed lymphosarcoma. One accessory lacrimal gland tumor was an adenocarcinoma. The patients ranged in age from 22 to 80 years (average, 58 years).

Of the five patients with adenocarcinoma of the orbital portion of the lacrimal gland: three died at 12 months, 15 months, and 24 months postexenteration of metastatic disease; one died of accidental causes 10 months postoperatively with recurrent tumor present; and the fifth is alive seven months postexenteration. Two of these five patients had extensive resection of involved bone. The patient whose adenocarcinoma had originated in an accessory lacrimal gland developed cervical lymph node metastases two years and four months postoperatively; treatment was with irradiation followed by neck dissection. He died three years and 10 months postexenteration of cardiac disease. One patient with mixed tumor had no recurrence after three years while the other was treated with chemosurgery for recurrence four months postoperatively and is alive with no further recurrence at four years and two months after operation. The latter patient had had frontal and maxillary sinusectomies at the time of orbital exenteration. The patient with a final diagnosis of lymphosarcoma underwent radiation therapy postoperatively and died tumor-free eight years postexenteration.

*Other orbital tumors*—Six patients presented with other types of orbital tumors (Table 6): sarcomatous tumor (four patients); benign, rapidly growing granulomatous inflammation (one patient); and sebaceous-gland carcinoma of the upper and lower eyelids (one patient). Their ages ranged from 15 months to 82 years.

Three of the four patients with sarcomatous tumors are alive five years and three months, 17 years, and 23 years postoperatively. The fourth died of tumor 22 months postexenteration. The one patient with sebaceous-gland carcinoma died seven months postoperatively from a probably primary lung tumor. One patient underwent exenter-

ation after multiple surgical procedures and irradiation had failed to control what was diagnosed microscopically as benign granulomatous inflammation. She died eight months postexenteration in another hospital with extensive pulmonary infiltration. An autopsy was not permitted.

## DISCUSSION

The compiled data by disease entity are presented in Table 7. While it is difficult to form conclusions from relatively small numbers of advanced tumor cases, it is our impression that orbital exenteration is a necessary and valuable procedure used either alone or in conjunction with radiation therapy and possibly local chemosurgery. Systemic chemotherapy was not administered to any patient in this series though consultation regarding its use was obtained in several cases.

In basal cell carcinoma, the results appeared to be good when all involved tissue and bone was removed. Twelve of our 14 pa-

tients had no recurrence (Table 1), while the two with recurrence survived seven years and nine years, ten months, before succumbing to their disease. Simons and associates[2] experienced similar good results with basal cell carcinoma. Naquin,[1] however, encountered six tumor deaths and one additional recurrence in 10 cases of basal cell carcinoma. It is obviously important that all involved tissue and bone be excised, including sinuses, if necessary.

Our results with cases of squamous cell carcinoma have been excellent with no tumor recurrences to date. This is at variance with the experiences reported by Naquin (recurrence in the one patient followed for longer than two months) and by Simons and associates (two tumor deaths in three cases).

Melanomas, being highly metastatic, usually carry a poor prognosis. While pre-exenteration evaluation for metastases was negative in our eight patients with melanoma, an early metastasis might well have been undetectable. While metastases and tumor deaths did occur in our postexenteration melanoma patients, one year without recurrence in four of eight, five years without recurrence in three of eight, and the five-year survival of one patient with recurrence attests to the benefits of orbital exenteration in otherwise hopeless cases. Choroidal melanomas were found to have a poor prognosis even after orbital exenteration by Simons and his team (one of five patients tumor-free at three years) and by Naquin (two of eight free of disease after two years). The two patients in our series with extension of choroidal melanoma both survived five years, but one had recurrence. Conjunctival melanomas were not reported by Simons' group; Naquin reported no recurrences in three patients. Our two tumor deaths in five exenterations were not as encouraging.

Rhabdomyosarcoma has been discussed extensively by other authors with a generally accepted survival rate of approximately 50%.[3] Our small series correlates well with this figure. Even though one of our cases is alive and tumor-free after nine and one-half years without postoperative radiation therapy, we believe that radiation therapy, postoperatively, even when no tumor is known to have been left, is of value considering the severity of this particular disease process. The course of radiation therapy is usually begun two to three weeks after the operation to allow for sufficient healing. Sagerman and associates[7] reported excellent results with radiation alone after biopsy of orbital rhabdomyosarcoma. This may well prove to be adequate therapy in this disease thus excluding the use of exenteration.

Of the lacrimal gland tumors, adenocarcinoma had a poor prognosis despite apparent complete removal. Three patients with orbital lacrimal gland adenocarcinoma died of metastatic disease and one died of other causes with known recurrence within two years of operation. Follow-up for the two patients with far advanced mixed tumor was too short to allow for definite conclusions, but the results are promising to date. Naquin reported recurrences in two patients with mixed tumor of the lacrimal gland while Simons and associates did not report specific data on lacrimal gland tumors. From our experience with the misdiagnosis of adenocarcinoma on frozen sections for what was diagnosed as lymphosarcoma on permanent sections, we believe it is best to have a biopsy with permanent sections before an exenteration is done. We feel the treatment of choice in lymphomatous disease is radiation therapy or systemic chemotherapy.

The technique of orbital exenteration as outlined has worked so well with skin grafts that we believe a temporalis muscle flap should be used only in children or in patients for whom care of the socket would be difficult. The advantages of a skin-lined socket are the ability to detect recurrences early, and the ability to treat them directly. The only minor problems encountered with a skin-lined orbit have been the care of des-

quamated skin and the occasional fistula developing between the orbit and the ethmoid air cells or the nose. None of the skin grafts has reacted unfavorably to postexenteration irradiation. We have not recently used the technique of orbital granulation as this also prevents observation for tumor recurrence.

All but one of the 48 patients in this series adjusted to their postoperative appearance and care with little difficulty. The one patient had significant alcoholic and depressive problems both before and after exenteration. Many of the patients, especially those with long-standing basal cell carcinoma, stated that they felt relieved that the tumor had been removed and that the possibility of recurrence could be closely observed. Many of the patients tried prosthetic devices attached either to spectacles or directly to the skin for cosmetic improvement but all decided that a patch was better. Their main objections to the prosthesis were: a fixed-stare appearance, difference in "skin" color as the facial skin changed during the seasons and with age, and sensitivity to the adhesives used to attach the prosthesis.

Each patient in this series presented with a neoplasm which could not be treated by any surgical procedure less radical than an orbital exenteration if all tumor was to be removed with adequate margins. However, many of these cases could have been treated easily at an early stage of their disease but were either neglected by the patient or had inadequate surgery and/or follow-up observation. Other cases had rapidly growing neoplasms, with orbital exenteration being undertaken as an attempt to eradicate a rapidly fatal process. The success of an orbital exenteration depends upon obtaining tumor-free margins at the time of surgery and the performance of surgery prior to metastases. As previously noted, the presence of metastases may be impossible to detect. The modalities of radiation therapy, local chemosurgery, and systemic chemotherapy are of value in many cases where all the tumor cannot be removed surgically. Since these modalities were not always used in this series, and when used, were only employed in conjunction with exenteration, as felt to be appropriate for the individual case, no conclusions can be drawn as to the adequacy of using them alone.

## Summary

Forty-eight orbital exenterations were done in patients with a variety of advanced orbital neoplasms. The data showed good results in basal cell and squamous cell carcinomas; the procedure was of definite but shorter-lasting benefit in cases of rhabdomyosarcoma, melanoma, malignant mixed tumors of the lacrimal gland, and a variety of other orbital tumors. Results with adenocarcinoma of the lacrimal gland were discouraging. Adjunctive radiation therapy was used when appropriate.

# ULTRASONIC DACRYOCYSTORHINOSTOMY

M. M. KRASNOV, M.D.
*Moscow, U.S.S.R.*

A number of workers have successfully employed ultrasonic techniques in general surgery, neurosurgery and dentistry but few have explored the feasibility of treating ocular diseases with ultrasound.

Purnell, Sokollu, and Holasek[1] studied the possibility of repairing retinal detachment with high-frequency focused ultrasonic coagulation, and Karlin[2] investigated the use of low-frequency applications to produce chorioretinal lesions. Kelman[3] developed an ultrasonic technique, which he called phacoemulsification, to emulsify a cataractous lens in order to remove it by aspiration.

My associates and I[4] studied the general principles of low-frequency ultrasonic energy and investigated its potentials in ophthalmology. During the course of our studies, we developed a low-frequency ultrasonic apparatus specifically suited to the purpose (Fig. 1).

This paper describes our adaptation of standard ultrasonic equipment to the requisites of ophthalmic surgery and discusses the clinical application of ultrasonic resection of lacrimal bone in dacryocystorhinostomy.

From the Second Medical Institute, Moscow.
Reprint requests to M. M. Krasnov, M.D., professor of ophthalmology, Second Medical Institute, M. Pirogovskaja I, Moscow, U.S.S.R.

## ULTRASONIC APPARATUS

Conventional low-frequency ultrasonic systems consist of three parts: (1) a pulse generator, (2) a transducer to convert the pulses into mechanical vibrations, and (3) a concentrator to amplify the oscillations and transmit them to the desired point.

The most distinctive innovation in the apparatus we used (designed by Goljamina[4]) was its ferromagnetic transducer. It has two decided advantages: (1) Its efficiency is greater than that of conventional transducers (nickel), and (2) cooling is unnecessary, making the instrumental more convenient for surgical purposes.

Clinically, the frequencies used were 44-50 kc; experimentally, frequencies up to 100 kc have also been tried.

Although it is customary to designate the power output of ultrasonic devices in watts, this unit of measurement is unsatisfactory when ultrasonic energy is used for surgery because it makes it difficult to estimate the amount of energy required to produce the desired therapeutic effect on the tissues be-

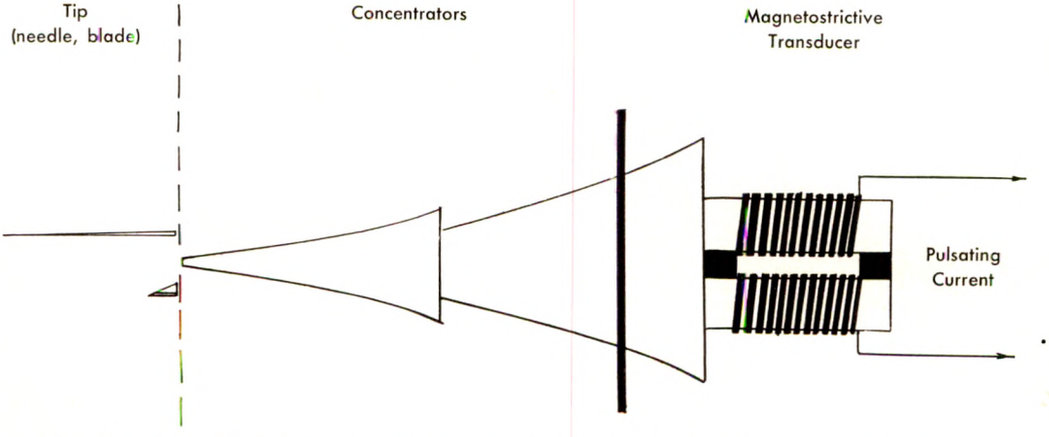

Fig. 1 (Krasnov). Block diagram of the low-frequency ultrasonic apparatus for ophthalmic surgery.

ing treated. It seemed preferable, although not ideal, to determine power output by measuring the oscillations at the concentrator tip. Oscillations up to 30 μ were used. The effect desired from the procedure dictated the type of concentrator tip: a blade for cutting, a needle for puncturing, a blunt tip for coagulating.

To correct distortions of the resonance equilibrium, which are caused by contact of the instrument tip with the tissue, an automatic frequency adjustor was incorporated in the apparatus. Installation of an "electric eye" made possible visual checking of the manual tuning. An on-off switch, conveniently operated by the surgeon, controlled the current that actuated the system.

Although the experiments conducted with this instrument included observations on the effect of low-frequency ultrasound in glaucoma, cataract removal (phacoemulsification), retinal detachment, and lamination of the cornea, only the technique for and the results of ultrasonic resection of lacrimal bone in dacryocystorhinostomy are reported here.

It is well known that the greater the acoustic resistance, the greater the loss of ultrasonic energy and, consequently, the greater its destructive power. Cutting the bone in a dacryocystorhinostomy demonstrated this clearly. Since the underlying mucosa offered less resistance to the passage of ultrasound, the effect of the ultrasonic energy on this tissue was reduced.

## Surgical technique

The first steps in the operation are conventional. After exposure of the lacrimal bone, the surgeon presses the tip of the ultrasonic instrument (a somewhat dull, spade-shaped blade is most useful) against the bone and switches on the current. The blade easily penetrates the bone in one or two seconds.

Starting from this first penetration, the surgeon continues cutting transversely with the side of the blade until he can remove a piece of bone of the desired size and shape (Fig. 2). The considerable heating that usually accompanies the cutting frequently chars the rim of the bone window, an incidental benefit for it helps to control bleeding. The mucosa may show some spots of coagulation but seldom is it perforated.

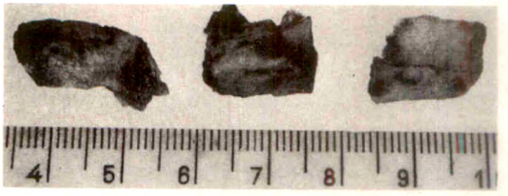

Fig. 2 (Krasnov). Bone fragments obtained by ultrasonic resection of lacrimal bone in dacryocystorhinostomy.

The usual routine completes the operation.

## Results

Follow-up periods of from two months to two and one-half years show that all but one of the 41 ultrasonic dacryocystorhinostomies performed to date were successful. These results indicate that ultrasonic resection of lacrimal bone in dacryocystorhinostomy is a simple, efficient and safe technique.

## Summary

Equipment specifically designed for exploration of the ophthalmic potentials of low-frequency ultrasonic surgery was used to investigate the effects of this modality in several eye diseases. Initial studies in 41 cases indicate that ultrasonic resection of the lacrimal bone in dacryocystorhinostomy is not only feasible but also efficient, simple, safe, and successful.

# MEDIAN CLEFT FACE SYNDROME

WILLIAM C. EDWARDS, M.D., WALLACE ASKEW, M.D., AND BERNARD WEISSKOPF, M.D.

*Louisville, Kentucky*

Ocular hypertelorism may occur as an isolated anomaly or in association with various congenital malformations of the facial structures, cranium, and brain. Syndromes well known to the ophthalmologist in which the eyes are widely spaced include hypertelorism of Greig, the Waardenburg syndrome, and Crouzon's disease. This paper describes the median cleft face syndrome in which the most prominent eye finding is hypertelorism.

## CASE REPORTS

*Case* 1—An infant girl was examined at the Ophthalmology Clinic of Children's Hospital at the age of nine months. The most striking finding was the grossly abnormal facial structure (Fig. 1). Pertinent external ocular findings included hypertelorism, epicanthal folds, telecanthus, and blepharophimosis. The horizontal palpebral apertures measured 12, right, and 15 mm, left. Prominent limbal epibulbar dermoid tumors were present (Fig. 2). The remainder of the ocular examination was within normal limits.

General physical examination showed a protuberance in the frontal area of the skull diagnosed as an encephalocele. The nares were extremely small and widely separated; there was a vestige of nasal tissue at each opening. Micrognathia, high-arched palate and a notched upper lip were present. The infant has shortening of the right tibia, right varus deformity of the foot, dislocation of the right hip, and polydactyly involving the lower extremities only (Fig. 3).

Psychological examination and IQ (Cattell infant scale) were below normal for age. A chromosome study showed normal female karyotype.

Pregnancy, delivery, and birth weight were normal. Family history revealed no ocular defects nor any similar developmental defects. Drugs taken during the first trimester of pregnancy were hyosamine-atropine-phenobarbital (Donnatal), meclizine HCl (Bonine), and vitamins.

From the Department of Ophthalmology and the Department of Pediatrics, Child Evaluation Center, University of Louisville School of Medicine, Louisville, Kentucky. This research was supported in part by Research to Prevent Blindness, Inc., NEI Training Grant EY 00023, and NEI Research Grant 00432.

Reprint requests to William C. Edwards, M.D., Department of Ophthalmology, University of Louisville, School of Medicine, 301 East Walnut Street, Louisville, Kentucky 40202.

*Case* 2—This 13-year-old Caucasian girl had multiple facial anomalies: hypertelorism, a broad nasal bridge, a midline depression near the tip of the nose and a low, V-shaped frontal hair line. The eyes were structurally normal although a refractive amblyopia was present in the left eye.

Other abnormalities included craniosynostosis involving the coronal suture, left-sided cleft lip and palate and possible mental retardation.

*Case* 3—This two and one-half-year-old Caucasian girl demonstrated mild hypertelorism, mild broadening of the nasal bridge, and a small midline depression near the tip of the nose. The only ocular abnormality apart from hypertelorism was a variable horizontal strabismus ranging from esotropia to exotropia. The child's intelligence was normal. No other significant physical abnormalities were detected.

## DISCUSSION

The term "ocular hypertelorism" was used by Greig in 1924.[1] His definition excluded cases in which there were midline facial defects.

The median cleft face syndrome was first described by DeMyer.[2,3] According to his criteria, this diagnosis is made by identifying

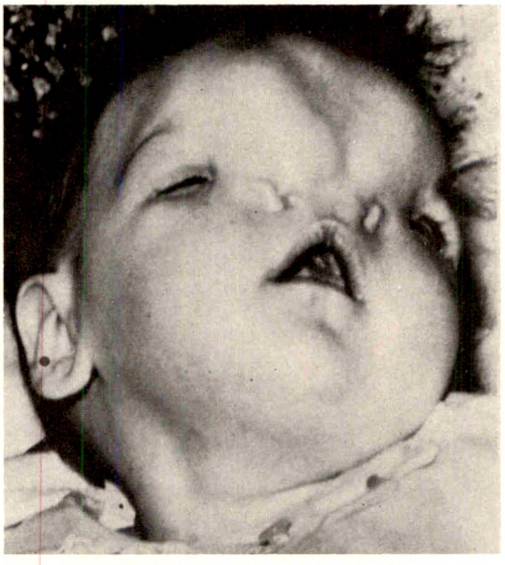

Fig. 1 (Edwards, Askew, and Weisskopf) Case 1. Nine-month-old girl with severe midline facial deformities.

two or more of the following anomalies in a patient: (1) ocular hypertelorism, (2) cranium bifidum occultum, (3) median cleft nose, (4) median cleft lip, (5) median cleft premaxilla. Other features which may be present are: (6) a low, V-shaped frontal hair line, (7) median cleft palate, and (8) primary telecanthus. Median lipomas, median teratomas, and frontal encephaloceles have been found rarely with a median cleft face syndrome. The eight anomalies listed above may occur alone or in combination in an otherwise healthy individual. They may also occur in patients with other extrafacial defects. This last group of patients may represent other diagnostic categories.

In addition to that of DeMyer, other reports have recently described cases with features of the median cleft face syndrome.[4,5] One author had previously used the term "frontonasal dysplasia" to designate this syndrome.[5]

The following ocular abnormalities have been described in patients with the median cleft face syndrome: hypertelorism, telecanthus, epicanthal folds, epibulbar dermoid tumors, exotropia, and microphthalmos (unilateral).

DeMyer has subdivided the median cleft face syndrome into four major facial patterns ranging from Facies I: all the major defects being present to a marked extent, to Facies IV: median cleft nose and hypertelorism only (the defects may be mild). Our three cases demonstrate a broad range of deformity falling within the syndrome.

Case 3 had two of the features of the median cleft face syndrome—mild hypertelorism and a small, midline depression near the tip of the nose.

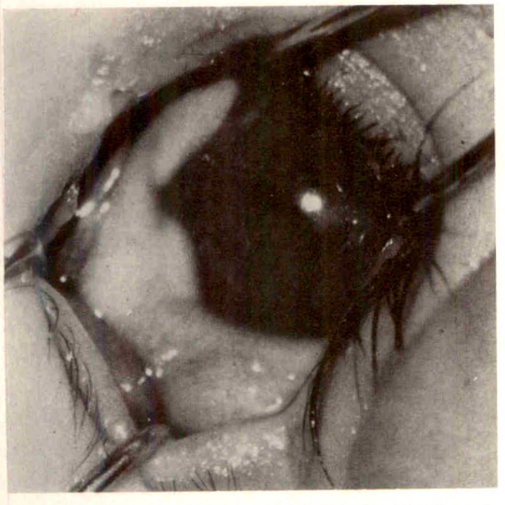

Fig. 2 (Edwards, Askew, and Weisskopf) Case 1. Left eye showing two limbal dermoid tumors.

Fig. 3 (Edwards, Askew, and Weisskopf) Case 1. Shortened right lower extremity, varus deformity of the right foot and polydactyly involving both lower extremities.

Case 2 is more severely affected demonstrating greater hypertelorism, a pronounced midline depression of the nose, and a low, V-shaped frontal hair line. In addition, the patient had craniosynostosis involving the coronal suture resulting in foreshortening of the head and a left-sided cleft lip and palate. These latter anomalies may remove this patient from the category of the median cleft face syndrome.

Case 1 illustrates severe hypertelorism and median cleft nose. She also had a notched upper lip and possibly a frontal encephalocele. This patient's facial features are compatible with those of the median cleft face syndrome and she closely resembles a published photograph of a child with this diagnosis.[5] Other congenital anomalies involving the lower extremities are also present in our patient. Extrafacial anomalies have been reported in patients with this syndrome, such as clinodactyly and partial thumb duplication.[2]

The finding of hypertelorism may be difficult to diagnose. Anomalies of other facial structures may make the eyes appear widely spaced where the actual intraocular and interorbital distances are not large. Posteroanterior skull radiographs may provide determination of intraorbital hypertelorism in patients with a craniofacial defect. Standards of normal interorbital distances determined roentgenographically for different age groups have been published.[6,7]

Ocular hypertelorism occurring alone in high degree or with certain other extrafacial anomalies carries a high probability of mental retardation[2]; however, if ocular hypertelorism is combined with one or more of the medial facial anomalies forming a pattern of the median facial cleft face syndrome, the probability is that the intelligence will be normal or near normal.[2] This is true even in the presence of severe facial malformation. Such a favorable likelihood of near normal or normal intelligence may not apply to patients with certain extrafacial anomalies in addition to features of the median cleft face syndrome.[2]

Abnormalities of the median facial structures may occur in association with hypotelorism. In these cases the probability of anomalous development of the brain and consequent psychomotor impairment can be correlated with the severity of the facial deformity. Only the patient with a mild degree of facial malformation may be expected to have a normal intelligence and potential for development. More severely affected individuals do not usually survive the first few years of life.[8]

In the view of one author[4] the median cleft face syndrome is not hereditary; however, DeMyer[2] has stated that familial occurrence of the full syndrome is quite rare, although individual features of the syndrome are more commonly familial. Although full-blown cases do not seem to be genetically transmitted, future investigation may reveal forme fruste defects in family members of individuals affected by the full syndrome.

In regard to etiology, possible relationship of drugs to birth defects may also be considered. In certain animals excessive administration of meclizine has shown teratogenic effects and has caused cleft palate, microstomia, and micromelia (short limbs).[9,10]

## Summary

Three cases are presented which demonstrate variations of a developmental disorder known as the median cleft face syndrome. The diagnosis of this syndrome is made by identifying two or more of the following anomalies in a patient: (1) ocular hypertelorism, (2) cranium bidfidum occultum, (3) median cleft nose, (4) median cleft lip, (5) median cleft premaxilla. The most consistent and prominent ocular finding associated with this syndrome is hypertelorism. Other ocular abnormalities include telecanthus, epicanthal folds, epibulbar dermoid tumors, exotropia, and microphthalmos. Some patients demonstrate mild anomalies of the mid-face region

whereas others have very marked deformities.

ACKNOWLEDGMENT

We thank Mr. Thomas Van Cader for these photographs.

### OPHTHALMIC MINIATURE

The Duke of York (afterwards James II) expressed a great desire to see old Milton of whom he had heard so much. The King felt no objection . . . and afterwards, James went privately to Milton's house, where . . . a free conversation ensued between those very dissimilar and discordant characters. The Duke asked Milton whether he did not regard the loss of his eyesight as a judgment inflicted on him for what he had written against the late king. Milton's reply was: "If Your Highness thinks that the calamities which befall us here are indications of the wrath of Heaven, in what manner are we able to account for the death of the King, your father? The displeasure of Heaven must, upon this supposition, have been much greater against him than against me: for I have lost only my eyes but he lost his head." Much discouraged by this answer the Duke took his leave.

## PSEUDO-EXFOLIATION OF THE LENS AMONG THE NAVAJO INDIANS

H. WADE FAULKNER, M.D.
*Phoenix, Arizona*

The reported incidence of pseudo-exfoliation of the lens in people over the age of 60 years has varied from 2% in Switzerland[1] to 17% in Norway.[2] Recently Aasved[3] reviewed the geographical distribution of pseudo-exfoliation and reported its incidence in Norway, England and Germany to vary from 2.7 to 7.7% in people over 60 years of age.

This paper reports the high incidence of pseudo-exfoliation of the lens among the Navajo Indians living on their reservation in this country.

### MATERIAL AND METHOD

Fifty consecutive new patients, 60 years of age and older, attending the eye clinic at the United States Public Health Service Indian Hospital in Tuba City, Arizona, were evaluated for pseudo-exfoliation. The evaluation included best corrected visual acuity, slit lamp examination, applanation tonometry, gonioscopy, and ophthalmoscopy after dilatation of the pupil with 10% phenylephrine HCl. The diagnosis of pseudo-exfoliation was made by observing the typical dandruff-like deposits on the anterior lens capsule, pupillary margin, and trabecular meshwork.

Three patients with pseudo-exfoliation (two were normotensive and one had glaucoma with field loss in one eye only) were hospitalized and topical dexamethasone, 0.1%, was administered to one eye four times daily for six weeks. They were followed with weekly applanation pressures and tonography.

From the Department of Ophthalmology, USPHS Indian Hospital, Phoenix, Arizona.
Reprint requests to H. Wade Faulkner, M.D., 1359 Springhill Avenue, Mobile, Alabama 36604.

### RESULTS

Nineteen (38%) of the 50 patients had bilateral pseudo-exfoliation of the anterior lens capsule. Three patients (6%) had glaucoma capsulare with pathologic cupping and glaucomatous field loss.

All three patients who were tested with topical corticosteroids were "non-responders." Intraocular pressure in the tested eye never exceeded 20 mm Hg. One of the patients tested with topical corticosteroids had glaucoma capsulare in one eye and there was pseudo-exfoliation of the lenses of both eyes. The tested eye was otherwise normal in all respects, including full fields, applanation pressures of 15 and 18 mm Hg, water provocative tonography, and grade four open angles.

### DISCUSSION

Pseudo-exfoliation of the lens is a common, although previously unreported, finding in elderly Navajo Indians. Glaucoma (glaucoma capsulare) is frequently associated with pseudo-exfoliation.[4] There is debate as to whether glaucoma capsulare is secondary to the pseudo-exfoliation or a manifestation of genetically inherited primary open-angle glaucoma. Eyes with a tendency toward genetically inherited primary open-angle glaucoma respond to topically administered corticosteroids with significant intraocular pressure elevations.[5] The incidence of positive corticosteroid responsiveness is approximately the same in the Southwestern Indians as in other United States population groups.[6]

Recently, Gillies[7] reported corticosteroid responsiveness in the opposite eye in only one of six patients with bilateral pseudo-exfoliation and unilateral glaucoma capsulare. This data, combined with a similar patient

reported here, strongly suggests that glaucoma capsulare is either a secondary glaucoma or at least a glaucoma not related genetically to corticosteroid responsiveness.

## Summary

Nineteen (38%) of 50 consecutive Navajo Indians, aged 60 years or more, who attended the eye clinic of the USPHS Indian Hospital in Tuba City, Arizona, were found to have psuedo-exfoliation of the lens capsule. In three (16%) of the 19, the pseudo-exfoliation was associated with open-angle glaucoma.

# PARADOXICAL ELEVATION OF EYELID ON SMILING

Trevor H. Kirkham F.R.C.S.

*Oxford, England*

An unusual synkinetic movement of the left upper eyelid which occurred only on smiling is reported for its rarity.

## Case report

A girl, aged 16 years, attended for a refraction appointment. Visual acuity was 6/6 in each eye. The ocular movements were full. There was a left blepharoptosis of 2 mm, but a good eyelid fold (Fig. 1) and large range of levator action was present. Bell's phenomenon was present equally on both sides. Movements of the jaws or tongue had no effect on the ptotic eyelid, but when she smiled, the ptotic eyelid elevated so that the palpebral apertures were symmetrical and it remained elevated for as long as she maintained her smile (Fig. 2). Both voluntary and involuntary smiling produced the synkinesis. No other facial movements had any effect on the position of the eyelid, and no synkinesis with other cranial nerves was demonstrable.

Fig. 1 (Kirkham). To show the left blepharoptosis.

Fig. 2 (Kirkham). The left eyelid elevates on smiling.

A photograph taken at the age of two years showed that the left blepharoptosis had remained unaltered over the years. There was no family history of any congenital abnormalities.

## Comment

The most frequent congenital synkinetic movement of the upper eyelid is the Marcus Gunn phenomenon of jaw winking; this is believed to be due to a part of the motor supply for the lateral pterygoid muscle terminating in the levator palpebrae superioris, which thus has a dual innervation. Rare synkinetic movements of the upper eyelid in association with contraction of other extraocular muscles are summarized by Duke-El-

Reprint requests to Trevor H. Kirkham, F.R.C.S., Eye Department, the London Hospital, Whitechapel, London E. 1, England.

der.[1] An interesting boy who had the Marcus Gunn phenomenon but who also had synkinetic eyelid retraction on sternomastoid contraction and on tongue protrusion was described by Parry[2]; no synkinesis occurred with facial movements. However, synkinetic eyelid retraction on smiling, but not on voluntary facial movements, as well as on activation of the ipsilateral sternomastoid and on coughing and performing the Valsalva maneuver, was described by Bradley and Toone.[3] Smiling, but not voluntary movement, produced the synkinesis which led them to believe that supranuclear connections between the nerves were involved and that a congenital abnormality of neuronal connections in the brain stem was the most likely explanation of the widespread synkinesis present in their case. The present case demonstrates that, whatever the anatomical site of the lesion, the final common pathway for voluntary and involuntary smiling is the same.

## Summary

A girl who showed congenital synkinetic retraction of the left upper eyelid on both voluntary and involuntary smiling is described.

## Ophthalmic miniature

"And you processed her?"

"I processed her. But giving drugs to a cat is no joke, Kemp! And the process failed."

"Failed?"

"In two particulars. These were the claws and the pigment stuff—what is it? At the back of the eye in the cat. You know?"

"Tapetum."

"Yes, the tapetum. It didn't go. After I'd given the stuff to bleach the blood and done certain other things to her, I gave the beast opium, and put her, and the pillow she was sleeping on, on the apparatus. And after all the rest had faded and vanished, there remained the two little ghosts of her eyes."

# MEETINGS, CONFERENCES, SYMPOSIA

EDITED BY THOMAS CHALKLEY, M.D.

## 91ST CONGRESS OF THE OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM

The meeting of the 91st Congress was held in the Royal College of Physicians, London, under the presidency of Prof. George Scott of Edinburgh April, 21-25, 1971. It was attended by 400 members together with guest speakers from all parts of the world.

The Bowman lecture, in honor of Sir William Bowman, the first President of the O.S.U.K., was delivered by Dr. Algernon B. Reese of New York. His highly informative lecture was entitled, "Expanding lesions of the orbit," a subject of increasing interest in the past few years, and one in which the speaker is a recognized authority with broad experience for many years. His very well-organized material was based on a meticulous study and survey of more than 500 cases. It put us far along the road of understanding the nature and the surgical treatment of these lesions. Dr. Reese's Bowman Lecture, in the words of a British colleague was "jolly good!" The extra high quality that a Bowman Lecture demands was fully achieved. Dr. Reese now joins with the immortal names of the other four Americans who have been honored by the Society's greatest honor. These are DeSchweinitz, Arnold Knapp, J. H. Dunnington, and Michael Hogan.

The first symposium was on the dry eye, the opening speakers being Prof. Claes Dohlman, Mr. Peter Wright, Dr. J. M. Gumpel, and Dr. Ian A. Mackie. Dohlman described his recent work on the role of the mucus derived from the conjunctival goblet cells, for the stability of the tear film. He thought that there were probably two basic types of the dry eye syndromes—a primary aqueous tear deficiency, such as occurs in keratoconjunctivitis sicca in rheumatoid arthritis, and a mucus deficiency in a condition such as the Steven-Johnson syndrome, early pemphigoid, and avitaminosis A.

Mr. Peter Wright discussed the management of the dry-eyed patient and the efforts being made to find the ideal tear solution. It would appear that gel contact lenses do not seem to be the answer. It seems doubtful if gel lenses will fulfill the promise excited on their introduction as a new therapeutic weapon.

The second symposium took the form of a discussion of the ischemic eye and the 16 papers on this subject, contributed by speakers from all over the world, constituted the most comprehensive review that has ever been held at one meeting of any society. Prof. W. R. Keatinge discussed the mechanism of vessel closure and stressed that the vessel wall tension is not greatly affected by distension. A critical internal closing pressure exists, below which the vessel closes completely. The large arteries can sometimes contract with enough force to shut the lumen completely in the presence of a normal arterial pressure. He pointed out that smooth muscle contraction is produced mainly by adrenergic nerve fibers. However, it may also be excited by direct irritation of smooth muscle cells. Recent work has shown that the adrenergic nerve fibers are distributed only to the outer part of the walls of the arteries and that they probably produce their effects in part by producing action potentials in the smooth muscle cells.

Dr. David Knox discussed the various etiologic factors in ischemic ocular disease and Dr. H. Bettelheim described the use of ophthalmodynamography in the investigation of acute and chronic ocular ischemia.

Dr. Clifford Rose and associates discussed the radiologic investigation and surgical treatment of sudden blindness due to extracranial vascular lesions and described their

findings in 28 patients with monocular blindness investigated by archangiography. Sixty-eight percent of these patients had lesions affecting the carotid and 48% had verified vertebral lesions: two patients exhibited the sublavian steal syndrome, which is amenable to surgery. Only 28% of such patients appeared to have lesions sufficiently severe to require surgery. The indications for surgery were clearly outlined.

Dr. S. S. Hayreh gave a most interesting account of his recent research on posterior ciliary artery occlusion and emphasized that the two (or three) large posterior ciliary arteries arising from the ophthalmic artery divide into multiple branches near the globe and supply the blood to the choroid, optic disk and the retrolaminar part of the disk in a segmental fashion.

Dr. Paul Henkind in reviewing ischemia of the posterior segment of the eye, stressed that the knowledge of the angio-architecture of the retina, choroid, and optic nerve head must be considered in conjunction with the microcirculatory dynamics of these regions if we are to understand the various patterns of ischemia that can occur. He discussed the role of ischemia in a number of conditions such as branch and central artery occlusions, diabetes, hypertension, giant-cell arteritis, and malignant atrophic papulosus (Degos' disease).

The many other papers read included a review of the clinical and electron microscopic aspects of corneal dystrophy by Dr. Michael Hogan, and the scanning electron microscopy of the cornea, by Drs. Haining and McLean. Mr. J. Penman gave a fascinating account of facial pain and its treatment, and Mr. Hung Cheng and co-workers described the use of fluorescein angiography in the study of the iris vessels.

Mr. Dermot Pierse showed an excellent film, illustrating some new points in the technique of iridocyclectomy.

The Congress was a great occasion, with the meetings of the International Council of Ophthalmology, of the Verhoeff Society (celebrating its 25th anniversary), and of the European Ophthalmic Pathology Society all there to stimulate lively disagreement, sometimes acrimonious! The annual banquet of the society was held on Thursday evening, April 22, in the Park Lane Hotel. It was formal, sparkling, and gracious traditional affair. After the toast to Her Majesty, the Queen, Sir John Richardson, President of the Royal Society of Medicine, proposed a witty toast to the health of the D.S.U.K. This was responded to by President Scott in most gracious terms. The customary "toast to the guests" was proposed by Prof. Norman Ashton, still in a state of blissful shock on learning of his election as Fellow of the Royal Society but a few weeks before. This back-bowing burden, however, did not prevent him from exceeding his reputation as the "Bob Hope" of Ophthalmology. Prof. Jules François, President of the International Council of Ophthalmology, then replied for the guests in impeccable English and with good humor. It was a very nice party.

The smashing success of this annual meeting of a great and ancient organization lies in the attraction of the largest-ever attendance by its own membership. The large lecture hall of the Royal College of Physicians was filled to capacity every day from nine o'clock in the morning until five in the afternoon.

The next annual Congress of the O.S.U.K. will be held in Edinburgh, the home of President Scott, April, 11 through 13, 1972. It promises to be a caledonian charivari. Inquiries regarding this meeting should be addressed to the Secretary, The Ophthalmological Society of the United Kingdom, Royal College of Surgeons, Lincoln's Inn Fields, London W.C., England.

George Scott, F.R.C.S.
*Edinburgh, Scotland*
Derrick T. Vail, M.D.
*Chicago, Illinois*

## ASSOCIATION FOR RESEARCH IN VISION AND OPHTHALMOLOGY SPRING MEETING

The Association for Research in Vision and Ophthalmology (formerly the Association for Research in Ophthalmology) held its annual spring meeting in Sarasota April 26–30, 1971. Over 800 registrants were recorded and the program listed close to 380 papers.

It is interesting to compare these data with those of the 1969 Spring meeting, at which time it was noted that "a record number of 469 scientists attended the annual meeting of the Association for Research in Ophthalmology . . . to hear an unprecedented number of nearly 200 papers."

The papers covered a wide spectrum of topics, including clinical research, physiology and pharmacology, anatomy and pathology, visual electrophysiology, immunology and microbiology, visual psychophysics and physiological optics, and biochemistry.

Those in ophthalmology who were fearful that expanding the organization to include a large number of basic scientists would mean a de-emphasis of clinical research can "take heart" from this meeting. The clinical research program was indeed far larger this year than ever before and covered enough of a variety of subjects to please most clinicians. Indeed, there were topics of obvious clinical interest scattered throughout the basic science seminars, and one section, Immunology and Microbiology, devoted almost an entire session to topics of clinical interest.

A major topic emphasized in several of the clinical research programs was ophthalmic genetics. All types of ocular hereditary diseases were discussed. Several new conditions were described and histochemical and electron microscopic findings were detailed in numerous well-known genetic abnormalities.

One of the clinical research sessions featured topics dealing with diabetic retinopathy. In a session on the retina, numerous papers on the technology of newer laser instruments used in the treatment of retinal conditions were presented. In this same meeting, there were several interesting papers dealing with new methods for the removal of non-magnetic foreign bodies from the vitreous.

In the sessions in Physiology and Pharmacology, the four areas emphasized were circulation and intraocular pressure, recent advances in drug dynamics and drug delivery systems, neurotransmitters and transport, and permeability.

A symposium on extragenticulate visual pathways was featured in a combined meeting of the Sections of Anatomy and Electrophysiology.

Honorary membership was given to Lorand V. Johnson, long-time secretary of the Association for Research in Ophthalmology. A "Past President Plaque" was given to Jin H. Kinoshita. The Proctor Medal was given to William A. A. Rushton, who presented "Color Vision: An Approach through the Cone Pigment" as the Proctor lecture. The Friedenwald lecture was given by Claes H. Dohlman, who spoke of the "Function of Corneal Epithelium in Health and Disease." Lorin Riggs was elected a trustee.

The next meeting will again take place in Sarasota, Florida, during the last week in April. The group owes thanks to the Florida members who arranged for the facilities and to the various section chairmen who organized the excellent programs.

## HERPES SIMPLEX CORNEAE—ITS CENTENNIAL OF RECOGNITION

Johann Friedrich Horner (the Horner of Horner's syndrome) was the first to recognize herpetic keratitis (Klin. Mbl. Augenheilk. 9:321, 1871). He described a unilateral affection in which the painful eye exhibited a crop of minute, clear vesicles on the corneal epithelium that soon ruptured leaving slightly clouded desquamated spots. The vascularization associated with phlyctenulosis was absent. Since the diseased eye at times was on the same side as herpetic vesicles on the lips or angle of the nose, Horner concluded that the affected cornea manifested the same herpetic infection as that seen on the face, lips, and genitals. The prior confusion with phlyctenules is exemplified in *A Treatise on the Diseases of the Eye* (1870) by Soelberg Wells, who, under "Phlyctenular corneitis (herpes corneae)" says, "Sometimes the phlyctenulae are very superficial and appear in the form of small, transparent vesicles or blisters, whose epithelial covering is soon shed, leaving a small excoriation, which may easily escape detection." The vesicular form of herpetic keratitis is uncommon and the more usual appearance was mis-

interpreted for many years. As late as 1905, Berry's *Manual of Practical Ophthalmology* showed a drawing labeled "Dendritic (mycotic) keratitis," with the textual description: "The cause is not known, though it is evidently a mycotic one. It is best treated by dabbing on to its surface some absolute alcohol with a camel's hair brush." However, the association of disciform keratitis with herpetic infection was noted by Ernst Fuchs in 1901 and the metaherpetic ulcer was described by Vogt in 1930.

Our knowledge of the disease was greatly expanded by the experimental revelations of Grüter. In 1912, he transmitted this human infection to the scarified cornea of rabbits, and in 1920 transferred the herpetic keratitis in an inoculated rabbit to the cornea of a blind man. In 1924, he isolated the virus from herpetic vesicles and confirmed Horner's clinical intuition that herpes of the cornea, face, and genitals were all caused by the same organism. In later studies Grüter observed in his rabbits the evolution of disciform keratitis from which he likewise recovered the herpes simplex virus. Grüter's evidence that the experimentally induced herpetic keratitis in the rabbit paralleled the naturally occurring disease in man established inoculation of the rabbit cornea as a means of definite diagnosis and as an ideal model for further studies. After the herpes virus was found to grow readily on the chorioallantoic membrane and one appropriate tissue culture cells, a suspension of pure virus of a desired strain is now obtainable. When dropped on the intact rabbit cornea, punctate epithelial lesions develop within four days. The intact basement membrane becomes softened and hence too aggressive chemical cauterization or mechanical scraping may expose the stroma to viral invasion. In both rabbit and man, the herpes simplex virus is shed in tears, saliva, and sputum between recurrences, and so the ever-present virus may precipitate an attack of herpetic keratitis whenever the tissue resistance of the cornea is temporarily lowered by any of numerous trigger mechanisms such as fever, allergy, emotional disturbance, or menstruation.

Herpes simplex is the most widespread of human viral visitations. The primary infection is usually transmitted by kissing and generally is subclinical, but occasionally causes a gingivostomatitis. The neutralizing antibodies which reach a maximum titer in two weeks confer no protection, and indeed, an attack of herpetic keratitis predisposes to recurrences. Since nine-tenths of the population past age 15 are carriers, serological testing for diagnosis is valueless. The same high titer of antibodies may be present before, during, and after herpetic keratitis. The initial attack of herpetic keratoconjunctivitis may be mistaken for epidemic keratoconjunctivitis. Besides a regional adenopathy, the cornea may show small white plaques that stain faintly with fluorescein but brightly with rose bengal. Subsequent recurrences are limited to the cornea and are potentially far more serious. The usual recurrence is the pathognomonic dendritic ulcer—occasionally, a superficial punctate keratitis. Corneal hypesthesia follows rather than precedes the attack and is evident after the first week. It is readily demonstrated by the instillation of an innocuous irritating solution such as ethylmorphine HCl (Dionin), 2%, or sulfacetamide, 30%, first instilled on the affected cornea and then on the other. The degree of hypesthesia is proportionate to the extent and duration of corneal ulceration and, when marked, increases the liability of a sequential metaherpetic ulcer that appears about three weeks after the herpetic keratitis has healed. The roundish ulcer apparently results from a trophic disturbance of the cornea; no virus is detectable by even the sensitive fluorescein antibody technique or electron microscopy.

In 1936, Gundersen made a detailed study of 221 cases of herpetic keratitis. Herpes appeared elsewhere on the face in three of eight patients, but involved only the cornea in the others. In a group treated by only

atropine and heat, one of four cases resolved, but more certain and quicker recovery followed local destruction of the virus by chemical cauterization of the ulcer and adjacent epithelium. Gundersen popularized the use of iodine. He applied Tr. iodine several times until a deep chestnut brown resulted, after which the iodine was neutralized by cocaine, 4%. Patching the affected eye proved of no value. In 1961, Sery discovered that the silver ion was a more potent inactivator of the herpes simplex virus than iodine or other chemical agents. After applying silver nitrate, 0.5%, to the affected areas for a few minutes, the eye was irrigated with sterile saline. If needed, treatment was repeated in three days. This method was not advised in stromal involvement because of the possibility of silver staining.

Topical cortisone for ocular affections was introduced in 1950 and its devastating action in herpetic keratitis was very soon evident. In cases given topical or systemic corticosteroids, serious complications were five times as frequent as in those not so treated. The inhibition of interferon promoted replication of virus, ameboid ulceration, stromal involvement, secondary infection, and corneal perforation. Other deleterious drugs are local anesthetics for home use, proteolytic enzymes and epinephrine.

A signal advance in the therapy of herpetic keratitis was inaugurated by Kaufman in 1962 with idoxuridine, a nucleotide analogue. If given early, resolution promptly occurs in two-thirds of cases. The 0.5% ointment given five times daily is preferable to the 0.1% solution instilled hourly. The iodoxuridine substitution for thymidine into the DNA of the herpes virus renders its DNA defective and incapable of replication. The action of the drug is limited to the surface epithelium where the virus is readily accessible. The healthy cells of the cornea are not appreciably affected, protected by their slow rate of multiplication and the greater permeability of virus-infected cells to iodoxuridine. If the eye responds favorable to treatment in five days, the drug should be continued for two weeks; if not, chemical cauterization is indicated.

Though the virus is present in stromal herpes, its mesodermal milieu may have a moderating effect on its dermotropic virulence. Stromal involvement is seldom evident for the first two to three weeks. The late occurrence suggests that an antibody-antigen reaction is an important factor, a view supported by the reversal of disciform edema, relief of symptoms, and reduction of scarring effected by small doses of corticosteroids. When iodoxuridine ointment is used with the corticosteroids, the safety of the latter is greatly increased. To lessen the inflammatory reaction of an associated uveitis, systemic phenylbutazone (Butazolidin) is safe and effective.

James E. Lebensohn

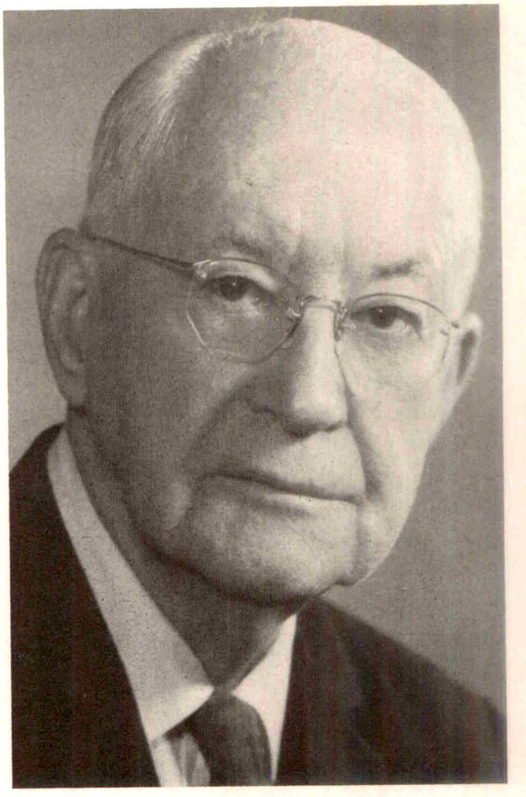
## OBITUARIES

### EVERETT LOGAN GOAR
### 1886–1971

Everett L. Goar, M.D., was born in Clinton County, Indiana, on November 13, 1886. He died at the age of 84 on April 25, 1971, in Houston, Texas, where he had practiced from 1921 until his retirement, January 1, 1971. He graduated from Kirklin, Indiana, high school in 1903 and from Indiana University, Bloomington, in 1907. After graduation from Rush Medical College, Chicago, Illinois, in 1909, he served his internship at Chicago's Cook County Hospital from 1909-11. During World War I, Dr. Goar became a Major in the Medical Corps. He studied ophthalmology at the New York Eye and Ear Infirmary in 1920 and at the University of Colorado in 1922, and was awarded Doctor of Ophthalmology degree from Colorado University in 1925.

Dr. Goar gave generously of his time and efforts to each of the many organizations to which he belonged. He served as president of the Harris County Medical Society, of the



Houston Academy of Medicine, and of the Texas Society of Ophthalmology and Otolaryngology, and of the American Ophthalmological Society, 1954-55. He served as Vice President of the American Academy of Ophthalmology and Otolaryngology. He was Chairman of Section on Ophthalmology of the American Medical Association. He was a member of American Board of Ophthalmology for nine years and Chairman of the Board, 1947-48. He was Director of the National Society for Prevention of Blindness, 1952-1960, and Chiarman of the Professional Committee of the Texas Society for Prevention of Blindness. For his role in organizing the Texas Society, he received the Dana Gold Medal award in 1962.

Dr. Goar was one of the men instrumental in the moving of Baylor University College of Medicine from Dallas to Houston, Texas, in 1943. He was Professor of Ophthalmology and Head of the Department from 1943 to 1957 and was Professor Emeritus at the time of his death.

He was primarily interested in teaching the young. For his work with the Boy Scouts, he received the Silver Beaver Scouting award in 1936. Professionally as a teacher, for many years he helped give courses at the Academy on slit-lamp examinations and wrote many articles on various subjects in this field, including his "Handbook of Ophthalmology" for medical students.

He was an active church member and lived by the Golden Rule and Ten Commandments. On February 22, 1971, when he was given the Good Citizen Award by the Paul Carrington Chapter of the Sons of the American Revolution, one of the speakers stated: "This evening we gather to say thank you publicly to a sincere and unassuming man who is universally acclaimed as one of the great ophthalmologists of the world."

Shortly after his retirement, he gave his office equipment to the remote province of Kasai, deep in the African Congo, where it will continue to be of service to people who cannot afford modern equipment.

Everett Logan Goar, M.D.

A devoted family man, he is survived by his wife, Eleise Hailey Goar, and three children, E. Logan Goar, Jr., Robert Jefferson Goar, and Mrs. Fred (Ann) Babb. With the passing of Dr. Goar, ophthalmology, mankind, and his associates have suffered a great loss. His contributions to ophthalmology will long be remembered.

Jacob F. Schultz

## ARCHIMEDE BUSACCA

Professor Archimede Busacca of San Paulo, Brazil, died March 25, 1971, in San Paulo. He is the author of Biomicroscopy and Histology of the Eye, in three volumes. In 1932 he described the floccule that bear his name which occur on the mesodermal surface of the iris in uveitis. His corneas were used for transplants immediately after his death.

## CORRESPONDENCE

### JAW-WINKING BLEPHAROPTOSIS

Editor,
American Journal of Ophthalmology:

The direct quotation ascribed to Raynold N. Berke in my paper discussing causes, types, and factors concerning congenital blepharoptosis (Am. J. Ophth. 71:696, 1971) should read: "After 20 years of trial and error I can honestly say that the surgical treatment of jaw-winking ptosis is no simple problem.

This is so because we must eliminate the jaw-winking phenomenon as well as correct the ptosis. This dual purpose can be accomplished only by excising a large part of the levator to release the bizarre behavior of the lid and then suspending the lid from the superior rectus or from the frontalis muscle.

If this principle is ignored and a resection of the levator done for the ptosis, then (at least in this author's experience) the ptosis will persist and the jaw-winking will be exaggerated.

If a large section of the levator is excised and the lid suspended from the superior rectus, an excellent result can be obtained only if the superior rectus is normal. But if this muscle is paretic, a progressive hypotropia will develop with the years; and since about two-thirds of all jaw-winkers have a weak superior rectus, some other procedure must be used for most such cases."

Edmund B. Spaeth

## BOOK REVIEWS

CHLAMYDIA AND CHLAMYDIA-INDUCED DISEASES. By Johannez Storz, DVM. Clothbound, 358 pages, table of contents, appendix, bibliography, index, 94 black and white figures. $20

This long-awaited volume on the chlamydia will be welcomed by ophthalmologists, microbiologists, veterinarians, urologists, gynecologists, and public health workers. Prof. Storz has been successful in bringing together in one volume much important information previously available only to the worker willing and able to review a variety of journals in many different disciplines. Prof. Storz has described the fascinating biology of the chlamydial agents as well as the nature and characteristics of the many chlamydia-induced diseases. These extraordinary organisms were long thought to be viruses but are now known to be small, bacteria-like intracellular parasites lying intermediately between the rickettsiae and the larger viruses. Their wide range of hosts encompasses birds, animals, and man. Both the reaction of vertebrates to the chlamydia and the pathogenic mechanisms by which the chlamydial agents induce such types of disease as pneumonia, enteritis, polyarthritis, abortion, and keratoconjunctivitis are well described. The problems relating to immunity and the many unsuccessful vaccination trials that have been made are all fully covered.

The ophthalmologist will find much of interest in this volume since several ocular diseases in addition to trachoma are now known to be of chlamydial origin. At least five chlamydial agents—those responsible for trachoma, inclusion conjunctivitis, lymphogranuloma venereum, parakeet psittacosis, and feline pneumonitis—are now known to attack the external human eye. Uveitis is now known to occur in lymphogranuloma venereum and in rare cases of inclusion conjunctivitis. It seems likely that some cases of Reiter's syndrome, with its conjunctivitis, keratitis, and uveitis, are of chlamydial origin; and it is certainly now well accepted that chlamydial urethritis and cervicitis are widespread in the population and responsible for the fact that inclusion conjunctivitis of the newborn is the commonest type of ophthalmia neonatorum in the United States.

Prof. Storz's volume is well illustrated and the bibliography complete.

Phillips Thygeson

# ABSTRACT DEPARTMENT

EDITED BY DAVID SHOCH, M.D.

## ARCHIVES OF OPHTHALMOLOGY

VOLUME 85 FEBRUARY, 1971 NUMBER 2

DOMINANT JUVENILE OPTIC ATROPHY. Caldwell, J. B. H., Howard, R. O. and Riggs, L. A. (Yale University School of Medicine, 333 Cedar St., New Haven, Conn., Arch. Ophth. 85:133-147, Feb., 1971.

Optic atrophy, with a dominant pattern of inheritance, may occur in childhood with an insidious onset, and may be unrelated to any other neurological, congenital, or developmental anomaly. The clinical and laboratory findings are described in two families with this condition. (8 figures, 4 tables, 35 references)—Authors' abstract

TOPICALLY APPLIED CORTICOSTEROIDS IN GLAUCOMA CAPSULARE. Pohjola, S. and Horsmanheimo, A. (Helsinki University School of Medicine, Helsinki), Arch. Ophth. 85:150-153, Feb., 1971.

Eleven (28%) of 39 patients with glaucoma capsulare responded to topical dexamethasone treatment with pressure elevation of 6 mm Hg or more. It seems that glaucoma capsulare is not genetically identical with primary open-angle glaucoma and should be regarded as secondary glaucoma. Interestingly, most responders (eight out of 11) had, in addition to glaucoma capsulare in one eye, primary open-angle glaucoma in the fellow eye. (5 tables, 8 references)—Authors' abstract

PHOTOCOAGULATION THROUGH THE GOLDMANN CONTACT GLASS. Fankhauser, F., Lotmar, W. and Roulier, A. (Universitats-Augenklinik, 3000 Bern, Switzerland), Arch. Ophth. 85:154-162, Feb., 1971.

From observation of the temporal development of photocoagulation lesions generated by a quasi-continuous ruby laser source described earlier, it was concluded that lesions less densely distributed would still result in satisfactory welding of the retina. Biomicroscopic follow-up of more than 200 cases has shown that this conjecture is essentially correct. Indeed, lesions of very low pulse energy lead to strong stimulation and proliferation of pigment epithelium. Among the cases only one, that is, 0.5% developed postcoagulative maculopathy (puckering syndrome); whereas, of a comparable number treated with the Zeiss xenon photocoagulator, 3.1% were afflicted with this disease. This result is ascribed to the large difference in light energy between the xenon arc and the Siemens ruby laser apparatus required to cover comparable areas of the retina with coagulates. (3 figures, 11 references)—Authors' abstract

HYDROPHILIC CONTACT LENSES IN CORNEAL DISEASE. Leibowitz, H. M. and Rosenthal, P. (University Hospital, 750 Harrison Ave., Boston 02118), Arch. Ophth. 85: 163-166, Feb., 1971.

Patients having a superficial, sterile, indolent corneal ulcer which failed to respond to conventional therapeutic modalities were fitted with a hydrophilic contact lens. The corneal epithelium was removed prior to lens fitting, and the lens remained in place for one week. In the series of patients described, the hydrophilic contact lens proved to be an extremely useful adjunct in promoting the healing of indolent corneal ulcers. The possible mechanisms by which this effect is accomplished are discussed. (1 figure, 2 tables, 5 references)—Authors' abstract

LOWERING OF INTRAOCULAR TENSION. Mehra, K. S., Singh, R., Char, J. N. and Pajyashree, K. (Medical Enclave, Banaras Hindu University, Varanasi-5, India), Arch. Ophth. 85:167-168, Feb., 1971.

The comparative effects of isosorbide and glycerin on lowering of intraocular tension (IOT) were studied in 54 patients. With isosorbide, a greater fall occurred in 31 patients; while with glycerin, a greater fall occurred in 23. Besides lowering IOT, isosorbide produced significantly fewer side reactions than glycerin. (3 tables, 4 references)—Authors' abstract

FABRY'S DISEASE: OCULAR FINDINGS IN A FEMALE CARRIER. Weingeist, T. A. and Blodi, F. C. (Department of Ophthalmology, University Hospitals, Iowa City 52240), Arch. Ophth. 85:169-176, Feb., 1971.

It is postulated that diffuse corneal haze in Fabry's disease (angiokeratoma corporis diffusum) is due to an abnormal accumulation of sphingolipid in the corneal epithelium. The whorl-like pattern which is seen clinically in the cornea is thought to arise from the formation of a series of sub-epithelial ridges in these patients. (10 figures, 20 references)—Joel G. Sacks

$G_{MI}$—GANGLIOSIDOSIS. Emery, J. M., Green, W. R., Wyllie, R. G. and Howell, R. R. (Eye Pathology Laboratory, the Johns Hopkins Hospital, Baltimore 21205) 85: 177-187, Feb., 1971.

Infantile $G_{MI}$—gangliosidosis, a combined mucopolysaccharide-ganglioside storage disease with important ocular manifestations, is characterized by psychomotor retardation from birth, hepatosplenomegaly, skeletal changes (resembling Hurler's syndrome), peripheral pitting edema, mild corneal haze, and cherry red spots of the maculae. Pathologic studies of the eye, not previously reported, show evidence of muco-polysaccharide storage in the cornea and ganglioside storage in retinal ganglion cells. (17 figures, 31 references) —Authors' abstract

CORRECTION OF THE SUPERIOR LID SULCUS WITH SUBPERIOSTEAL IMPLANTS. Soll, D. B. (Department of Ophthalmology, University of Pennsylvania and Frankfort Hospital, Philadelphia), Arch. Ophth. 85:188-190, Feb., 1971.

A silicone implant with a self-sealing balloon on the posterior surface has been devised to fill the orbital volume from below as a means of correcting this defect. (5 figures, 5 references)—Joel G. Sacks

RECTUS MUSCLE UNION IN SIXTH NERVE PARALYSIS. Frueh, B. R. and Henderson, J. W. (Department of Ophthalmology, N309 University Medical Center, Columbia, Mo. 65201), Arch. Ophth. 85:191-196, Feb., 1971.

A rectus muscle union transferred muscle action without altering insertions on 11 eyes in nine patients with sixth nerve paralysis. Medial rectus tendon recession was also performed and is indicated for deviations greater than 25 prism diopters. The rectus muscle union tends to produce equal or superior cosmetic results and incidence of fusion, less vertical muscle imbalance, but a smaller amplitude of abduction than variations of Hummelsheim's technique. The rectus muscle union is recommended for the treatment of persistent sixth nerve palsies. (6 figures, 3 tables, 14 references)—Authors' abstract

OXYGEN STUDIES IN RETROLENTAL FIBROPLASIA. Flower, R. W. and Patz, A. (Johns Hopkins University Applied Physics Laboratory, 8621 Georgia Ave., Silver Spring, Md. 20910), Arch. Ophth. 85:197-203, Feb., 1971.

The effects of increased arterial partial oxygen tensions ($po_2$) on retinal circulation of the young kitten were investigated by observing changes in the velocity of fluorescein wave fronts in the major arterial branches of the retina. Changes in velocity were correlated with simultaneous carotid arterial $po_2$ determinations. These studies on the larger retinal vessels are the first of a series aimed at determining levels of arterial $po_2$ that can be sustained without damage to any components of the retinal vascular bed. (8 figures, 6 references)—Authors' abstract

CILIARY BODY TEMPERATURES IN CRYOSURGERY. de Roetth, Jr., A. (Institute of Ophthalmology, Columbia-Presbyterian Medical Center, New York), Arch. Ophth. 85:204-210, Feb., 1971.

Intraocular temperatures were investigated during cryosurgery of the ciliary body in albino rabbit eyes. A significant temperature differential was noted between the temperature of the cryosurgical probe and the temperature within the involved tissue. Attempts were made to relate temperature changes in the ciliary body of these rabbit eyes to the clinical course following cryosurgery for the treatment of glaucoma. The need for −80C as the optimum operating temperature is further emphasized, and the drastic changes following freezing with lower temperatures are illustrated. (2 figures, 3 tables, 8 references)—Authors' abstract

EYE CHANGES IN AUTOIMMUNE NZB AND NZB × NZW MICE. Kessler, H. S., Cubberly, M. and Manski, W. (Department of Microbiology, Room 12-515, College of Physicians and Surgeons, Columbia University, 630 W. 168th St., New York), Arch. Ophth. 85:211-219, Feb., 1971.

All of the 7- to 11-month-old NZB × NZW $F_1$ mice investigated presented ocular changes which, in many respects, are analogous to those associated with Sjogren's syndrome in humans. The lacrimal and the salivary glands showed infiltrations and epimyoepithelial islands; however, lobular architecture was preserved. Superficial erosions of the conjunctival epithelium, thinning of the cornea, and formation of keratin granules in the epithelial cells without cornification were common. Lesions in the anterior chamber, lens, iris, and retina, and a decrease in lacrimation was observed. Many such changes which have not been described in Sjogren's syndrome may be associated with the immunopathological findings in these mice. Enucleation is not warranted in Sjogren's syndrome and therefore histological changes with time are not easily followed clinically in patients with this syndrome. (18 figures, 10 references)—Authors' abstract

HERPES SIMPLEX VIRUS-INDUCED CONGENITAL CATARACTS. Cibis, A. and Burde, R. M. (Washington University School of Medicine, 660 Euclid Ave., St. Louis 63110), Arch. Ophth. 85:220-223, Feb., 1971.

Herpes simplex virus (HSV) was cultured from the lens aspirate of a dense cataract present in the right eye of an 18-month-old healthy white girl. A small linear anterior cortical opacity was present in the other eye along with an unusual pattern of chorioretinal scarring. (2 figures, 24 references)—Authors' abstract

DRUSEN OF THE OPTIC DISC AND THE DEVELOPMENT OF FIELD DEFECTS. Cohen, D. N. (Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Boston), Arch. Ophth. 85:224-226, Feb., 1971.

Two young adults with drusen of the nerve head in association with evidence of vascular disturbance experienced the sudden onset of arcuate scotomata. (14 references)—Author's abstract

## BULLETIN DE LA SOCIÉTÉ BELGE D'OPHTALMOLOGIE

VOLUME 153 1969

COMBINED OPERATION FOR GLAUCOMA AND CATARACT. (French) François, J. (Gand), Bull. Soc. Belge Ophtal. 153:623-631, 1969.

Eighty-eight percent of 31 cases obtained a good fistula when a modified Scheie procedure was combined with cataract extraction. (5 figures, 1 table, 47 references)—Frank J. Weinstock

EARLY TREATMENT OF TRAUMATIC CATARACT. (French) Missotten, L. and Van Vlimmeren, H., Bull. Soc. Belge Ophtal. 153: 632-637, 1969.

In ocular injuries with a traumatic cataract, primary repair of a perforating wound was carried out. Ten to fifteen days later, aspiration of the cataract was done under local anesthesia. Fifteen of 23 cases resulted in 10/10 vision. Only five patients persisted in wearing a contact lens. (6 figures, 1 table, 1 reference)—Frank J. Weinstock

BIOMETRIC STUDY OF THE ANTERIOR SEGMENT OF THE EYE IN ANGLE CLOSURE GLAUCOMA. (French) Delmarcelle, Y., Luyckx, J. and Weekers, R. (Clinique ophthalmologique de l'Université de Liège), Bull. Soc. Belge Ophtal. 153:638-650, 1969.

In most cases of angle closure glaucoma, increased thickness of the lens is a major factor. Other factors are reduction of the height of the corneal dome and advancing position of the insertion of the iris on the wall of the globe. (6 figures, 1 table, 9 references)—Frank J. Weinstock

ANNULAR ELEVATION OF THE RETINA. (French) Michiels, J., Heffinck, P. and Rommel, J. (Clinique ophthalmologique de l'Universite de Louvain), Bull. Soc. Belge Ophtal. 153:651-670, 1969.

Three cases with a probable inflammatory etiology are presented. (15 figures, 23 references)—Frank J. Weinstock

INSULIN IN THE AQUEOUS HUMOR OF MAN (RADIO-IMMUNOLOGICAL DETERMINATIONS). (French) Toselli, C. (Clinique ophthalmologique Université catholique de Rome), Bull. Soc. Belge Ophtal. 153:671-674, 1969.

Diagnostic paracenteses were carried out and analyzed. The quantity of insulin in the aqueous was 12 ± 2 $\mu$ U/ml which was 38.7% the value of insulin in the plasma (31 ± 8 $\mu$ U). (11 references)—Frank J. Weinstock

CLINICAL MEASUREMENT OF THE CHOROIDAL BLOOD PRESSURE. (French) Fritz, A., Bull. Soc. Belge Ophtal. 153:702-712, 1969.

Blanching of the pink color of the optic disc with pressure on the globe is related to the choroidal blood pressure. The choroidal pressure varies due to the vasomotor activity of the choroid. Below a mean retinal artery pressure of 46 to 55 mm Hg the choroidal pressure exceeds the retinal pressure by 1.3 to 7.7 mm Hg whereas above this level the choroidal pressure is 4.8 to 14.1 mm Hg lower. (2 figures, 1 table, 16 references)—Frank J. Weinstock

## CANADIAN JOURNAL OF OPHTHALMOLOGY

VOLUME 5 JULY, 1970 NUMBER 3

CRYOFIXATION—CONTROL OF OCULAR SHAPE AND MOVEMENT BY CRYOADHESION. Shea, M. (828 Medical Arts Building, 170 St. George Street, Toronto 180, Ontario, Canada), Canad. J. Ophth. 5:207-214, July, 1970.

Prior to intraocular surgery, cryofixation ring is placed approximately 7 mm from the limbus and adheres to the sclera for its entire area of contact. This device prevents indentation of the globe by lid pressure, prevents distortion of the globe, and eliminates rotational movement about an axis vertical to the plane of the cryofixation ring, thus facilitating incision of the cornea and intravitreal manipulation. Because the cryofixor is rigidly mounted to the operating table, no patient movement can be permitted and general anesthesia is required. Two of 27 patients developed localized choroidal hemorrhages which did not affect the outcome of the surgical procedure. (4 figures, 4 references)—R. Theodore Goldberg

THE EFFECT OF AIR POLLUTANTS ON THE EYE. Waheed, M. A. and Basu, P. K. (Department of Ophthalmology, University of Toronto, 1 Spadina Crescent, Toronto 179, Ontario, Canada), Canad. J. Ophth. 5:226-230, July, 1970.

A sample of an organic extract of atmospheric pollutants was applied directly to the palpebral conjunctiva of albino rabbits. After eight days there was a small but definite decrease in the number of goblet cells. It is possible that this reduction occurred by direct injury of the goblet cells or the extract might have affected the goblet cell precursors and thus interfered with the production of fresh cells. (4 figures, 1 table, 16 references)—R. Theodore Goldberg

THE USE OF MAGNESIUM ON HERPETIC ULCERS OF THE CORNEA. (French) Côté, G., Smith, G. and Rochette, J. (Hôpital du Saint-Sacrement, 1050 Chemin Ste-Foy, Québec, P. Q., Canada), Canad. J. Ophth. 5:231-238, July, 1970.

Large doses of systemic magnesium in rabbits produced noxious effects. In contrast, in man, small doses systemically produced satisfactory effects. A topical solution of 10% magnesium sulphate gave good results in both man and rabbits. (10 figures, 7 references)—Authors' abstract

CORNEAL COMPLICATIONS OF TOPICAL ANESTHETIC ABUSE. Willis, W. E. and Laibson, P. R. (Will Eye Hospital, 1601 Spring Garden Street, Philadelphia, Pennsylvania), Canad. J. Ophth. 5:239-243, July, 1970.

Nine patients are reported in whom topical anesthetics were used repeatedly to relieve the pain of corneal lesions. In six of these there was extension of edema and erosions because of the anesthetic. Topical anesthetics may interfere with normal corneal re-epithelialization by inhibiting corneal respiration and decreasing epithelial mitotic activity. The danger of repeated applications of topical anesthetics is emphasized. (2 figures, 1 table, 14 references)—R. Theodore Goldberg

REMOVAL OF NON-MAGNETIC INTRAOCULAR FOREIGN BODIES USING THE IMAGE INTENSIFIER. Anhalt, E. F., Oppenheim, R. S. and Konkal, J. (Winnipeg Clinic, St. Mary's Avenue and Vaughan St., Winnipeg 1, Manitoba, Canada), Canad. J. Ophth. 5:244-247, July, 1970.

The authors describe a technique for localizing and removing nonmagnetic intraocular foreign bodies in the presence of opaque media, with the aid of the image intensifier. Once the forceps are introduced into the globe, the position of both the foreign body, and the forceps can be magnified on a large viewing screen. By rotating the ampule 90° the operator can view both the forceps and the intraocular foreign body in two planes 90° apart. With alternating perpendicular and horizontal views, the forceps can be guided to the foreign body. (5 figures, 4 references)—R. Theodore Goldberg

MICROSPHEROPHAKIA. Michaud, C. (450 est, rue Sherbrooke, Ste 250, Montréal 24, P. Q. Canada), Canad. J. Ophth. 5:252-254, July, 1970.

The etiology, symptoms, signs, and treatment of this condition are reviewed. The author stresses the importance of thorough examination of all high myopes, particularly myopic children with elevated intraocular pressure, to detect this entity. (2 references)—R. Theodore Goldberg

MYCOLOGY OF EYE BANK EYES I. STUDIES ON THE FROZEN-STORED DONOR MATERIAL. (Department of Ophthalmology, University of Toronto, 1 Spadina Crescent, Toronto 179, Ontario, Canada), Canad. J. Ophth. 5:255-263, July, 1970.

Eighteen out of 32 frozen-stored donor eyes were found to be contaminated with a variety of fungi. The sterilization of donor eyes with merthiolate, pretreatment with glycerine and freezing at −65°C. and thawing, and even three subsequent saline washings of the eyes did not appear to have much effect in removing fungi from the donor eyes. Frozen-stored cornea was found to be a suitable media for the growth of both pathogenic and non-pathogenic fungi. (14 figures, 17 references)—R. Theodore Goldberg

CHLOROQUINE RETINOPATHY IN THE RABBIT. Ramsey, M. S., Bloodworth, J. M. B. and Engerman, R. L. (Department of Pathology, University of Wisconsin, 470 North Carter Street, Madison, Wisconsin 53705), Canad. J. Ophth. 5:264-273, July, 1970.

Oral administration of chloroquine to rabbits for 35 weeks produced the following light and electron microscopic findings in the retina and choroid: (1) membranous cytoplasmic bodies present in the enlarged ganglion cells and to a lesser degree in other cells of the retina, especially enlarged pigment epithelial cells, (2) mixed osmiophilic bodies present in all layers of the retina and especially in the enlarged pigment epithelial cells, and (3) migration of pigment granules from the pigment epithelium to the outer layers of the sensory retina. The authors suggest that the basic defect in chloroquine retinopathy is a drug-induced lyosomal disorder. (9 figures, 23 references)—R. Theodore Goldberg

TRANSVITREAL ELECTROCOAGULATION OF RABBIT FUNDAL VESSELS. Fejer, T. P. and Shea. (Department of Ophthalmology, Faculty of Medicine, University of Toronto, 1 Spadina Crescent, Toronto 179, Ontario, Canada), Canad. J. Ophth. 5:274-283, July, 1970.

Because of the limitations of photocoagulation in obliterating vessels which are projecting into the vitreous in retinitis proliferans, the authors investigated the transvitreal electrocoagulation of rabbit fundal vessels. They passed an insulated coagulating needle through the pars plana of the rabbit. Thirteen eyes were treated. In five the treated vessels were completely obliterated, seven showed a 75% decrease in vessel diameter, and one showed a 50% decrease in vessel diameter. (6 figures, 6 references)—R. Theodore Goldberg

EXPERIMENTAL PHLYCTENULAR KERATITIS. Davis, P. L., Watson, J. I. and Sapp, G. A. (Department of Ophthalmology, Royal Victoria Hospital, Montreal, Quebec), Canad. J. Ophth. 5:284-292, July, 1970.

The authors believe that phlyctenular keratitis occurs when cell wall antigens from lid bacteria enter the cornea at sites of corneal epithelial loss and combine with specific precipitating antibodies. To test this hypothesis, bovine serum albumen was used to immunize

rabbits. Their abraded corneas were then challenged with the immunizing antigen. The control eyes did not react, but the test dyes developed lesions which grossly and histopathologically resembled those of human phlyctenular keratitis. (12 figures, 10 references)—R. Theodore Goldberg

A METHOD FOR STUDYING THE ANTIBODY-PRODUCING CELLS FROM THE CORNEAL AND CONJUNCTIVAL TISSUES. Basu, P. K. and Carré, F. (Department of Ophthalmology, University of Toronto, 1 Spadina crescent, Toronto 179, Ontario), Canad. J. Ophth. 5:293-296, July, 1970.

Rabbits were immunized with sheep serum in Freund's complete adjuvant and two weeks later they were challenged with an intracorneal injection of the same serum. Four days later samples of the conjunctiva, cornea, and limbus were implanted in tissue culture. The migrating lymphoid cells were trypsinized after four days and tested for their plaque-forming capabilities. A special shallow glass chamber was used to facilitate observation and photography of the plaques. (3 figures, 6 references)—R. Theodore Goldberg

## JAPANESE JOURNAL OF OPHTHALMOLOGY

VOLUME 14 JULY-SEPTEMBER, 1970 NUMBER 3

A NEW CORNEA-POSITIVE POTENTIAL IMMEDIATELY FOLLOWING THE EARLY RECEPTOR POTENTIAL. Yonemura, D. and Hasui, I. (Department of Ophthalmology, School of Medicine, Kanazawa University, Takara-machi, Kanazawa, Japan), Jap. J. Ophth. 14:159-171, July-Sept., 1970.

In the albino rat this appears between the negative phase of the early receptor potential, and the a-wave. The amplitude of this newly described wave is directly proportional to the stimulus intensity, and the threshold is extremely high. (11 figures, 30 references)—Paul A. Hein, Jr.

GENETIC STUDIES ON DEFECTIVE COLOR VISION IN JUNIOR HIGH SCHOOL STUDENTS. Ichikawg, H., Majima, A., Komatsu, S. and Tokita, H. (Department of Ophthalmology, Central Hospital of Japanese National Railways, Tokyo), Jap. J. Ophth. 14:202-209, July-Sept., 1970.

Virtually the entire junior high school population of Rishiri Island was studied. Color vision defects were found in 6.83% of the males, 1.93% being protan and 4.76% deutan. Among females, 0.8% showed defects, 0.16% protan and 0.64% deutan. (4 tables, 1 reference)—Paul A. Hein, Jr.

FINE STRUCTURE OF EXTRAOCULAR MUSCLES IN MYASTHENIA GRAVIS. Sakimoto, T. (Department of Ophthalmology, School of Medicine, University of Tokyo Bunkyo-ku, Tokyo), Jap. J. Ophth. 14:210-222, July-Sept., 1970.

Small, abnormal muscle fibers were grouped within apparently normal ones. In the center of these abnormal fibers were found numerous exceptionally large mitochondria, some of which showed inclusion bodies. The findings are not unlike those of thyroid myopathy. (11 figures, 1 table, 36 references)—Paul A. Hein, Jr.

## OPHTHALMOLOGICA

VOLUME 160 1970 NUMBER 5

THE CAUSES OF BLINDNESS IN 156 VISUALLY AND MENTALLY DEFECTIVE CHILDREN. Copper, A. C. and Schappert-Kimmijser, J. (Zutphen, the Netherlands), Ophthalmologica 160:292-302, 1970.

These children were the inmates of an institution for the multiply handicapped. The mental status of most of the subjects precluded valid testing of photoreceptor function and made the ophthalmological examination incomplete. From the combined medical data the probable cause of blindness could be determined in about 70% of the cases. There remained about 22 congenital cataracts and 17 gross congenital ocular anomalies without any clue to the cause of the defect. A preliminary comparison was made between the principal causes of blindness in mentally defective and mentally normal children. In the latter hered-

ity accounted for twice as much blindness as in the former. (13 tables, 3 references)—Peter C. Kronfeld

REFLECTIONS OF LIGHT FROM THE OCULAR FUNDUS. Planten, J. T. (Leeuwarden, the Netherlands), Ophthalmologica 160:303-305, 1970.

The paper deals with the well-known irregular reflections from the area around the disc and around the macula which are seen through the direct ophthalmoscope and the dilated pupil and are normally most pronounced in youngsters between 8 and 14 years of age. Examination with the fundus contact glass indicates that these reflections are located between retina and vitreous. According to the essayist's observations the pattern of these reflections becomes more marked in pathological conditions associated with slight elevations of the intracranial pressure. Inflammation of the optic nerve can also be accompanied by an increase in the number of reflecting ridges and folds. The author offers the theory that under the conditions of raised intracranial pressure fluid from the perivascular spaces in the optic nerve seeps into the boundary between retina and choroid (cfr. Gärtner, Ophthalmologica 153: 367, 1967)—Peter C. Kronfeld

INJECTION OF RADIOACTIVE $S^{35}$: A NEW TREATMENT FOR IRIS AND CONJUNCTIVAL CYSTS. Mesker, R. P., Oosterhuis, J. A. and van der Schoot, J. B. (Department of Ophthalmology and Radiology, University of Amsterdam), Ophthalmologica 160:308-313, 1970.

$S^{35}$, an emitter of soft beta-rays, was used for the authors in two cases, one large congenital anterior chamber cyst and one large posttraumatic subconjunctival cyst. Injected as the highly soluble sodium sulfate, the isotope was ineffective; as insoluble, finely suspended barium sulfate it produced regression of the cysts. Both injections were well tolerated, without any adverse effects on lens epithelium or corneal endothelium coming to the fore. The authors add that it may be wise to remove the contents of the cyst by aspiration some time after injection of the radioactive barium sulfate in order to promote more shrinkage of the cyst. (6 figures, 13 references)—Peter C. Kronfeld

MALIGNANT MELANOMA OF THE CHOROID: AN UNUSUAL VARIANT. Donders, P. C. (Groningen, the Netherlands), Ophthalmologica 160:314-318, 1970.

The medium-sized choroidal tumor (from an 58-year-old, otherwise well female) appeared, at first glance, to be of vascular origin. It was composed of fairly loose tissue containing a large number of vessels of various sizes and of vacuoles some of which were filled with blood cells. Around the blood vessels the tumor tissue was more compact and made up of large irregularly shaped cells with polymorphous nuclei. Some of the cells contained melanin. The tumor had invaded the sclera and was, therefore, probably malignant. After considering various vascular tumors the author feels that the diagnosis, from the presence of melanin and the invasive tendency, must be malignant melanoma. (4 figures, 6 references)—Peter C. Kronfeld

READING DISORDERS. Velzeboer, C. M. J., de Wit, J. and Hagedoorn, J. M. (University Eye Clinic, Vrije Universiteit, de Boelelaan, Amsterdam), Ophthalmologica 160:319-320, 1970.

There is unanimity in the Netherlands regarding the role of the peripheral visual organ in developmental dyslexia. A systematic search for organic or perceptual ocular anomalies in the pupils of the Pedologic Institute in Amsterdam has failed to show any relationship between ocular anomalies and dyslexia. "The best way to handle a child with dyslexia must be found by cooperation between doctor, psychologist and teacher. The pedagogue, with great ingenuity and patience, must try to help the pupil overcome his difficulties."—Peter C. Kronfeld

READING PROBLEMS IN HEMIANOPIA. Pameijer, J. K. (Deventer, The Netherlands), Ophthalmologica 160:322-325, 1970.

For left-sided hemianopia a black ruler placed at right angles and close to the beginning of the lines usually works well. A middle-aged patient with a right-sided hemianopia was aided by 1) turning the reading material 180 degrees so that the reading could be done from right to left, and 2) by inverting the now upside-down print by means of a Dutch telescope. (3 figures)—Peter C. Kronfeld

HISTOLOGY OF CONGENITAL GLAUCOMA. Manschot, W. A. (Rotterdam, the Netherlands), Ophthalmologica 160:326-329, 1970.

An eye with apparently congenital glaucoma was treated by cyclodiathermy when the patient was two years old, and with hypotensive medication from then on. Eight years later when the cornea was enlarged, globular and opaque, the fundus not visible and the pressure high, the blind, painful eye was enucleated. Histologically the canal of Schlemm was found to be open, its wall lined with endothelium and its intrascleral outflow channels patent. The canal was separated from the anterior chamber by a dense, sclerosed tissue which the author interprets as the compressed, hyalinized corneoscleral meshwork, damaged by the unrelieved pressure. The histological findings favor the view that goniotomy, even at this late stage, might have normalized the intraocular pressure. (2 figures, 6 references) —Peter C. Kronfeld

FLUORESCEIN ANGIOGRAPHY OF THE OPTIC DISC IN GLAUCOMA. Oosterhuis, J. A. and Gortzak-Moorstein, N. (Department of Ophthalmology, University of Amsterdam), Ophthalmologica 160:331-353, 1970.

Baseline values for normal fluorescence of the disc are provided by the typical large physiological cups of normal eyes. In the floor of these large cups fluorescein brings out a strikingly dense system of vessels which add up to more fluorescence than the vessels on the rim of the cup. In glaucomatous eyes the authors report diminished fluorescence of the disc which correlates roughly with the degree of glaucomatous cupping and with the restriction of the visual field. In patients with totally excavated discs and only small residual fields, fluorescence of the disc was absent. The color of the disc as judged by ophthalmoscopy (without fluorescein) can not be considered a reliable yardstick for its vascularization. (15 figures, 24 references)—Peter C. Kronfeld

X-RAY PHOTOS OF THE OPTIC FORAMEN. Bleeker, G. M. (X-ray Department of the University Eye Hospital, Amsterdam), Ophthalmologica 160:354-368, 1970.

Reliable pictures of the optic foramen can only be obtained when the central beam of the X-ray tube coincides with the axis of the canal which, in the normal skull, forms an angle of 37° with the sagittal plane and of 30° with the line joining the external auditory meatus with the inferior orbital rim. In pictures taken in this manner the optic foramen appears in the infero-temporal area of the orbit. In a series of pictures of the same patient the effect of slight deviations from the proper position of the head are demonstrated. Right-to-left size differences of 1 mm or more are usually significant, the larger foramen usually being the one altered by a pathological process. (23 figures)—Peter C. Kronfeld

AN UNNECESSARY MISTAKE. Planten, J. T. (Leeuwarden, the Netherlands), Ophthalmologica 160:369-371, 1970.

In three cases reported by the author opacities of the media precluded ophthalmoscopic examination of the posterior segment. When acute glaucoma developed and resisted conservative therapy, the author performed iridencleises on two of the patients, finding the iris unusually friable and the postoperative course longer than usual. In these two and in a third unoperated case the primary disease proved to be a malignant melanoma of the choroid. (2 figures)—Peter C. Kronfeld

NORRIE'S DISEASE. Hamburg, A. (Bussum, the Netherlands), Ophthalmologica 160: 375-377, 1970.

The occurrence of this oculo-acoustico-cerebral degeneration in three sons from a Dutch family is reported. Bilateral blindness due to pseudogliomas was discovered shortly after birth. At the present time only the second boy, age five, shows a serious mental defect. The EEG of all three cases is abnormal in that it shows peaks which increase during sleep. A great-uncle of the mother died in a school for the blind at the age of 12 which is the only clue to a genetic origin of the disorder. (1 reference)—Peter C. Kronfeld

OPERATION FOR ECTROPION ASSOCIATED WITH ANOPHTHALMOS. Hagedoorn, A. and Keur, J. H. W. (University Eye Clinic, Wilhelmina Gasthuis, Amsterdam), Ophthalmologica 160:379-382, 1970.

Three double-armed sutures are inserted in the region of the lower fornix, passed through

the periosteum near the lower orbital rim, brought out through the skin and fastened there with tape. Very much like the von Hess sutures of ptosis, the sutures advocated by the authors give rise to strands of scar tissue which run in the same direction as the inferior tarso-orbital ligament and take on this ligament's lost function. (5 figures)—Peter C. Kronfeld

## Journal of Neurology, Neurosurgery and Psychiatry

Volume 33 April, 1970 Number 4

Spurious papilledema and visual field contraction after head trauma. Dale, R. T. and Galin, M. A. (Departments of Neurology and Ophthalmology of the New York Medical College), J. Neurol. Neurosurg. Psychiat. 33:166-171, Apr., 1970.

Two patients with bilateral papilledema after head trauma, without increased intracranial pressure are discussed. Bilateral contraction of the visual fields, apparently on a permanent basis, was noted in both patients. The pathophysiology is believed to be related to indirect injury to the optic nerve. (8 figures, 13 references)—Joel G. Sacks

Mucocoele of the sphenoidal sinus as a cause of recurrent oculomotor nerve palsy. Friedmann, G. and Harrison, S. (The Neuro-Otological Department, the National Hospital for Nervous Diseases, Queen Square, London W.C. 1.), J. Neurol. Neurosurg. Psychiat. 33: 172-179, Apr., 1970.

The neurological symptoms and signs in 40 cases of sphenoidal mucocoele have been reviewed. Of these, 23 cases had optic nerve involvement; 15 cases had oculomotor nerve involvement; 2 cases had trochlear nerve involvement; 4 had abducens nerve involvement; 38 had facial pain and 12 had exophthalmos.

Two cases recurrent oculomotor nerve palsy caused by a sphenoidal mucocoele are described. (5 figures, 2 tables, 48 references)—Joel G. Sacks

## Neurology

Volume 20 May, 1970 Number 5

Polymyoclonia with opsoclonus. McLean, D. R. (Neurological Unit, Boston City Hospital, Massachusetts), Neurology 20:508-512, May, 1970.

The case reported was 50 years old; this is the oldest patient reported with this syndrome. Persistent abnormal eye movements two years after the acute illness were a unique feature which had not been previously reported. (15 references)—Joel G. Sacks

Facial pulses in internal carotid artery occlusion. Fisher, C. M. (Massachusetts General Hospital, Boston, Mass.), Neurology 20:476-478, May, 1970.

Abnormal pulses may be felt about the orbit and in the region of the nasolabial fold in patients who have had occlusion of one or both internal carotid arteries. These abnormal pulses arise as the result of dilatation of the vessels that carry anastomotic flow from the branches of the external carotid artery into the distal internal carotid artery by the way of the ophthalmic artery and its orbital branches. (1 figure, 1 reference)—Joel G. Sacks

Unruptured aneurysm of the supraclinoid carotid artery. A treatable cause of blindness. Bird, A. C., Nolan, B., Gargano, F. P. and David, N. J. (Departments of Ophthalmology, Radiology and Neurology, University of Miami School of Medicine, Miami, Florida), Neurology 20:445-454, May, 1970.

Five patients with giant aneurysms arising from the supraclinoid portion of the internal carotid artery have been described. In four of them the initial complaint was loss of vision in one eye, and if not treated, this progressed to blindness within a few months. Three patients benefited from carotid clamping in the neck. Two patients with profound visual loss in the postoperative period eventually showed spectacular visual improvement. (5 figures, 1 table, 12 references)—Joel G. Sacks

## Annals of Internal Medicine

Volume 72 May, 1970 Number 5

Pseudotumor of the orbit and limited Wegener's granulomatosis. Cassan, S. M., Divertie, M. B., Hollenhorst, R. W. and Harrison, E. G. (Sections of Medicine, Ophthalmology, and of Surgical Pathology, Mayo Clinic and Mayo Foundation; and the Mayo Graduate School of Medicine, Rochester, Minn.), Ann. Intern. Med. 72:687-693, May, 1970.

A patient with bilateral orbital pseudotumor and bilateral cavity pulmonary lesions is reported. This patient was considered to have the limited form of Wegener's granulomatosis that has been described recently, and his 15-year survival with this disease when last seen is unequaled in the literature. Orbital pseudotumor and its relationship with multifocal fibrosclerosis, polyarteritis nodosa, and Wegener's granulomatosis are reviewed. (6 figures, 40 references)—Authors' abstract

## Aerospace Medicine

Volume 41 April, 1970

Aftereffects of various alcoholic beverages on positional nystagmus and coriolis acceleration. Ryback, R. S. and Dowd, P. J. (USAF School of Aerospace Medicine, Brooks Air Force Base, Texas 78235), Aerospace Med. 41:429-435, April, 1970.

Bourbon appears to have a stronger effect than vodka on positional nystagmus and coriolis acceleration (that occurring when the head is tilted relative to a plane of rotation). (5 figures, 3 tables, 38 references)—Stan Muenzler

## Journal of Pediatrics

Volume 77 July, 1970

Microcirculation in young adults with cystic fibrosis: retinal and conjunctival vascular changes in relation to diabetes. Chazan, B. I., Balodimos, M. C., Holsclaw, D. S. and Shwachman, H. (The Children's Hospital Medical Center; and the Departments of Medicine and Pediatrics, Harvard Medical School), J. Pediatrics 77:86-92, July, 1970.

Conjunctival biomicroscopy and retinal photography were utilized in 67 patients with cystic fibrosis, ages 15 to 26 years, to detect a possible prediabetic vascular change. Examination revealed venular congestion and tortuosity as well as venular and arteriolar red cell aggregation. These changes were related to the severity of the cystic fibrosis and not to glucose intolerance. Both clinical and chemical diabetes occur more frequently in older patients with cystic fibrosis than in normal subjects. The diabetes is not related to the severity of the cystic fibrosis. A prediabetic vascular change could not be reliably detected by this study. (2 figures, 1 table, 32 references)—Authors' abstract

# NEWS ITEMS

EDITED BY THOMAS CHALKLEY, M.D.
*700 North Michigan Avenue, Chicago, Illinois 60611*

For adequate publicity, notices of postgraduate courses, meetings and lectures must be received *at least* three months prior to the date of occurrence.

### CLINICAL CONGRESS: AMERICAN COLLEGE OF SURGEONS

The 57th annual clinical congress of the American College of Surgeons will be held in Atlantic City, New Jersey, on October 18-22, 1971. The postgraduate course in ophthalmic surgery will be offered on October 18th, 20th, and 22nd, under the direction of Robinson D. Harley of Philadelphia.

For further information contact Mr. T. E. McGinnis, American College of Surgeons, 55 East Erie Street, Chicago, Illinois 60611.

### SOCIETY OF CONTEMPORARY OPHTHALMOLOGY

The winter meeting of the Society of Contemporary Ophthalmology will be held on February 27 through March 3, 1972, at the Diplomat Hotel, Hollywood, Florida.

The emphasis of the meeting will be on contemporary ophthalmology through continuing education. Lectures will be presented by the permanent faculty. Ophthalmologists interested in presenting papers on new material must submit a 150-word, titled abstract before October 1, 1971, to John G. Bellows, M.D., 30 North Michigan Avenue, Chicago, Illinois 60602.

### SECOND INTERNATIONAL OPHTHALMIC MICROSURGERY MEETING IN SAN FRANCISCO

The Eye Foundation of California will sponsor the second international ophthalmic microsurgery meeting, to be held on September 15-18, 1971, in San Francisco. The first two days of the meeting will be devoted to practical microscopic instruction at the San Francisco Eye and Ear Hospital. Lecturers for this session include F. Barraquer, Bogata, Colombia; J. Beale, U.S.A.; Prof. J. Draeger, West Germany; and E. Smith of Canada. The last two days of the meeting will be held at the Fairmont Hotel, and will consist of presentations, short papers, movies, and panel discussions. Lecturers will include J. Boberg-Ans, Denmark; Charles Kelman, U.S.A.; E. Malbran, Argentina; and R. Troutman, U.S.A.

The Foundation Gold Medal Award for World Eye Surgical Excellence will be presented to Ramon Castroviejo during the second portion of the congress.

Fees for both sessions will be $425, while the fee for the last two days alone will be $100. In either case, the additional fee for wives is $25.

Further information may be obtained from John Beale, San Francisco Eye and Ear Hospital, 1801 Bush Street, San Francisco, California 94109.

### CONTINUING EDUCATION IN OPHTHALMOLOGY

The American Academy of Ophthalmology and Otolaryngology program of continuing education includes an ophthalmic basic and clinical science course. The course presents a core of ophthalmic information divided into eight sections. Each section consists of an essential reading list, designed for completion in a period of two or three months

The registration is $50. For application and information contact C. M. Kos, M.D., Executive Secretary-Treasurer, American Academy of Ophthalmology and Otolaryngology, 15 Second Street SW, Rochester, Minnesota 55901.

### ESTELLE DOHENY EYE FOUNDATION

The annual postgraduate conference of the Estelle Doheny Eye Foundation will be held on October 18-19, 1971, in Los Angeles. Principal speakers will be Ramon Castroviejo and Frank W. Newell.

Further information may be obtained from the Estelle Doheny Eye Foundation, 272 South Lake Street, Los Angeles, California 90057.

### PLASTIC AND CORNEAL SURGERY SYMPOSIUM: BASCOM PALMER EYE INSTITUTE

The Bascom Palmer Eye Institute of the University of Miami School of Medicine, and the Florida Lions Eye Bank at Miami, announce the fourth biennial symposium on ophthalmic plastic and corneal surgery, to be held on March 26-31, 1972, at the Diplomat Hotel, Miami Beach, Florida.

Additional information may be obtained by writing to the Ophthalmic Plastic Surgery Symposium, Bascom Palmer Eye Institute, P.O. Box 875, Biscayne Annex, Miami, Florida 33152.

### OPHTHALMOLOGISTS SERVE PROJECT HOPE IN WEST INDIES

Ophthalmologists Hansjoerg Kolder, Iowa City, Iowa, and Edward A. Dunlap, New York City, have joined the staff of the hospital ship SS HOPE while this floating medical center is docked in Kingston, Jamaica, to carry out a 10-month medical and teaching mission in the West Indies which began in mid-January.

This is the SS HOPE's second decade of service. Approximately 125 staff members are serving for the entire voyage; Drs. Kolder and Dunlap joined more than 20 other specialists who serve for two-month periods.

Dr. Dunlap, who joined the staff of the hospital ship in March, is a clinical professor of ophthalmol-

ogy and acting division head of the New York Hospital-Cornell Medical Center. He has previously served with the SS HOPE in Ecuador and Ceylon.

Dr. Kolder, who joined the ship's staff in May, is associate professor of ophthalmology at the University of Iowa in Iowa City.

### Postgraduate Institute: New York Eye and Ear Infirmary

The Postgraduate Institute of the New York Eye and Ear Infirmary announces the 14th in a series of postgraduate courses for specialists in ophthalmology to be presented October 4 through December 11, 1971.

The following courses will be offered: diagnostic ultrasonography, pathology, uveitis, ocular geriatrics, ocular radiology, neuro-ophthalmology, motor anomalies, perimetry, biomicroscopy, ophthalmoscopy, radioisotopes in ophthalmology, fluorescein angiography, reading disability, indirect ophthalmoscopy, ocular adnexal pathology, ocular therapeutics, practical applanation tonometry, glaucoma, tonography and applanation tonometry, refraction, enucleation and evisceration, corneal contact lenses, plastic eye surgery, surgery of the orbit, lacrimal sac surgery, microsurgery in glaucoma, microsurgery of the cornea, microsurgery in cataracts, clinical perimetry and review in basic subjects in ophthalmology.

For a catalogue and further information contact Jane Stark, registrar, Postgraduate Institute, New York Eye and Ear Infirmary, 310 East 14th Street, New York, New York 10003.

### Safety lens now mandatory

Effective December 31st, 1971, the Food and Drug Administration requires that all eye glasses sold thereafter must have impact-resistant lenses.

The FDA issued the ruling with encouragement from the National Society for the Prevention of Blindness, but with opposition from the American Optometric Association.

More than 75 manufacturers and distributors of sun glasses requested postponement of at least a year, but FDA Commissioner Charles C. Edwards said the December 31st deadline gives the industry enough preparation time.

In first proposing the rule last September 30, Edwards said use of impact-resistant glass or plastic would increase the price of a pair of prescription glasses by between one and six dollars, but that it would help prevent many of the 120,000 injuries caused each year by broken lenses.

The final rule, published in the Federal Register, May 15, states that impact-resistant lenses are safer than ordinary lenses but still "not shatterproof or breakproof," a fact that the FDA said every wearer should be told. The National Society for the Prevention of Blindness had urged adoption of the rule as "one of the most important advances in the promotion of eye safety to date."

### Surgery Course: New York Eye and Ear Infirmary

A two-day course on dissection of the orbit, ocular adnexae, facial structures, and chiasmal area on individually assigned cadavers, with special emphasis on lacrimal, orbital, and eyelid plastic surgery, will be held at the New York Eye and Ear Infirmary on October 23-24, 1971. The course is under the direction of Lester T. Jones in association with Harold Kirshner. Enrollment is limited. The fee is $100.

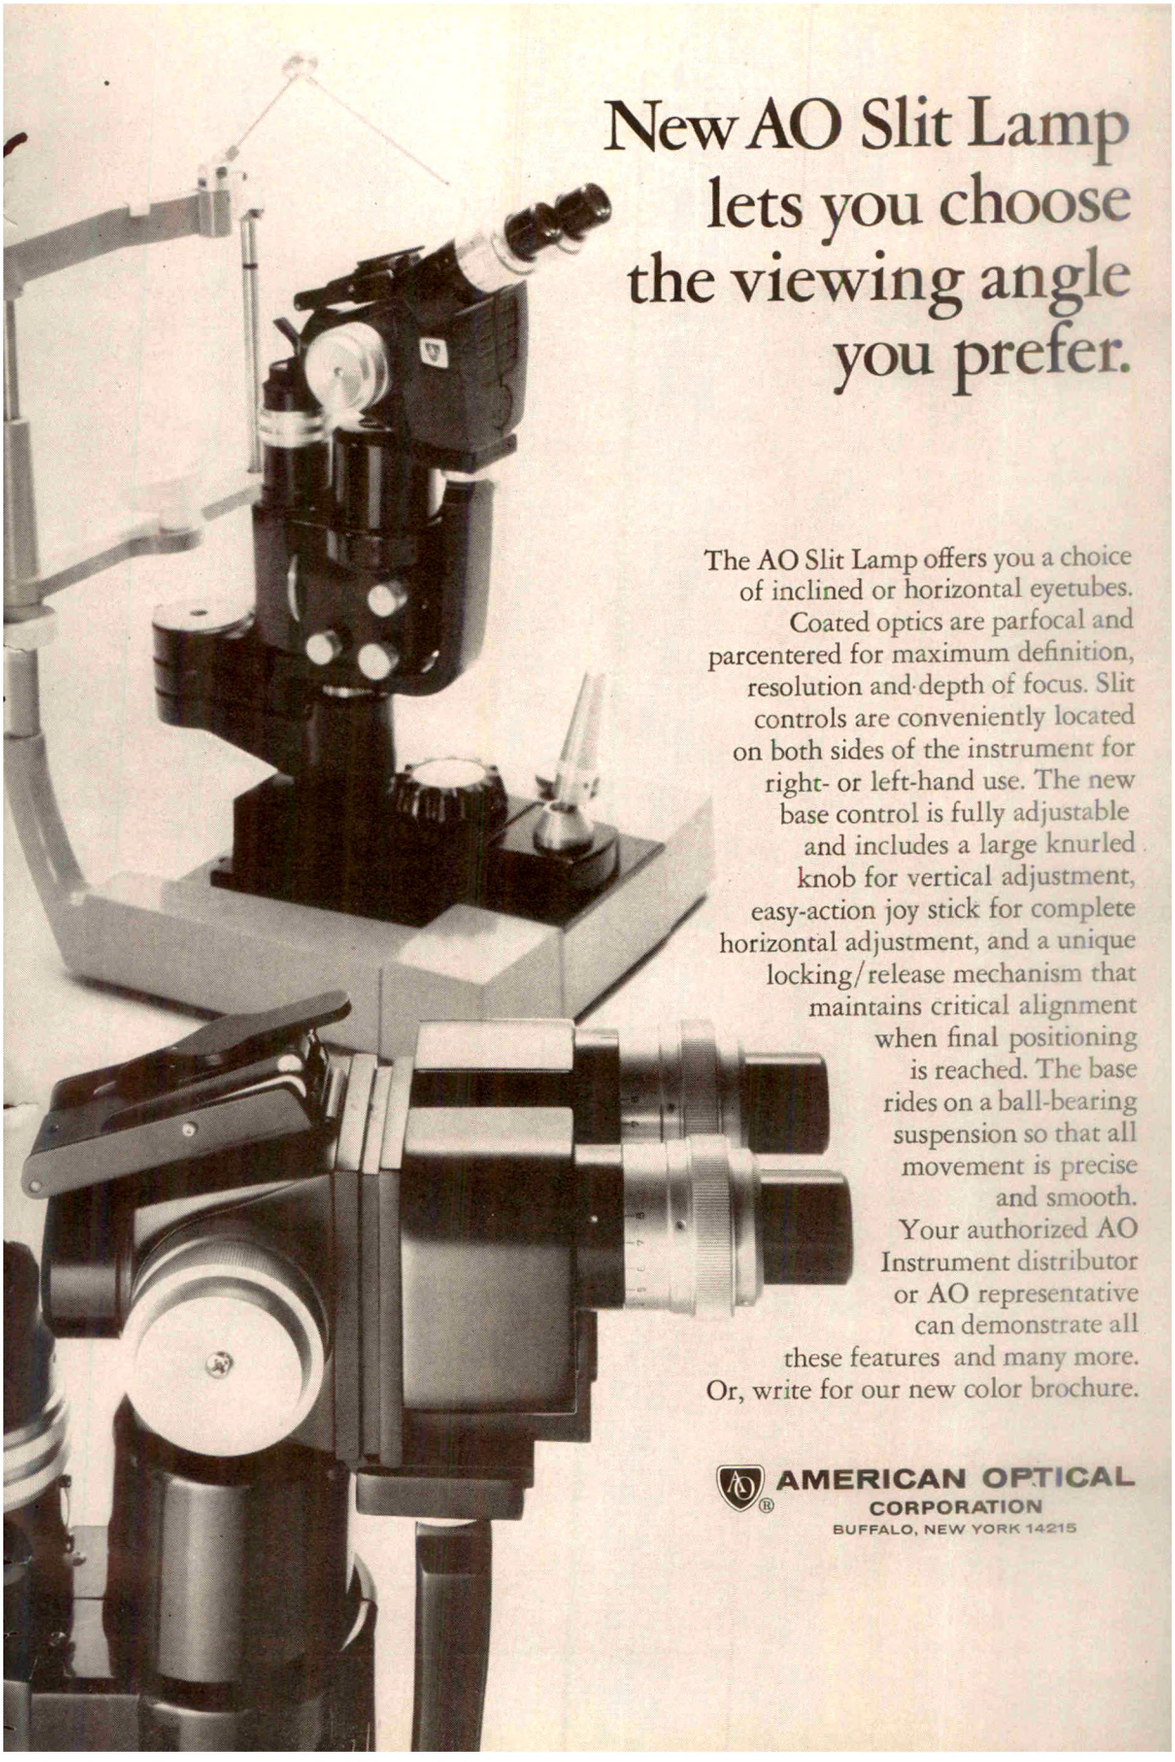
For additional information contact Jane Stark, registrar, Post Graduate Institute, New York Eye and Ear Infirmary, 310 East 14th Street, New York, New York 10003.

### University of Texas at Galveston

The department of ophthalmology at the University of Texas Medical Branch at Galveston held its fifth annual postgraduate and alumni meeting on April 3, 1971. Marshall Parks was guest speaker.

The alumni association elected R. Sloan Wilson president, and Charles Broman secretary-treasurer for the coming year. Gaynelle Robertson, who retired in January, was presented with a golden apple award for his years of dedicated service to the department in the field of ophthalmology.

### Orbital Symposium: New York Medical College



The department of ophthalmology of the New York Medical College announces a one-day orbital symposium October 30, 1971. Speakers will include members of the faculty as well as guests.

Preregistration is required. Registration forms, together with a program of the meeting, may be obtained from Mrs. Ruth Green, Department of Ophthalmology, New York Medical College, 1249 Fifth Avenue, New York, New York 10029.

## Personal

### Jules François

The first distinguished service honorary medal of the American Society of Contemporary Ophthalmology was presented to Jules François, professor of ophthalmology at the University of Ghent, Belgium, at the society's annual meeting, March 4-6, 1971, in Hollywood, Florida. Prof. François was selected by the governing board of the society for his outstanding contributions and excellence in ophthalmology. He has also been the recipient of the Gonin Medal and the Alfred Vogt prize, and is past president of the Royal Academy of Medicine of Belgium, Doctor Honoris Causa of six universities, and is a member of the Committee for the International Conference on Human Genetics.

# New AO Slit Lamp lets you choose the viewing angle you prefer.

The AO Slit Lamp offers you a choice of inclined or horizontal eyetubes. Coated optics are parfocal and parcentered for maximum definition, resolution and depth of focus. Slit controls are conveniently located on both sides of the instrument for right- or left-hand use. The new base control is fully adjustable and includes a large knurled knob for vertical adjustment, easy-action joy stick for complete horizontal adjustment, and a unique locking/release mechanism that maintains critical alignment when final positioning is reached. The base rides on a ball-bearing suspension so that all movement is precise and smooth.

Your authorized AO Instrument distributor or AO representative can demonstrate all these features and many more. Or, write for our new color brochure.

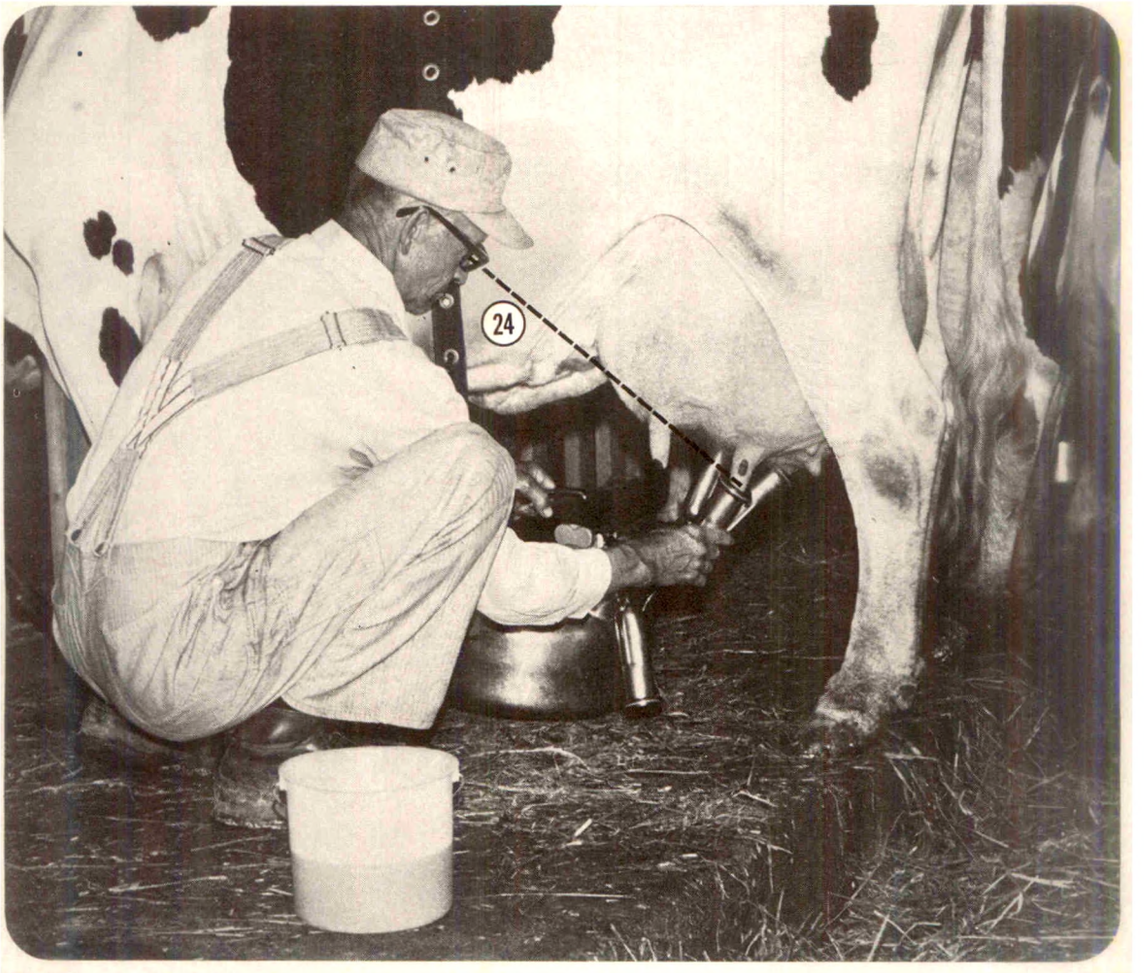
## BRITISH JOURNAL OF OPHTHALMOLOGY

This Journal publishes original articles on every aspect of the ophthalmological sciences by practising ophthalmologists and research workers all over the world. While welcoming reports on experimental work, the editors nevertheless pay special attention to the practical problems of eye disorders and their treatment, to give as much help as possible to ophthalmic surgeons and all concerned with clinical ophthalmology. All articles are in English and carry summaries wherever appropriate.
Book reviews, shorter notes, and correspondence also appear at frequent intervals.

*Published Monthly* *Annual Subscription $26.50*

## OPHTHALMIC LITERATURE

OPHTHALMIC LITERATURE is the key to virtually all published information on ophthalmology. Each issue consists of carefully prepared, informative abstracts in English of relevant articles in medical and scientific journals throughout the world; each abstract is classified under one of forty specific headings, with cross references where necessary. Summaries of new books and new editions on the subject are included under the appropriate headings. An author index is also included in each issue.



In its comprehensiveness OPHTHALMIC LITERATURE is unique among abstracting journals in the world.

*Six issues a year, plus index* *Annual Subscription $26.50*

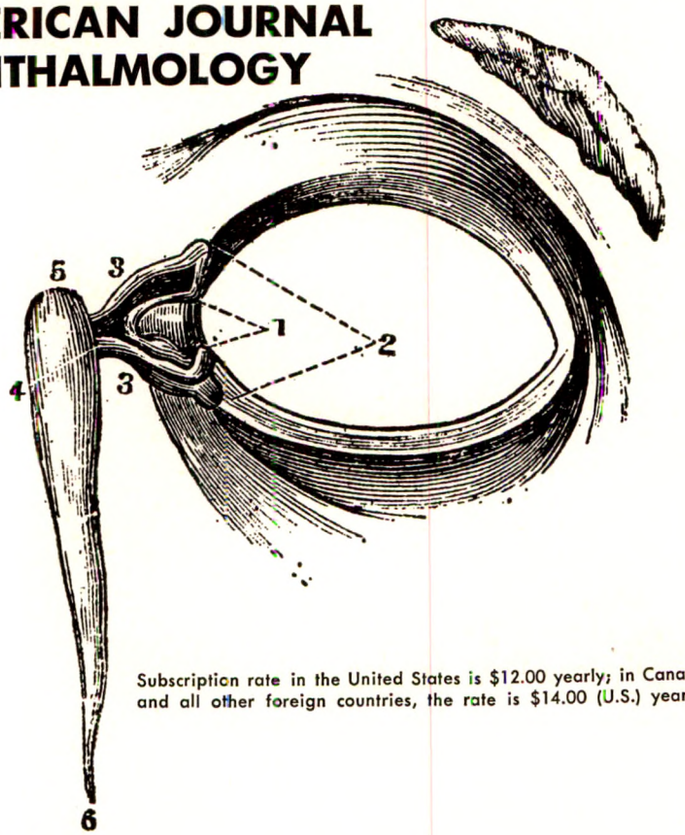
*These two world famous ophthalmic journals can be ordered at the special combined subscription rate of: $45.50*

**Subscriptions in the United States can be ordered through the BRITISH MEDICAL JOURNAL, 80 Brighton Avenue, Boston, Mass., 02134.** Subscriptions for all other countries should be ordered direct from the Subscription Manager.

**BRITISH MEDICAL JOURNAL, B.M.A. House, Tavistock Square, London, WCIH 9JR, England**
***or through any leading subscription agent or bookseller***

*Occupational Vision Studies*
*(From Study #32, Volume II, Guide to Occupational and Other Visual Needs)*

# Dairy farmer



Not too many years ago, the dairy farmer's vision needs consisted of the ability to see keenly in the distance and at arm's length, to take care of his herd. Today, however, he is part farmer and scientist, part machinist and businessman; his vision needs are many and varied.

From keeping extensive books on the business aspects of his farm to working with equipment and machines, the dairy farmer requires good intermediate to near vision, which formerly was a small part of his vision needs. Fortunately for him, today's professional man can prescribe lens forms, including multifocal to meet the dairy farmer's most critical visual requirements.

The dairy farmer's vision problems may be found in Volume II of the Guide and the multifocals to help with his vision problems may be found at any of the full-service labs carrying

## FELLOWSHIPS AVAILABLE

•

The Heed Ophthalmic Foundation provides fellowships for advanced study or research in ophthalmology. Applicants must be graduates of medical schools accredited by the American Medical Association and citizens of the United States. Deadline for submission of applications: December 31 for a fellowship starting the following July. Please direct all inquiries and requests for application forms to:

The medi-FLOW device is available either in a 6-pack or single unit through your usual source of ophthalmic supplies.

medi-FLOW™

battle-proved in Viet Nam* . . . now amplifying the armamentarium of civilian ophthalmology.

The medi-FLOW device delivers controlled medication to the cornea and conjunctiva either rapidly or slowly, as you desire.

It is a uniquely designed clear plastic scleral lens with a polyethylene tube and Luer-lock adaptor for attaching either a syringe or I.V. set. The lens incidentally protects the cornea from eyelid trauma, reduces discomfort rapidly, and aids in the prevention of symblepharon formation—all outstandingly valuable assets of medi-FLOW.

# ELECTROLYSIS FOR EYELASH REMOVAL

This permanent hair remover features the only patented self-correcting needle in existence. Battery operated instrument sterilizes itself when current flows. No puncture safety feature helps prevent infection. Simple enough to be used by laymen (for cosmetic purposes only).

Thousands of units sold for such varied professional application as removal of inverted eyelashes to cosmetic use.

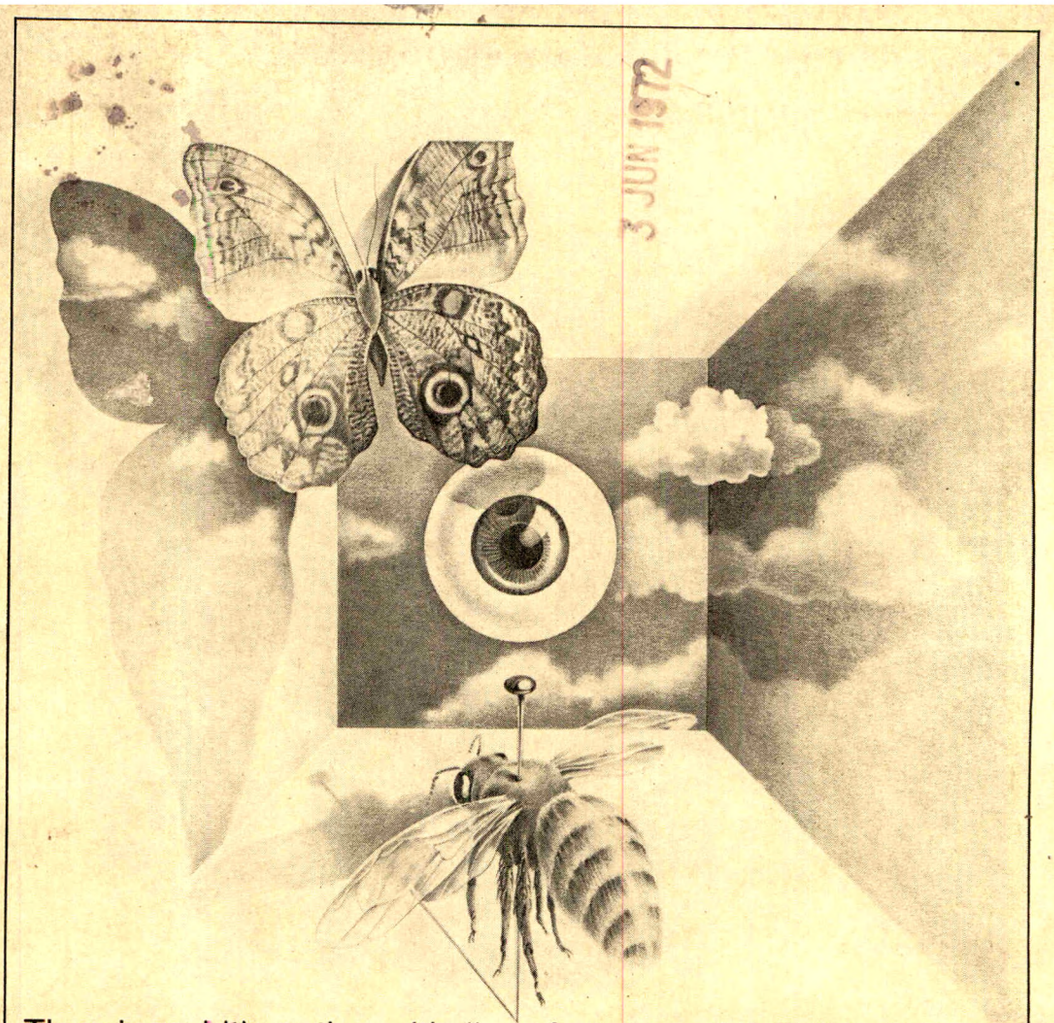
# Apollo Space Flight Veteran: Methulose, for dry eyes!



Methulose artificial tears lubricate sensitive ocular tissues to provide comfortable, soothing relief from eye dryness and irritation without blurring vision. Little wonder it is a big item on Apollo flights where dry eyes could present serious problems.

Meanwhile, back on earth, Methulose might be the simple solution to the dry-eye problems of many of your patients. A non-irritating buffered aqueous solution containing Methylcellulose U.S.P. preserved with Benzalkonium Chloride 1:25,000, it is available in 15cc and 30cc direct application plastic containers. Write for a generous supply of 5cc starter samples.

## There's no biting sting with "comfort strength" Epifrin ½%, 1%

Epifrin® (l-epinephrine) has long offered the most economical, convenient l-epinephrine available to glaucoma patients. Now, with "comfort strength" Epifrin ½% and 1%, the biting sting is gone too! Evaluate our "comfort strengths" with your glaucoma patients. Have them compare the comfort of EPIFRIN ½% with any other l-epinephrine. You'll find there is no significant difference in patient acceptance. There is growing documentation of the efficacy of these lower concentrations. (1, 2) Lower concentrations also mean reduced side effects and no blurring or impaired vision. Now the economy and convenience of "comfort strength" Epifrin® ½% and 1% make a lot more sense.

**References:** 1. Kronfeld, P.C.: Invest. Ophth. 3258 (June) 1964. 2. Harris, L. S.; Galin, M.A.; and Lerner, R.: Annals of Oph. 219 (June) 1970. **Prescribing Information:** Contains: levo-epinephrine (as the HC1)...2%, 1%, ½%. with: benzalkonium chloride, sodium metabisulfite, disodium edetate, and purified water. **Indications:** Chronic simple glaucoma. **Contraindications:** Should not be used in patients who have had an attack of narrow angle glaucoma since dilation of the pupil may trigger an acute attack. **Warnings:** Undesirable side reactions may include eye pain or ache, browache, headache, conjunctival hyperemia, and allergic lid reactions. Adrenachrome deposits in the conjunctiva and cornea after prolonged epinephrine therapy have been reported. Epinephrine has been reported to produce macular edema in some aphakic patients. **Precautions:** Should be used with caution in patients with a narrow angle since dilation of the pupil may trigger an acute attack of glaucoma. **Dosage:** The usual dosage is one drop in the affected eye(s) once or twice daily. However, the dosage should be adjusted to meet the needs of the individual patient. **Note:** Protect from excessive light and heat. If the solution discolors or a precipitate forms it should be discarded. **How Supplied:** 0.5% and 1.0% strengths in 15 cc plastic dropper bottles. 2% in 5 cc and 15 cc plastic dropper bottles. On prescription only.

**Epifrin** (l-epinephrine)

# THE CORNEAL GRAFT: A MULTIPLE VARIABLE ANALYSIS OF THE PENETRATING KERATOPLASTY

THOMAS E. MOORE, JR., M.D., AND SAMUEL B. ARONSON, M.D.
*San Francisco, California*

Since the early period of keratoplasty, ophthalmic surgeons have anticipated a good outcome in the grafting of any diseased cornea. In the past, success could be attained only in patients with good prognosis. To maximize the possibility of success, we attempted to identify and define accurately the operative variables associated with graft failure.

Early in this attempt, it became evident that variables could be subdivided into two general groups according to time of occurrence: (1) the period of early graft reaction, and (2) the delayed reaction period. The early period (Fig. 1) extended from the time of surgery until suture removal. Arbitrarily selected variables in this period were: (1) selection of the donor graft tissue, (2) therapeutic protocols before and after surgery, (3) adjunctive medical therapy in the postoperative period, and (4) standardization of surgical technique to permit classification of each procedure. Variables evaluated and compared include: (1) morphologic status of the host eye, (2) etiologic and syndromal diagnosis of the host eye, (3) surgical procedures, (4) suture materials and techniques, (5) microbially-induced reactions, (6) immunologic status of the host, and (7) tissue noncompatibility. The variables found to be essential in the early graft period were: (1) morphologic classification, (2) surgical procedure, and (3) suture material.

Reprint requests to Thomas E. Moore, Jr., M.D., Suite 309, 45 Castro Street, San Francisco, California 94114.

The period of delayed graft reaction begins when the early graft reaction ends and extends indefinitely. Variables in this period include: (1) microbiology of the external eye, (2) immunologic factors in the host response, (3) pre- and postoperative morphology of the host eye, and (4) socioeconomic status of the recipient. Morphologic structure and socioeconomic status proved to be the critical variables in delayed graft failure.

The combination of early and delayed graft results makes up the long-term graft results for this series. Patients have been followed for a maximum of five years, so that definite long-term prognoses cannot be presented. However, the incidence of delayed graft reaction appears to diminish with time, so that reasonable projections can be made.

To evaluate clinical variables more extensively simultaneous studies were done in the rabbit. The early graft period was designated arbitrarily at 75 days, although sutures were removed between 10 and 14 days. Such early suture removal was required if a successful graft was to be achieved. The variables studied in this period were: (1) the surgical procedure, (2) suture toxicity, (3) pathogenic and indigenous bacterial toxicity, (4) tissue noncompatibility, and (5) genetic variability of the host. The factors of principal significance were: (1) the surgical procedure, (2) the suture material, and (3) genetic composition.

The delayed graft reaction was evaluated in rabbits 90 days following surgery. Delayed reactions were studied under both spontaneous and experimental conditions.

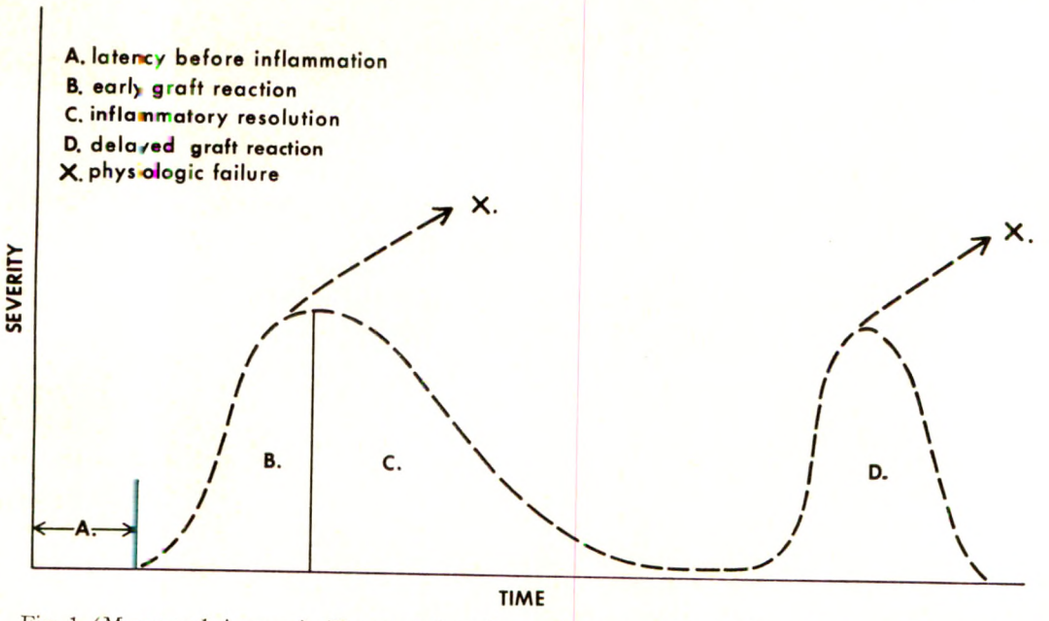

Fig. 1 (Moore and Aronson). The corneal graft reaction. The early graft reaction comprises periods B and C in a successful graft and B and X in graft failure. The delayed graft reaction comprises D in a successful graft and X in graft failure.

Variables evaluated include: (1) bacterial and antigenic stimuli, (2) immune competence of the host response, and (3) the severity of structural alteration. The rabbit graft experiments strongly support the observations made in the human series and provide a much more accurate appraisal of several factors in graft failure, e.g., the role of the tissue noncompatibility reaction. However, these observations cannot be used to verify aspects of the human data, but only to support it.

Finally, a large number of variables have been analyzed by discriminant function. This procedure provides statistical evidence to support some of our observations, e.g., the surgical procedure and suture toxicity. Similarly, it demonstrates that others are not statistically valid, e.g., immunologic evaluation. The strength of this technique is that an independent evaluation has utilized prospective data from our graft series and has placed in perspective the importance of each studied variable.

Although these studies have fallen somewhat short of our projected goal—namely, to graft successfully *any* vision-reducing cornea—they present an integrated approach to the corneal graft whereby that goal can one day be reached.

## HISTORICAL REVIEW

Historically, corneal grafting may be divided into two periods. The first period, or period of feasibility, extended from approximately 1844 (Kissam[1]) until approximately 1950.

In the early period, physicians sought to establish a satisfactory technique. During the 19th and early 20th centuries, there was a series of initial attempts, including the first clinical report[1] describing a xenograft from pig to man. The second period extends from 1950 through the present.[2] Power[3] reported allografts in a series of animal experiments in 1872; however, distinct confirmation of the basic principle of tissue noncompatibility was not readily accepted until the reports by Medawar on skin rejection in 1946[4,5] and those by Billingham and Boswell,[6] and by Maumenee,[7] that dealt specifically with the grafted cornea. Although many attempts to implant artificial materials (keratoprosthesis) were undertaken during this period, none met with success.

Implementation of a reproducible surgical technique was hampered considerably by the quality of instruments and suture material during the early period. Reported preferences for the trephine (round graft),[8] the double knife (square graft),[9] and the free-hand graft reflect the primitive technology of instrument-making. Crudeness of suture and needles during this period dissuaded the surgeon from using direct appositional techniques and favored overlay fixation. This obviously affected the results of the keratoplasty procedure.

The reason for the emergence of the lamellar keratoplasty as the procedure of choice during this period is obscure. Undoubtedly, the techniques for preparation and preservation of the donor cornea adversely affected the outcome of penetrating grafts. This problem was compounded by the technical problems of the period and the lamellar graft emerged as the favored procedure, as this enabled the surgeons to avoid the risks of intraocular surgery. Large series of lamellar graft results were assembled by surgeons between 1930 and World War II.[10,11]

The final factor of importance during this period was the suppurative infections that occurred following many graft procedures.[12,13] Inadequacies in managing these severe inflammatory reactions often led to phthisis bulbi, glaucoma, and enucleation. These complications caused the corneal surgeon to hesitate in undertaking a graft procedure. Whether these reactions were usually due to pathogenic bacteria is unknown; however, the advent of antibiotics seems to parallel the decline of such reactions.[2]

Since World War II, advancements in corneal grafting have been rapid. Several events contributed to this advancement.

First, the problems of instrumentation, suture, and pathogenic infection were surmounted, thus eliminating many of the technical difficulties of reproducible corneal surgery. The combination of the operating microscope,[14-16] microsurgical instruments,[17,18] and fine suture material and needles,[19] allowed reproducible, direct appositional suturing in penetrating keratoplasty. Wound dehiscences, or the "slipped grafts," are now infrequently seen, so that emphasis on a good visual result has made the penetrating graft preferable to the lamellar graft.

Perhaps of equal, if not greater, importance has been increased understanding of corneal physiology. Various reports[20-22] emphasized the importance of precise methods for donor cornea selection, especially with respect to age and history of corneal disease. Similarly, the length of time that a viable donor cornea can be retained at 4°C was determined. The establishment of eye banks was of particular importance in this regard; through them, an adequate number of viable donor corneas became available to the corneal surgeon.[23-25]

Studies of the vital role of the corneal endothelium and its effect on corneal hydration have exerted a major influence on selection

and handling of the donor cornea at surgery.[26-30] Evidence for persistence of the endothelium throughout the life of the graft[29-32] has convinced the surgeon of the necessity for extreme caution in the handling of the donor graft. The donor cornea is no longer placed in a holder with the endothelium facing downward before being placed in the recipient eye, a procedure which frequently compromised the endothelium. Now, every effort is made to avoid damage to the endothelium.

Since the end of World War II, the various factors involved in host acceptance or rejection of allogeneic tissue has been a major topic of investigation. Power[3] demonstrated the superiority of the allograft over the xenograft in animal experiments. Medawar[4-5] introduced the concept of histocompatibility within a given species. In skin grafting experiments within a species, rejection occurred if donor and recipient were not genetically histocompatible. While this reaction was not as severe as with heterologous tissue, it led to destruction of the donor tissue nonetheless.

Applied to corneal surgery, graft rejection was expressed as the "second set" reaction.

At some interval after having received a corneal graft, the host animal receives a skin graft from the same donor animal. The corneal graft subsequently undergoes a graft reaction.[33,34] This phenomenon was explained by the assumption that "skin immunization" stimulated immunologic components to react with the tissue of the donor cornea. Although similar reactions have been reported in man,[35,36] a direct relationship to an immune event has not been established.

Attempts to identify specifically the site of tissue antigenicity have been generally unsuccessful.[37-39] All layers of the cornea appear to demonstrate allogeneic antigenicity.[40,41] Many corneal surgeons remove the epithelium from the donor cornea before grafting.[42]

Other experiments on tissue incompatibility indicate that the cornea is less antigenic than skin, kidney, and heart.[43,44] When grafting experiments in rabbits are controlled for allograft variables, the incidence of tissue incompatibility is small regardless of the type of graft. Many workers have indicated that when such reactions do occur, they can be easily controlled with corticosteroid.[45-47] Such observations in animals have led many observers to question the importance of tissue incompatibility in the human graft reaction.[48-49] Logically, tissue incompatibility should occur, yet it does not seem to represent a major cause of graft failure.

During the current period of corneal grafting, inflammatory reactions other than tissue incompatibility have not received adequate evaluation. The rules of precise surgery, prevention of infection, and meticulous control of the donor cornea in great part have sufficed to answer these questions. Perlon sutures alone, according to the experience of Harms[50] and Mackensen and associates,[51] improve graft results significantly.

Finally, the field of keratoprosthesis has again emerged as a substitute for allograft keratoplasty. A series of plastic procedures ranging from the insertion of membranes within the diseased cornea[52-54] to sophisticated composite apparatuses that allow for refractive correction to be added to the device[55-58] have become the subject of experimental studies. On the whole, these are reserved for eyes with extremely poor prognoses. It is still too early to evaluate their effectiveness.

## METHODS

All patients were selected for keratoplasty by identical criteria and they came from three sources. The first group, from San Francisco General Hospital (SFGH), was composed almost entirely of indigent walk-in patients. The second group, from the University of California Hospitals (UC), was composed of both referrals and walk-in patients with fixed incomes. The third group consisted of private patients, principally those referred to one of us (T.E.M., Jr.) for corneal surgery. Although this last group was initially composed of patients of moderate incomes, after July 1, 1968, indigent patients were included as a result of Medicare and Medicaid legislation.

While we attempted to include every patient with visual acuity (VA) of less than 20/100 attributable to a corneal lesion the corneal disease which we categorically excluded from surgical consideration was severe keratitis sicca (xerophthalmia), primarily because we had no technique for maintenance of corneal epithelium following penetrating keratoplasty in such eyes. Other patients in whom surgery was considered contraindicated according to our criteria were: (1) those with systemic disease who were poor anesthetic or survival risks, and (2) those who were mentally disturbed. There were also a certain number of patients who refused surgery.

Graft results are expressed in terms of patients, eyes, and cases. This series was comprised of 133 patients and 144 eyes, but there were 163 cases, since some eyes were operated upon more than once. A "case" is a single penetrating keratoplasty, and since one eye in this series received three keratoplasties, it is listed, therefore, as three cases. Only 12 patients in this series required bilateral surgery. All operations were performed between April 3, 1965, and June 28, 1969.

Corneal disease was classified by clinical-morphologic, etiologic, and immunologic criteria. Primary bases for clinical and morphologic classification were: (1) presence or absence of corneal neovascularization, and (2) evidence of intraocular inflammation. Morphologic stages are categorized in six groups (Fig. 2), each demonstrating progressively severe structural change. The category: 0+ indicated corneal distortion from inflammatory disease, without scarring or neovascularization. Predominantly, patients in this category were those with keratoconus (Fig. 3-A) and those with familial dystrophies (Fig. 3-B), including Fuchs'. (Two patients in this category received allografts in clear corneas of blind eyes, when autografts were taken from these corneas to be placed in the second, sighted eye.) A classification of 1A+ indicated central stromal scarring without vascularization and intraocular inflammation, including contusive or lacerative lesions (Fig. 3-C). A classification of 1B+ indicated corneal opacity or scarring with a history of intraocular inflammation, principally composed of aphakic bullous keratopathy (Fig. 3-D). A classification of 2+ indicated superficial corneal scarring and neovascularization without active intraocular inflammation, most frequently composed of patients with previous microbial inflammation (Fig. 3-E). A classification of 3+ indicated deep corneal scarring, superficial and deep stromal vascularization, presumptively free of intraocular disease (Fig. 3-F). A classification of 4+ included 3+ patients with definite signs of inflammation, whether active or inactive (Figs. 3-G and 3-H). In certain cases, it was difficult to decide accurately to which one of these last two groups a patient should be assigned. Diagnoses in the last two groups were predominantly microbial infections, chemically-induced keratitis, and atopic keratitis (Figs. 3-F through 3-H). When possible, cases were initially classified twice—

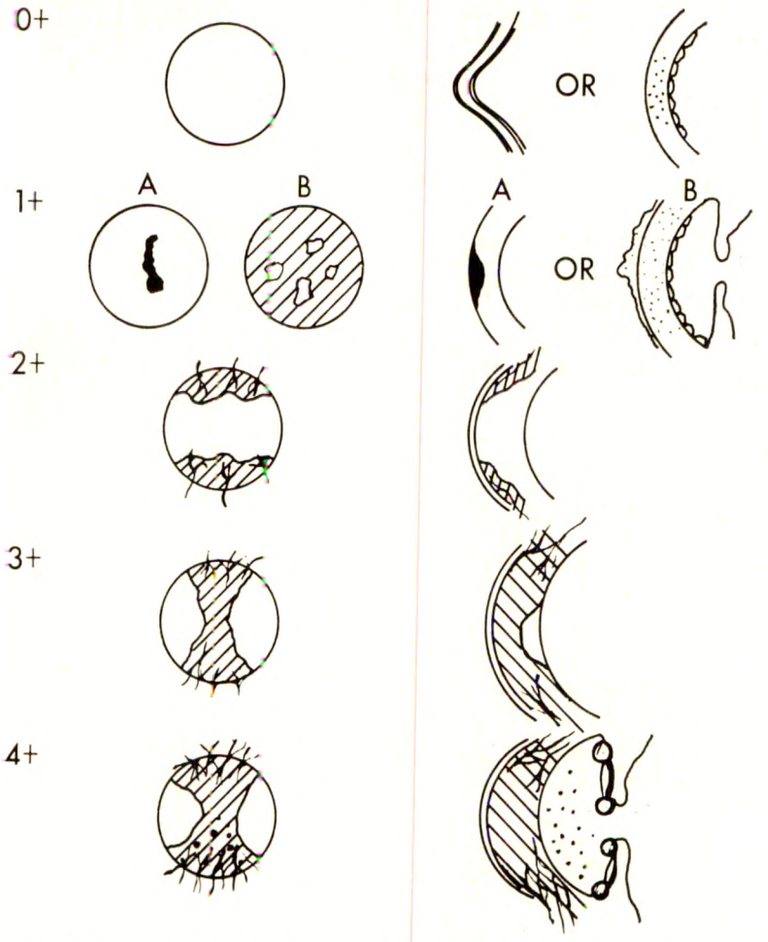

Fig. 2 (Moore and Aronson). Morphologic classification of corneal disease.

first during active inflammation, and then again after corneal inflammation subsided on combined corticosteroid and antimicrobial therapy.[1] Both of us (T.E.M., Jr., and S.B.A.) evaluated and classified each patient independently and then compared our results. When disagreement occurred we discussed our reasons for each designation and then reached a common decision (Table 1).

Classification by etiology or clinical syndrome included the following groups: (1) keratoconus, (2) familial corneal dystrophies (including Fuchs' dystrophy), (3) aphakic bullous keratopathy, (4) trauma, (5) herpes simplex keratitis, (6) herpes zoster keratitis, (7) bacterial keratitis, (8) idiopathic stromal keratitis, (9) physically or chemically induced keratitis, and (10) other diagnoses (Table 2).

Diagnosis of keratoconus, familial dystrophies, aphakic bullous keratopathy, trauma, and physical or chemical stimuli was based upon history and clinical morphologic evaluation. Herpes simplex keratitis required identification of an epithelial dendrite by an experienced observer, a positive culture, or identification by electron microscopy. Herpes zoster ophthalmicus was diagnosed on the basis of its peculiar dermatomal pattern (usually unilateral) with vesicular skin lesions. Bacterial keratitis was diagnosed by conjunctival culture. Other diagnoses included: (1) primary ischemic corneal necrosis,[2] (2) atopic keratitis, (3) interstitial ker-

atitis (syphilitic or idiopathic), (4) clear corneas for autograft, and (5) corneal leukoma secondary to sympathetic ophthalmia.

The etiologic and morphologic categories overlapped to some degree (e.g., aphakic bullous keratopathy was principally classified as 1B+, but herpes simplex keratitis was frequently 3 or 4+, Table 3).

Classification according to immunologic criteria involved evaluation of each patient by certain tests and subsequent comparisons of test results with the short- and long-term outcome of the penetrating graft. Tests were run several times during the period in which the patient was followed; these included preoperative evaluation, four to six months' postoperative evaluation, and re-evaluation at yearly intervals thereafter. Immunologic testing included: (1) protein electrophoresis, (2) qualitative immunoelectrophoresis, and (3) quantitative immunoglobulin determination for IgG, IgA, IgM, and early IgG. Quantitative values for any given patient over a prolonged period of time varied slightly, ranging between 10 to 15%. This was not true in patients with chronic systemic inflammatory disease; in these cases, there was usually a progressive increase in IgG.

Preoperative bacterial cultures were taken only when patients showed some signs of active corneal or external disease. Similarly, postoperative cultures were taken when bacterial origin of clinical inflammation was suspected. Cultures were plated on blood, chocolate, and mannitol agars, and evaluated for pathogenic and indigenous bacteria.

Preoperative therapy[3-5] was contingent upon classification and consisted of three general protocols: Group 1 consisted of patients with active central stromal keratitis (CSK), and these patients were assigned to a combined regimen of corticosteroid and specific therapy. Group 2 consisted of patients

who presented with inactive CSK, and these patients received either corticosteroid alone or the combined regimen. Group 3 patients were those with a good prognosis and inactive CSK at presentation and they received no corticosteroid.

*Group* 1—Patients in this group were placed on hourly corticosteroid drops (prednisolone acetate 1% suspension), combined with the appropriate topical antimicrobial agent, usually in equivalent dosage—e.g., herpes simplex keratitis patients were treated with topical prednisolone acetate 1% drops, six A.M. to 10 P.M., with IUDR (Herplex) in matched dosage. Therapy was continued until active inflammation subsided.* If a central scar remained, and visual acuity was 20/100 or less, the patient was continued on hourly topical corticosteroid therapy until the time of surgery.

*Group* 2—Patients in Group 2, whose disease was inactive at the time of their initial presentation, were treated with topical corticosteroid hourly (prednisolone acetate 1%, six A.M. to 10 P.M.) for seven to 10 days before surgery. When herpes simplex was identified, the patient was also placed on a matched dosage of IUDR. Appropriate antibiotic therapy was used only following positive culture identification.

Groups 1 and 2 comprised the prophylactic corticosteroid series and included the first 95 patients.

*Group* 3—Patients in Group 3 were those considered to have a good prognosis, based upon a combination of morphologic and immunologic signs. They were not started on corticosteroid until they demonstrated evidence of postoperative inflammation.[5] In the last 45 cases of this series (Cases 118 to 163), all 45 grafts were sutured with 10-0 Ethilon (Ethicon) suture. The combined morphologic and immunologic classification is given in Table 4. Patients in the 0+, 1A+, 1B+, and 2+ morphologic categories (a total of 26 cases in Group 3) were not treated preoperatively with corticosteroid, but 3+ patients with $\leqq$8.0 units early IgG and 4+ patients with $\leqq$9.0 units early IgG (a total of 19 cases) were treated according to the preoperative treatment protocol. This schedule has markedly simplified the pre- and postoperative keratoplasty procedure in eyes with a good prognosis.

Donor corneas were selected from subjects between the ages of seven and 60 years who were without evidence of corneal

* In the past, if a patient's cornea perforated before inflammatory activity subsided, the procedure was immediate keratoplasty. Now, however, the procedure of choice is to cement a hard contact lens to the anterior cornea overlying the perforated area, using isobutyl cyanoacrylate adhesive.[6,7] Corticosteroid therapy is then continued until inflammation resolves sufficiently to allow surgery.

TABLE 4

PROTOCOL FOR PRE- AND POSTOPERATIVE CORTICOSTEROID THERAPY ACCORDING TO MORPHOLOGIC CLASSIFICATION

| Morphologic Group | Preoperative Corticosteroid | No Preoperative Corticosteroid |
|---|---|---|
| 0+ | | All |
| 1A+ | | All |
| 1B+ | | All |
| 2+ | | All |
| 3+ | <or=8.0 early IgG units | >8.0 early IgG units |
| 4+ | <or=9.0 early IgG units | >9.0 early IgG units |

disease on slit lamp examination. Infectious hepatitis was the only systemic diagnosis which excluded donor eyes. Eyes were enucleated within six hours of death and placed in moist chambers which were stored at 4°C. Most donor eyes were used within 24 hours, and never more than 42 hours, postmortem.

Before surgery, donor eyes were rinsed in an ophthalmic solution of polymyxin B, neomycin, and gramicidin (Neosporin), and then examined under the operating microscope for intrinsic defects in Bowman's and Descemet's membranes, or endothelial dystrophy. Only eyes free of intrinsic corneal pathology were used for keratoplasty.

Tissue or blood-group typing was not undertaken.

*Surgical procedure*—The surgery protocol was already well established. One of us (T.E.M., Jr.) was the surgeon in charge in every case, performing all the surgery in private cases and supervising every detail of the procedure in staff cases. In this way, the surgery was comparable in every case.

To evaluate the effect of surgical modifications over a given period, the series has been subdivided into four time intervals. During the first (1965–67) and second (1967–68) periods, interrupted silk suture was used; during the third period (1968–69), interrupted 10-0 nylon (Ethilon) suture was used; and in the last period (1969), continuous 10-0 Ethilon suture was used. Because of the change in suture material and suturing technique, only the first and second periods give an accurate comparison of the effect of experience on surgical results.

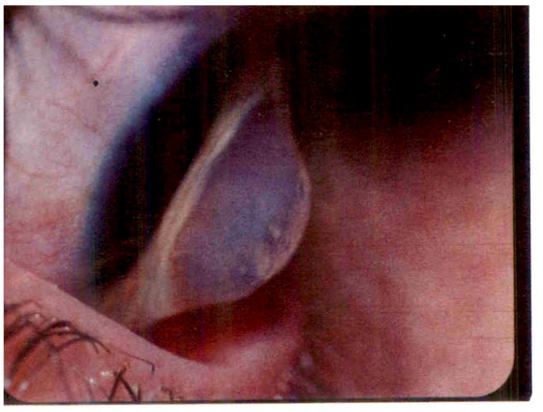
Almost every operation was done under general anesthesia. The techniques of anesthesia were relatively comparable. Hyperosmotic agents were used in aphakic cases and in combined procedures. Every procedure was performed under the Zeiss operating microscope or diploscope.

There were three fundamental surgical procedures: (1) a simple penetrating keratoplasty without an iridectomy, (2) a combined cataract extraction and penetrating keratoplasty with iridotomy or iridectomy, and (3) penetrating keratoplasty with anterior chamber revision. The last procedure included gross synechialysis, subtotal or total iridectomy, anterior and posterior membrane excision, cataract extraction, vitreous membrane excision and vitreous aspiration, and evacuation of hemorrhage. This group of cases was extremely heterogeneous and included patients who had had previous multiple surgery, massive trauma, and severe chemical burns. All of these patients were in the 4+ category and represented the poorest prognostic group of the entire series.

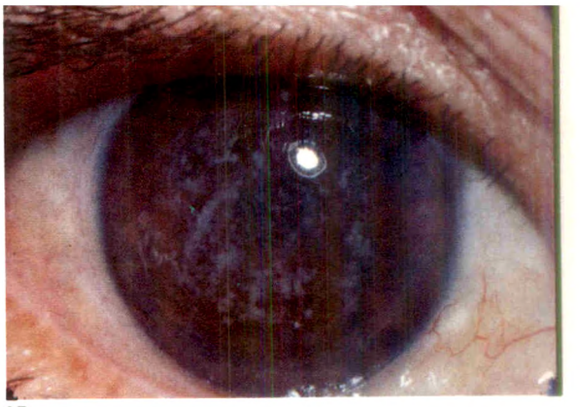
*Technique for simple penetrating keratoplasty*—The eye was secured with bridle sutures on all four rectus muscles. The area of the recipient cornea was measured. This usually encompassed the entire lesion; however, when the lesion extended to the limbus, it was transected with the corneal trephine. Once the graft size and position had been determined, a paracentesis wound was made with a Graefe knife. The donor button was denuded with a cyclodialysis spatula, care being taken not to damage Bowman's mem-

brane. The donor corneal button was trephined (Grieshaber-Franceschetti trephine), perforating the anterior chamber; the incision was completed with straight corneal scissors. Almost all corneal buttons in this series were between 7.0 and 8.0 mm in diameter, although they ranged in size from 6.5 to 10.0 mm.

Next, the recipient button was cut in the same fashion as the donor, except that no special effort was made to perforate the anterior chamber with the trephine. In combined procedures, peripheral iridectomies or iridotomies were performed in the 12, three, six, and nine o'clock meridians. The donor button was positioned and sutured in the same meridians. If interrupted sutures were used, three to six sutures were placed in each quadrant, totaling 12 to 24 sutures (e.g., 7.0 mm:12 sutures, 7.5 to 8.0 mm:16 sutures) per graft. If a continuous Ethilon suture was used, between four and six loops were placed in each quadrant. Sutures were inspected for accuracy of apposition and then they were tied. (The continuous nylon suture was tied in the 12 o'clock meridian with the knot buried beneath the bulbar conjunctiva.) The wound was inspected for watertight integrity and absence of anterior synechiae. When necessary, the anterior chamber was reformed, with balanced salt solution injected through the paracentesis wound. The pupil was dilated, the eye was double-patched, and the patient was taken to the recovery room.



*Combined surgical procedure*—Combined keratoplasty–cataract procedures were done through the trephination wound. Anterior segment revisions, being extremely heterogeneous, cannot be described as a set format.



*Postoperative procedure*—Following surgery, the patient's operated eye remained double-patched for the first 36 to 48 hours. At the end of this period, active postoperative therapy was started. In Groups 1 and 2 this included hourly prednisolone acetate 1% drops from six A.M. to 10 P.M. for six weeks after surgery; at that time, the dosage was tapered and finally discontinued. In most cases, corticosteroid was discontinued by the second week after suture removal (about 18 to 22 weeks after surgery). Acetazolamide (Diamox), 1000 mg/day, and KCl, 20 mEq/day, were started simultaneously with topical corticosteroid as prophylaxis against corticosteroid-induced glaucoma. An ophthalmic solution (Neosporin) was given four times daily throughout the first week, and sulfisoxazole (Gantrisin) drops were given twice a day until suture removal. Mydriatic drops (phenylephrine 10%, cyclopentolate 2%) were also given twice daily for the first seven days and then only given symptomatically. In confirmed herpes simplex cases, topical IUDR was used in matched dosage with topical corticosteroids. Similarly, in bacterial keratitis, the appropriate topical antibiotic was used in matched dosage with the corticosteroid.

When glaucoma was present, the patient was maintained on antiglaucoma medication. (The sequence of topical medication which we have followed has been 1 to 4% pilocarpine, then epinephrine 1%, then phospholine iodide 0.125 to 0.25%, and finally oral glycerol,[8] approximately 1 g/kg.) If maximal

medical antiglaucoma therapy was not adequate, surgery was undertaken. All efforts were made to avoid further surgery, except in cases of acute angle-closure glaucoma; in all, only four cases required glaucoma surgery.

As noted, the protocol was revised for patients in the favorable immunomorphologic groups (Table 4). In this protocol, postoperative corticosteroid medication was only used on evidence of inflammation in the graft or anterior chamber. Hourly topical corticosteroids were then used until inflammation subsided. Antiglaucoma medications were used only in response to increased intraocular pressure. Antibiotics and mydriatics were used in the same fashion as in the first protocol.

When severe inflammation persisted even in the presence of hourly topical corticosteroids, daily or twice daily subconjunctival corticosteroids (0.8 ml dexamethasone, 4 mg/ml, and 0.2 ml xylocaine 2%) were administered in the area adjacent to the site of greatest activity until the reaction subsided. Similarly, if evidence of peripheral ischemia occurred,[2] subconjunctival heparin (500 mg) was employed every other day until revascularization occurred.

As a rule, private and UC patients were hospitalized from 10 to 20 days following surgery and examined daily by slit lamp. SFGH patients were usually hospitalized up to 12 weeks to ensure adherence to the postoperative protocol. Once discharged, patients were seen one to three times a week until sutures were removed. Following suture removal, the frequency of visits was gradually diminished to one visit every six months (Table 5). Patients were warned, however, that if they experienced blurred vision, photophobia, ocular pain, or redness, they must be seen immediately. Patients who lived at a distance were often seen by their referring ophthalmologist, who began therapy according to the protocol described below. If the patient did not respond within several days, he was sent back to us for evaluation and subsequent therapy.

When a delayed graft reaction was diagnosed, nonspecific and specific therapy were started immediately. In order to determine appropriate specific therapy, bacterial or viral identification was made by culture or pertinent clinical history.

The therapeutic regimen consisted of hourly topical prednisolone acetate 1% (Prednefrin Forte) from six A.M. to 10 P.M. to the involved eye, plus the appropriate

Fig. 9 (Moore and Aronson). A-F Microbial toxicity (early graft reaction). G-H. Tissue incompatibility (early graft reaction). (A) Patient 9, demonstrating severe pseudomonas infection. (B) Same patient following inflammatory inactivation with combined corticosteroid Polysporin therapy. (C) Same patient four days after surgery, demonstrating a pseudomonas, suture-tract abscess following penetrating keratoplasty. (D) Same patient 12 weeks after surgery, demonstrating a clear graft. Note area of corneal scarring in the eight o'clock meridian. (E) Patient 10, three weeks postsurgery, demonstrating inflammatory infiltrate and neovascularization around interrupted sutures. The continuous suture is free of reaction. (F) Same patient one week after removal of interrupted suture. Note involution of conjunctival neovascularization. (G) Patient 11, demonstrating graft failure seven months after surgery. (H) Same patient (high magnification). Note that many superficial and deep vessels enter the donor cornea between suture tracts.

Fig. 11 (Moore and Aronson). Postoperative morphologic classification. (A) Absent host neovascularization following keratoplasty in keratoconus. (B) Mild host neovascularization following grafting in aphakic bullous keratoplasty. Note superficial vessels in the host cornea at four and 10 o'clock positions. (C) Moderate host neovascularization following grafting in herpes simplex keratitis (3+). Note superficial and deep vessels throughout the host cornea. (D) Moderate host neovascularization following graft for alkali keratitis. Note sequential distribution of neovascularization.

TABLE 5

FREQUENCY OF OCULAR EVALUATION

| Time Period | Frequency of Visits |
|---|---|
| During hospitalization | Daily |
| As outpatient until suture removal | Two to three times a week |
| Three to six months | Once a month |
| Six months to one year | Once every three months |
| One to two years | Once every six months |
| Thereafter | Once a year |

antimicrobial agent. If there is no appreciable clearing by 48 hours, subconjunctival corticosteroid injections are given as frequently as two times a day. Therapy is continued until total corneal clearing occurs, usually within two to four weeks, but if no appreciable change is noted at the end of this time, it is assumed that irreversible endothelial damage has occurred, and active medication is slowly discontinued. Rarely, a patient will clear spontaneously after a prolonged period of time.

### GRAFT REACTIONS

In evaluation of graft successes or failures, a successful graft is defined as an optically clear graft on slit lamp examination except in the area of suture tracts. Short-term or early success is defined as a clear graft up to the time of suture removal (approximately three to four months). Long-term success is a graft that remains clear after this time.

*Graft failure*—This refers to an irreversible graft reaction, usually caused by primary or secondary physiologic failure of the corneal endothelium resulting in corneal edema or severe stromal scarring with central opacity of the donor cornea. Early graft failure occurred prior to suture removal, while a delayed graft failure occurred any time after suture removal.

*Early graft reaction*—The severity of early graft reactions varied markedly among patients. The degree of severity was classified as minimal, moderate, or severe (Fig. 4-A). A minimal reaction in a nonvascularized host shows virtually no vascular invasion of the host cornea. In vascularized hosts, neither engorgement nor proliferation of vessels occurs. Moderate reactions were either corneal or uveal, or both. In these cases, inflammation began at the donor–host interface and extended into the peripheral donor cornea. The central donor cornea remained free of inflammation. The uveal reaction seeded the central and inferior donor and host endothelium with keratic precipitates, often leading to corneal edema. Moderate reactions seldom led to graft failure. When graft failure occurred, it resulted from secondary ocular involvement (noncorneal) such as phthisis bulbi or glaucoma with wound failure. A severe reaction extended throughout the entire donor cornea with both corneal and uveal involvement. These cases demonstrated early graft failure.

*Delayed graft reaction*—Opacification of the cornea may occur at any time following the removal of sutures. Patients complained of suddenly decreased vision, pain, photophobia, and limbal hyperemia. It is important to note that the patients in this group were under their own recognizance during this period, so that the effect of the interval elapsing between onset of these reactions and the patient's re-presentation for examination and treatment proved very difficult to assess.

As in the early graft reaction, delayed graft inflammation is of corneal or uveal origin (Fig. 4-B). The typical reaction in almost every case is a combination of inflammatory infiltrate and edema which extends into the central cornea from the limbus, involving both host and donor corneas during active inflammation (early active stage, Fig.

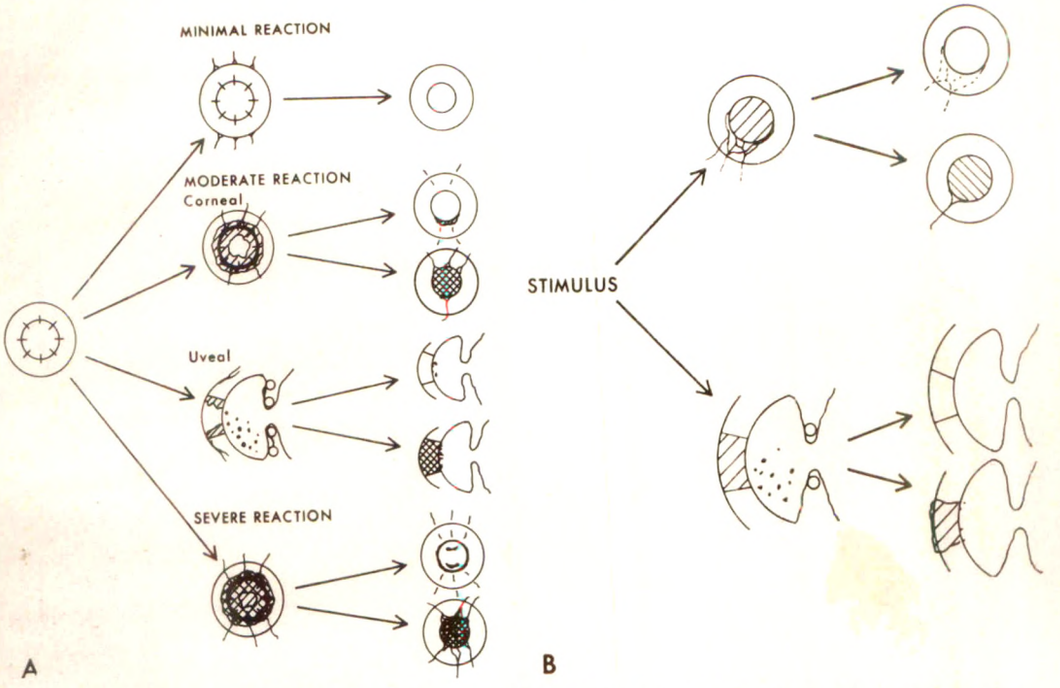

Fig. 4 (Moore and Aronson). (A) Patterns of inflammation in early graft reactions. (B) Patterns of inflammation in delayed graft reactions.

5). In inflammatory resolution, clearing of the host cornea precedes donor clearing. In delayed graft failure, the recipient cornea clears, but the donor cornea remains clouded (stage of endothelial decompensation). We have assumed that secondary physiologic failure of the donor endothelium occurs in the course of the inflammatory episode and that resultant failure is represented by bullous keratopathy.

*Evaluation of the early graft reaction*—The variables affecting the outcome in the early period include: (1) physiologic properties of the donor cornea, (2) surgical factors, (3) the effect of suture material and technique on the graft, (4) the role of conjunctival microbes, and (5) tissue noncompatibility (Fig. 6).

*Donor failure*—The clinical course of graft failure can be described accurately in many cases. Primary donor failure is characterized by non-clearing opacification of the corneal donor button from the time of surgery.[9] There is minimal corneal inflammatory response in donor or host tissue. When the donor button is replaced (usually by the 10th day) and studied histologically, there is a striking absence or degeneration of endothelial cells. Secondary epithelial and stromal edema are pronounced. The corneal stroma is surprisingly free of inflammatory cells.

*Surgical failure*—Logically, surgical failure subdivides into two types. The first results from technical error. It is manifest in some form of wound failure, compromise, or malposition of the donor–host margin. In some cases, the graft will succeed, but a large descemetocele or iris adhesion or incarceration remains at the donor–host margin, interfering with the optical quality of the graft. If donor endothelium is surgically damaged, the graft will appear as primary donor failure.

The second type is surgically induced inflammation, usually presenting as a traumatic uveitis or hyphema. Apparently, it is directly related to the extent and duration of the surgery.

*Suture toxicity reaction*—Suture toxicity

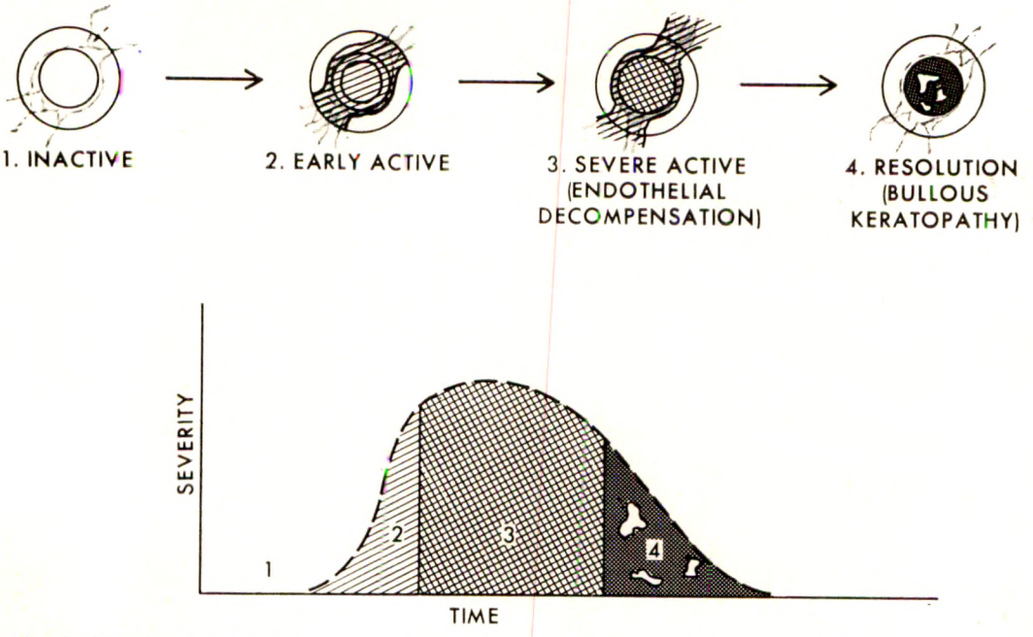

Fig. 5 (Moore and Aronson). Sequential stages in delayed graft reaction. The uveal pattern of disease proceeds through the same inflammatory stages. However, the inflammation is less severe.

presents initially as infiltrate in and around suture tracts, first in the recipient, then in the donor. This reaction gradually progresses to heavy vascularization of the suture tracts; coalescence and proliferation of these vessels can eventually culminate in neovascularization and scarring of the central donor cornea. The selection of patients and the type of suture used has been presented in Table 6, where 8-0 virgin silk (Ethicon), 9-0 virgin silk (Ethicon), and 10-0 nylon (Ethilon) sutures were compared for severity of toxic reaction. Seven cases of graft failure with silk suture were reoperated with Ethilon and appear as cases in both series.

Since graft failure decreased sharply with the advent of interrupted nylon suture, other criteria were necessary to evaluate differences in reaction between interrupted and continuous nylon suture. Such criteria were subdivided into objective and subjective classes. Objective signs of infiltrate formation and neovascularization of the suture tract are classified as absent, mild, or severe. Patients were also questioned for subjective symptoms of pain and photophobia. We must emphasize that a majority of the interrupted nylon cases (37 cases) were evaluated restrospectively so that this aspect of our study is affected by subjective interpretation.

*Microbially induced graft failure*—This commonly presents as a discrete suture abscess which is usually limited to one or two suture tracts and which may rapidly involve most of the donor cornea. If not aborted immediately, this reaction will proceed to graft failure. Pathogenic bacteria are responsible for this reaction.

Whether or not indigenous (nonpathogenic) bacteria produce a toxic reaction which may lead to graft failure is difficult to determine. The indigenous reaction is characterized by infiltrate formation and secondary vascularization around the knots of interrupted nontoxic nylon suture. When the conjunctival sac is cultured, the growth of Staphylococcus epidermidis or diphtheroids is usually prolific. When the interrupted suture is removed and epithelium allowed to close the

suture tract, the reaction disappears (Fig. 9-E and F). The continuous nylon suture allows epithelium to grow over it in a sheet free of defects; the only epithelial defect is at the suture knot when it is not placed beneath the bulbar conjunctiva (Fig. 10-G and H).

To evaluate this reaction, a series of cultures were taken from patients who had had interrupted and continuous nylon sutures. Five individuals from each group with positive cultures for indigenous bacteria were compared for the presence or absence of clinical signs described under suture toxicity.

*Tissue incompatibility reaction*—A tissue incompatibility reaction (homograft, allograft) proved exceptionally difficult to differentiate from suture or indigenous microbial reactions. Undoubtedly, this difficulty is compounded when high-dosage topical corticosteroid is used. Historically, tissue incompatibility reactions have been depicted as

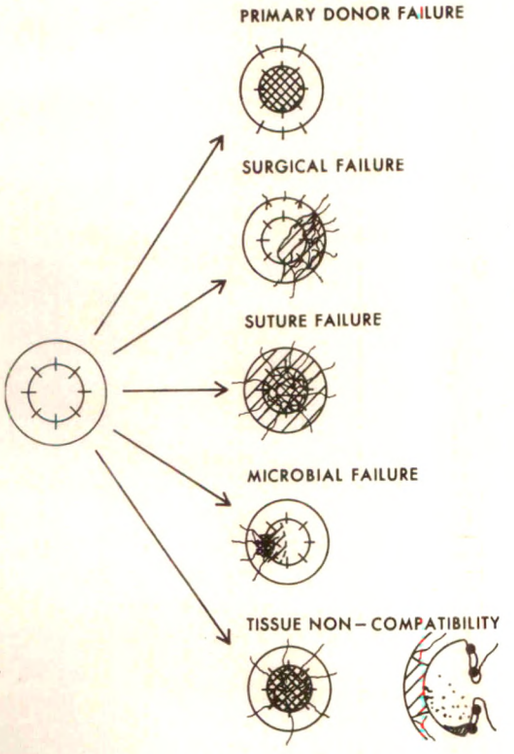

Fig. 6 (Moore and Aronson). Types of graft failure (early graft reaction).

TABLE 6

DISTRIBUTION OF SUTURE AMONG CASES

| Morphologic Class | 8-0 Silk (Interrupted) | 10-0 Ethilon (Interrupted) | 10-0 Ethilon (Continuous) |
|---|---|---|---|
| 0+ | 15 | 12 | 5 |
| 1A+ | 1 | — | — |
| 1B+ | 11 | 3 | 3 |
| 2+ | 12 | — | — |
| 3+ | 25 | 6 | 3 |
| 4+ | 31 | 30 | 6 |
| Total | 95 | 51 | 17 |

neovascularization of the donor graft or as a predominantly uveal reaction with initial rejection of donor endothelium. Although we have seen such classically described reactions, we could not differentiate tissue incompatibility from the other identifiable variables. Our experience suggests that the tissue incompatibility reaction is probably a concurrent reaction and is occasionally diagnosed by exclusion. In this series, we have been able to identify only one case as representing this mechanism.

*Late graft reaction*—The principal sources of stimuli for the delayed graft reactions have been diagrammed in Figure 7 and include: (1) surgical trauma, (2) exogenous stimuli, (3) endogenous uveitis, and (4) tissue incompatibility. (One again, this last diagnosis can only be made after excluding other potential causes.) The traumatic reaction is a consequence of direct mechanical destruction of donor endothelium, while the other three reactions are related to the acute inflammatory pathway.

The course of the delayed graft reaction may be self-limited or progressive to graft failure. There has not been an identifiable self-limited reaction within this series. Because we consider the donor endothelium to be highly susceptible to inflammation, we immediately treat such reactions with corticosteroid.

Other operative factors in the delayed graft reaction in addition to the stimulus include the

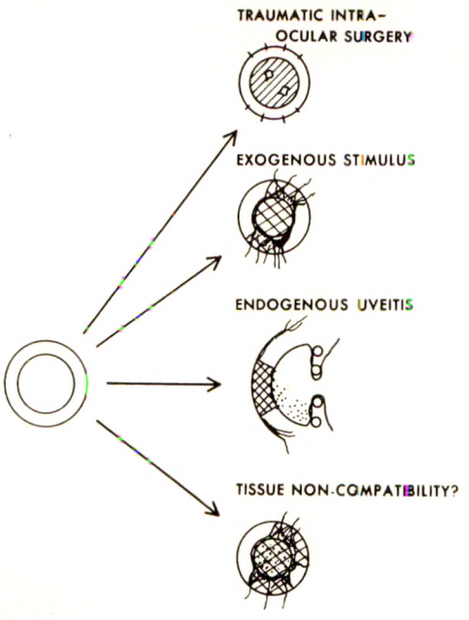

Fig. 7 (Moore and Aronson). Types of graft failure (delayed graft reaction).

immunologic characteristics of the host response, the degree of preoperative and postoperative morphologic change, and the socioeconomic status of the individual.

Stimulus evaluation for bacteria-induced inflammation was performed as described earlier. The herpes simplex virus was identified by corneal clinical morphology, culture, or electron microscopic identification. Upper respiratory virus was diagnosed by history of a concurrent or recent upper respiratory episode of disease or "flu syndrome." A diagnosis of topical allergy (epinephrine, hair spray) was based upon continued use of the allergen before the onset of corneal inflammation and disappearance of inflammation after the allergen was withdrawn. Each of the cases designated as idiopathic demonstrated some evidence of corneal vascular insufficiency[2] (two alkali keratitis, one Mooren's ulcer); however, there was no evidence of a specific stimulus. The postsurgical failure demonstrated endothelial decompensation immediately after surgery and never cleared.

Host response was evaluated by comparing the quantitative immunologic test results (Table 7) of delayed graft reaction and failure patients with those of patients without subsequent reactions.

Delayed graft reaction patients were compared by morphologic criteria both pre- and postoperatively. The preoperative classification has already been described. The postoperative classification (Fig. 11) was based upon the degree of neovascularization of the host cornea and has been divided into absent (Fig. 11-A); minimal (Fig. 11-B), in which a single arborizing branch approached the donor cornea; and moderate (Fig. 11-C and D), in which a number of vessels extended to the donor margin.

As a final variable, patients were divided into three socioeconomic groups: the private patients series; the UC clinic series, in which patients paid a reduced rate for hospital and outpatient care; and the SFGH or charity clinic series, drawn almost entirely from the indigent wards. The major differences be-

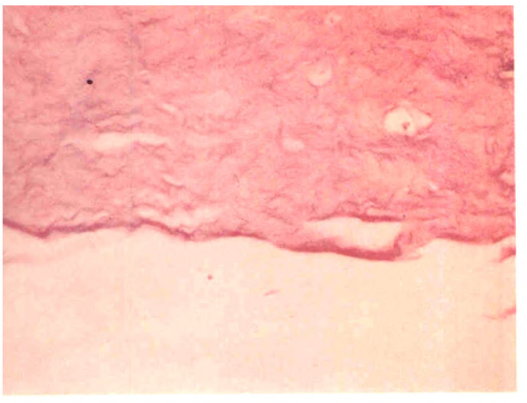
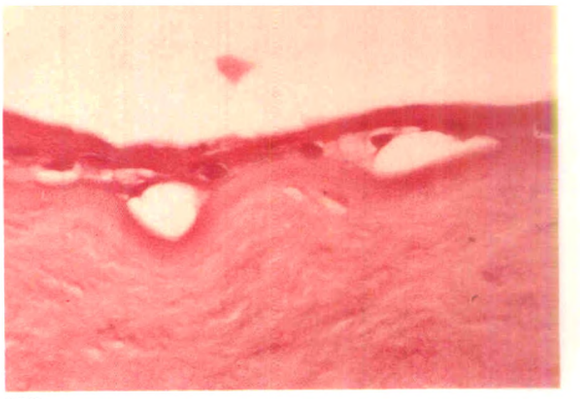
The majority of all graft failures occurred during the first 12 weeks. Of the preoperative prognostic criteria, the clinical and morphologic classification appears to be the most significant (Table 8). The case success rate dropped from 100% in 0+ recipients to 80% in 4+ recipients; 18% of cases with poor prognosis (3 and 4+) failed, compared with 5% for those with good prognosis (0, 1A, 1B, and 2+). Success rates in 1B, 3, and 4+ groups improve when analyzed by eyes and by patients. This indicates that multiple surgical procedures enhance the potential for eventual success in these groups.

Etiologic classification closely parallels the clinical and morphologic evaluation (Table 9). The good prognosis groups (e.g., keratoconus, corneal dystrophies, corneal trauma) all demonstrated 100% success. The inflammatory corneal conditions such as herpes simplex, herpes zoster, bacterial and idiopathic stromal keratitis demonstrated similar success rates. The physical and chemical keratitis group showed the poorest success rate, 77%.*

Etiologic evaluation, when grouped for eyes and patients, showed marked improvement over case results (herpes simplex, 87 vs 78%). As in the poor prognosis groups, multiple surgical procedures improved success rates. (Etiologic classification per se was not statistically evaluated since there was no comparative basis for diagnostic categories.)

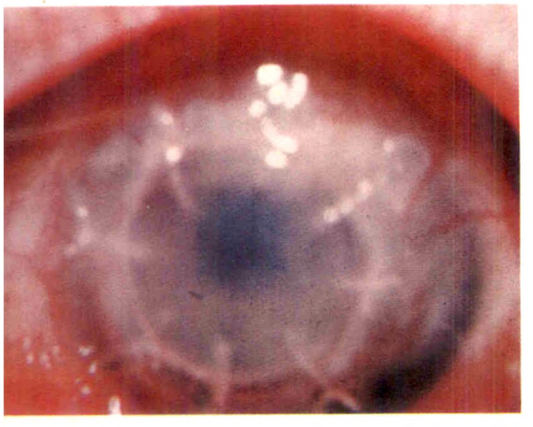


Prognosis by immunologic parameters has been evaluated by several techniques. A comparison of mean values for successful and failed cases (Table 10) revealed no significant differences ($> 2$ SD) for any testing procedure when compared with a normal population. This was true whether or not the series was differentiated by clinical–morphologic classification.



However, when a sharp cut-off distribution curve is plotted, early graft prognosis can be projected from early IgG. When the mean values for each clinical-morphologic group are plotted as the cut-off point, very few failures demonstrated early IgG values which were greater than the mean (Table 11). This has clinical usefulness for group 3 and 4+ cases, in which this early IgG distribution is the basis for selection of pre- and postoperative treatment regimens.

When the treatment administered is based on early IgG determination, the overall success rate for these cases is slightly higher than for cases treated prophylactically, providing nylon suture has been used. Because of silk suture toxicity, comparison cannot be made between the silk suture prophylactic corticosteroid group and the early IgG prognostic



* This rate of success may improve with pre- and postoperative treatment of intravascular coagulation. Since we have used heparin in this group, four of six cases (four of five eyes and patients) have had successful grafts during the early period. This percentage is not far different from results in the other specific etiology groups.

* Where more than one keratoplasty was performed, eyes and patients are designated according to most recent classification.

nylon suture groups (Table 12). This finding is particularly interesting since it demonstrates that adoption of the combined immunomorphologic criteria for selection of therapy yielded results equal to those of the routine prophylactic corticosteroid regimen.

*Evaluation of the individual variables leading to early graft failure*—Primary donor failure occurred only once in this series. Patient 1 received a 58-year-old donor's cornea 18 hours after the donor's death without deviation from our protocol. The donor cornea never cleared and by the fifth postoperative day it became apparent that the donor button was physiologically incompetent. A second penetrating keratoplasty was perpormed on the sixth postoperative day with a successful early result.

## CASE REPORT

Patient 1 was a 53-year-old Mexican American man with a history of long-standing idiopathic stromal keratitis, preoperative morphologic class 4+. A 7.5 mm penetrating keratoplasty was performed on his right eye; 16 interrupted 8-0 virgin silk sutures were used to secure the graft. The opposite eye of the donor was not used for surgery and was fixed in buffered Formalin. The graft was hazy on the second postoperative day; by the fifth day, the haziness had become more pronounced. Epithelial and stromal edema as well as folds in Descemet's membrane were present. The diagnosis of primary donor failure was made, and the patient was returned to surgery for regrafting. A second 7.5 mm donor button was placed in the right eye and secured with 16 interrupted silk sutures. The patient's postoperative course was relatively uneventful.

*Histology*—Sections of the failed donor cornea revealed stripping of endothelium from most of the posterior cornea. A large area of Descemet's membrane was missing from the temporal aspect as well (Fig. 13-A). The epithelium and stroma showed fine edematous change (Fig. 13-B). Polymorphonuclear leukocytes were noted entering the periphery of the donor cornea, indicating some degree of reaction. The control cornea (opposite eye) showed no evidence of endothelial change. We have assumed that destruction of endothelium and Descemet's membrane resulted from traumatic handling at the time of surgery.

Examples of surgically induced early graft failures are readily demonstrated. Wound failure occurred much more fre-

quently when silk suture was used (Table 13). It presented as a separation of the donor and recipient cornea with suture erosion of either area. The disappearance of this complication with the advent of nylon suture is most readily explained by this suture's elasticity and plasticity. Swelling of either donor or host tissue no longer produced suture tract erosion.

Patient 2 demonstrates a wound dehiscence involving silk suture. The poor quality of the temporal aspect of the host cornea made suturing extremely difficult. On the fourth postoperative day, the margin of the

donor cornea swelled and pulled three silk sutures out of host tissue. An iris prolapse resulted. After the cornea was resutured, a severe graft reaction occurred and the graft went on to failure (Fig. 13-C).

### CASE REPORT

Patient 2 was a 62-year-old Caucasian man, alcoholic and unemployed, with a history of idiopathic stromal keratitis and failed lamellar keratoplasty, preoperative morphologic class 3+. The patient was regrafted with a 7.5 mm penetrating graft sutured with 16 interrupted virgin silk sutures. At surgery it was noted that the cornea was extremely thin temporally, therefore, long recipient suture bites were placed. The patient was started on protocol postoperative medication. By the fifth postoperative day, a marked swelling of the donor cornea was noted temporally. By the eighth day, three sutures had pulled out of the recipient cornea and a frank wound dehiscence presented. The donor cornea was braced with a Werb splint, which was kept in position for three weeks and removed after the wound had healed sufficiently. By this time, irreversible donor infiltrate and neovascularization had occurred (Fig. 13-C). The patient was regrafted successfully with a 7.5 mm penetrating keratoplasty (Fig. 13-D). Following cataract extraction, the patient's visual acuity was correctable to 20/20 with a contact lens.

TABLE 12

RESULTS OF PROPHYLACTIC VS SELECTED CORTICOSTEROID THERAPY

| | Total Cases | Successful Grafts | |
|---|---|---|---|
| | | No. | % |
| Corticosteroid prophylaxis | | | |
| Silk suture | 95 | 77 | 81 |
| Nylon suture | 22 | 20 | 91 |
| Corticosteroid on indications | | | |
| Nylon suture | 46 | 45 | 98 |

A more frequent form of wound dehiscence or slippage occurs following suture removal. Such an example occurred in case 3, when silk sutures were removed eight weeks following surgery. The resultant inferonasal descemetocele was so large (Fig. 13-E) that a contact lens was contraindicated and spectacle correction was 20/200.

### CASE REPORT

Patient 3 was a 52-year-old Caucasian man with a long history of alkali keratitis. There was no evidence of intraocular disease, so preoperative morphologic classification was 3+.

TABLE 13

COMPLICATIONS OCCURRING IN THE EARLY GRAFT PERIOD

| Type of Complication | Silk Suture | | | Nylon Suture | | |
|---|---|---|---|---|---|---|
| | Total Cases | Complication | | Total Cases | Complication | |
| | | No. | % | | No. | % |
| Early wound dehiscence | 95 | 10 | 11 | 68 | 2 | 3 |
| Late wound slippage | 95 | 2 | 2 | 68 | 4 | 6 |
| Total | 95 | 12 | 13 | 68 | 6 | 9 |

An 8.0 mm penetrating keratoplasty was performed and sutured with 16 interrupted 8-0 virgin silk sutures. The patient's postoperative course was relatively uneventful. However, when suture removal was begun (eight weeks postoperatively), a wound separation appeared in the eight o'clock meridian. Remaining sutures were left in position and the eye was double-patched. A large descemetocele formed between seven and nine o'clock (Fig. 13-E). Because of this large wound defect and the unsatisfactory visual result, the patient was regrafted and a cataract extraction was performed with a successful result (Fig. 13-F).

There was no significant difference between silk and nylon suture cases in the incidence of late wound slippage (Table 13). However, nylon suture considerably prolongs wound healing; if it is allowed to remain in position for an adequate period of time, late wound slippage can be avoided. It is important to note that silk sutures were removed at approximately 12 weeks and nylon sutures between 16 to 18 weeks following surgery.

An unusual type of early wound failure was encountered in one case sutured with nylon. In patient 4, a continuous nylon suture was cut unintentionally during removal of an anchoring suture three weeks postoperatively. As the suture retracted, a large inferior wound dehiscence resulted, which required resuturing (Fig. 13-G). The remaining postoperative course was uneventful with a resultant clear donor cornea (Fig. 13-H).

### Case report

Patient 4 was a 70-year-old Caucasian woman with Fuchs' corneal dystrophy, morphologic classification 0+. The right eye had been operated upon one year previously, with an excellent corneal result. However, fundus examination revealed a discrete macular hole. A 7.5 mm penetrating keratoplasty was performed on the left eye. The button was anchored with four interrupted nylon sutures followed by a continuous nylon suture. On the second postoperative day, an intumescent lens developed with consequent pupillary block, and by the sixth postoperative day, intractable glaucoma developed. A peripheral iridectomy was performed. The intraocular pressure was not satisfactorily controlled. On the eighth postoperative day, an intracapsular lens extraction was performed with glaucoma control subsequently achieved.

The patient's further course was uneventful. However, on the 21st postoperative day, the nylon stay sutures were removed, and while the six o'clock suture was being removed, the continuous nylon suture was unintentionally cut. The continuous suture unraveled, the wound dehisced and was plugged by iris (Fig. 13-G). The patient was taken to surgery, where the ends of the continuous sutures were tied inferiorly (with a resultant anterior synechia). The remainder of her postoperative course was uneventful. Five months postoperatively, the sutures had been removed (Fig. 13-H) and her visual acuity was correctable to better than 20/50.

The overall effect of surgical trauma and its relationship to graft failure is difficult to evaluate. The culmination of such trauma is glaucoma or hypotony which may be preceded by severe uveitis or endophthalmitis. In either case, the success of the graft is dependent upon normalization of ocular pressure. The postoperative uveitis may directly destroy the graft by destroying donor endothelial cells. Case 5 developed a progressive endophthalmitis during the fifth postoperative week which eventually led to phthisis bulbi and consequent graft failure. This blind, painful eye was enucleated after 14 weeks (Fig. 12-B).

### Case report

Patient 5 was a 65-year-old Caucasian woman referred because of a perforated right cornea secondary to a 25-year history of herpes simplex keratitis over which a bridge flap had been pulled and had retracted (Fig. 12-A). A penetrating 8.0 mm keratoplasty was performed and sutured with 16 interrupted 8-0 virgin silk sutures. In spite of continuous topical corticosteroid and IUDR therapy, this keratoplasty resulted in graft failure, probably attributable to silk suture toxicity.

After one year, the patient's failed graft was reoperated, morphologic classification 4+. This time, an 8.0 mm penetrating keratoplasty was performed using 16 interrupted Ethilon sutures. During the first postoperative week, the patient developed a hypopyon which rapidly cleared following topical and subconjunctival corticosteroid therapy. Her postoperative course was uneventful until the sixth week, by which time topical corticosteroid and IUDR had been tapered to four times a day. She then developed a relatively severe iridocyclitis. Corticosteroid therapy and IUDR were increased to hourly drops, and subconjunctival injections were resumed three times a week. Although her cornea remained clear during this period (four weeks), the anterior chamber and vitreous reaction were relatively constant and the graft clouded (Fig. 12-B). Intraocular pressure decreased until by the end of the 10th

week the eye became phthisical. The patient now requested enucleation, and her eye was removed in the 14th postoperative week.

The classification of this inflammation as secondary to surgical trauma is difficult to justify because of the long hiatus after surgery. Two other alternatives provide possible explanations for this delayed intraocular inflammation: (1) an intraocular herpes simplex infection, or (2) intravascular clotting secondary to corticosteroid therapy. Selected uveal sections were scrutinized extensively by electron microscopy, but no trace of herpes simplex virus was found. Histologic evaluation of uveal vasculature showed no active evidence of intravascular clotting. The inflammatory reaction had subsided markedly and was now present only in the anterior eye (Fig. 12-C and D). The choroid and retina were relatively free of inflammation.

The composite of individual surgical complications reflects the reproducibility of the surgery. Evaluation of early success rates (12 weeks) through successive chronologic intervals roughly indicates the overall proficiency of the surgical group (Table 14). There is a marked improvement throughout the course of the first three time periods, from 75 to 85 to 96% success. An analysis of this improvement suggests that the change from 75 to 85% success probably represents refinements in surgical technique and postoperative management; the subsequent improvement to 96% must be attributed to the adoption of nylon suture. Whether surgical improvement was also a factor in this increased success cannot be determined. Of particular interest is an evaluation of the rates of success achieved by the staff surgeon compared to that of the residents in this series. (As noted earlier, the surgical procedure was standardized by the supervision of the staff surgeon, T.E.M., Jr., in every case.) Early graft results were similar for each group (Table 15).

A second evaluation was the influence of surgical trauma, as expressed by the type of surgical procedure, upon graft outcome (Table 16). As already noted, three different surgical groups were evaluated. Although the agonal period (first several weeks after surgery) showed a greater complication rate in combined procedures, the overall results at the end of the early period did not differ significantly for all groups. Therefore, extent of intraocular surgery does not necessarily affect the outcome of the graft. However, the incidence of reduced vision from secondary complications is somewhat higher in the more complicated surgical cases (Table 17).

| Total | 48 | 12 | 20 (78%) | 80 |
| Nonrelated variables | 42 | 4 | 8 | 54 |

* PK = penetrating keratoplasty.

The complication rate, 78%, was much higher in the penetrating keratoplasty plus anterior segment revision than in the other procedures. This difference apparently reflects a combination of the preoperative condition of the eye and the effect of a complicated surgical procedure. The relationship of the different surgical procedures to long-term effects appears to be much the same as the 12-week results (Table 18). Most of the complications which related to the type of surgical procedure occurred in the early graft period In summary, the extensiveness of the surgical procedure has had negligible effect on graft outcome but is related to the overall visual result of the operated eye.

The role of suture toxicity in graft success proved to be a crucial variable. The occurrence of wound dehiscence was considerably diminished when routine use of nylon suture was adopted (Table 13). Silk suture toxicity occurs as a progressive inflammatory reaction extending into the donor suture tracts and, eventually, into the central donor cornea with graft failure. Case 6 demonstrated a severe reaction to silk suture which culminated in graft failure (Fig. 10-A). He was subsequently operated with nylon suture and had an uneventful course (Fig. 10-B).

CASE REPORT

Patient 6 was an eight-year-old Mexican boy who presented with unilateral herpetic stromal keratitis, morphologic classification 3+. His right eye had previously been operated upon with a lamellar keratoplasty which became opaque. A 7.5 mm penetrating keratoplasty was performed, sutured into position with 12 virgin silk 8-0 sutures. Despite heavy corticosteroid coverage, the suture tracts demonstrated neovascularization, coalescence of these new vessels, progressive graft opacity, and, finally, graft failure (Fig. 10-A). The patient was operated upon 18 months after the original proce-

dure; this time, an 8.0 mm donor button was sutured in position with 16 interrupted 10-0 Ethilon sutures. (The corneal button was negative for herpes virus on culture and electron microscopy.) The postoperative period was relatively uneventful; corticosteroids were discontinued by the sixth postoperative week (Fig. 10-B). Sutures were removed 12 weeks postoperatively. The patient demonstrated visual acuity of >20/25 over 15 months following surgery.

Patient 7 also demonstrated silk suture toxicity with consequent graft failure (Fig. 10-C). A successful result was achieved in a subsequent keratoplasty with nylon suture (Fig. 10-D).

### Case report

Patient 7 was a 49-year-old Mexican man with a long-standing history of herpes simplex stromal keratitis, morphologic classification 4+. A penetrating 7.5 mm graft was sutured with 12 interrupted 8-0 virgin silk sutures. Suture tracts rapidly vascularized; however, the central cornea remained clear through the sixth postoperative week. At this point, a surge of vessels invaded the temporal graft which could not be controlled by subconjunctival corticosteroid therapy. The graft became opaque and eventually failed. The patient demonstrated epithelial bullae with sporadic epithelial breakdown; one such occasion resulted in superinfection with pneumococcus and subsequent severe opacity and vascularization (Fig. 10-C).

The patient was re-operated upon 11 months later, at which time an 8.0 mm penetrating keratoplasty was sutured into position with 16 interrupted 10-0 Ethilon sutures. The postoperative course was quiet, although the patient has required maintenance corticosteroid and IUDR (1 drop once a day). The graft has been clear for over one year (Fig. 10-D), with visual acuity greater than 20/25 (contact lens).

In another patient (patient 8), 8-0 silk and 10-0 nylon sutures were alternately interrupted in a penetrating graft. The difference in degree of reaction rapidly became apparent (Fig. 10-E) and the silk sutures had to be removed.

### Case report

Patient 8 was a 13-year-old Negro boy with bilateral keratoconus, morphologic classification 0+. The left eye had been operated upon one year ago using 8-0 virgin silk with a successful result. Because of this, it was decided to alternate 8-0 virgin silk and 10-0 Ethilon sutures in the right eye so that a comparison could be made concerning the degree of toxic inflammogenesis. By the fourth postoperative week, the silk suture tracts showed severe infiltrate formation with some evidence of neovascularization, while the nylon sutures were relatively free of infiltrate in suture tracts (Fig. 10-E). Silk sutures were subsequently removed, the patient progressing to a successful keratoplasty.

TABLE 19

Comparison of results with several sutures
(Early graft reaction)

| Suture Group | Total Cases | Clear Grafts | % Success |
|---|---|---|---|
| All cases | 163 | 142 | 87 |
| Silk suture | 95 | 77 | 81 |
| Ethilon suture | 68 | 65 | >95 |
| Poorer prognosis | | | |
| Cases | 99 | 81 | 82 |
| Silk suture | 55 | 40 | 73 |
| Ethilon suture | 44 | 41 | 93 |
| Better prognosis | | | |
| Cases | 64 | 61 | 95 |
| Silk suture | 40 | 37 | 92 |
| Nylon suture | 24 | 24 | 100 |

A similar comparison between 9-0 virgin silk and 10-0 nylon was made in a keratoconus case. The silk suture showed an enhanced degree of infiltrate formation in suture tracts (Fig. 10-F).

When continuous nylon suture is used in a cornea with good prognosis, clinical inflammogenesis is no longer recognizable. This was demonstrated in a keratoconus case in which the suture tract, eight weeks postoperatively, was absolutely free of infiltrate (Fig. 10-G and H). Therapy was limited to maintenance corticosteroid (once a day).

Overall evaluation of suture effect reveals a marked increase in early graft success when nylon suture is used (Table 19): The rate of success is now > 95% compared to a previous 81%. A comparison of cases with poor prognosis emphasizes the significance of this difference in success. Ninety-three percent of nylon suture-treated patients demonstrated successful keratoplasties, while silk suture success fell to 73%. Naturally, cases with better prognosis showed a less significant difference, 100 vs 92%. It seems likely that the more reactive, vascular-

ized host cornea (3 and 4+) responded more vigorously to silk suture than the less reactive group with the better prognosis. On a less significant level, this difference in suture toxicity has been demonstrated in seven eyes, each of which had experienced one or more graft failures with silk suture and which succeeded when nylon suture was used.

Evaluation of the exogenous environment in relation to graft results concentrated on conjunctival microbes. Pathogenic bacterial reactions present as a suture abscess, which, if not immediately and actively treated, will progress to destroy the graft. Patient 9 incurred pseudomonas infection following surgery. However, corticosteroid and polymyxin B therapy was instituted rapidly, and the central donor cornea was kept free of inflammation (Fig. 9).

### Case report

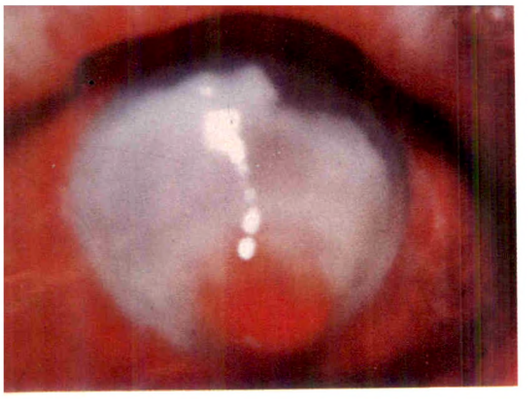
Patient 9 was a 53-year-old Caucasian woman. She had a resolved pseudomonas corneal ulcer (Fig. 9-B), morphologic classification 4+. Before keratoplasty she was transferred to the pulmonary therapy service to increase her vital capacity for general anesthesia. During this period (approximately three weeks), ocular medication was discontinued.

When she returned to the eye service, she was inadvertantly taken to surgery without being recultured for pseudomonas. An 8.0 mm penetrating keratoplasty with partial iris excision was performed. The donor cornea was secured with 16 interrupted 8-0 virgin silk sutures. Postoperative medication, started two days after surgery, included hourly polymyxin B and topical corticosteroid four times daily. By the fourth postoperative day, a suture abscess was diagnosed in both recipient and donor corneas in the eight o'clock meridian (Fig. 9-C). Conjunctival cultures were taken, serum drawn for immunologic evaluation, and the patient immediately started on twice daily subconjunctival corticosteroid injection as well as hourly Polysporin drops. Pseudomonas was identified on culture, and IgM deficiency (80 mg/100 ml) noted on immune globulin determination. The area of suture abscess rapidly contracted so that by the ninth postoperative day it was limited to the suture tract. Cultures were negative at this time. Therapy was decreased to hourly corticosteroid drops and Polysporin four times a day. The patient demonstrated an uneventful course thereafter. Following suture removal, she demonstrated a clear graft (Fig. 9-D).

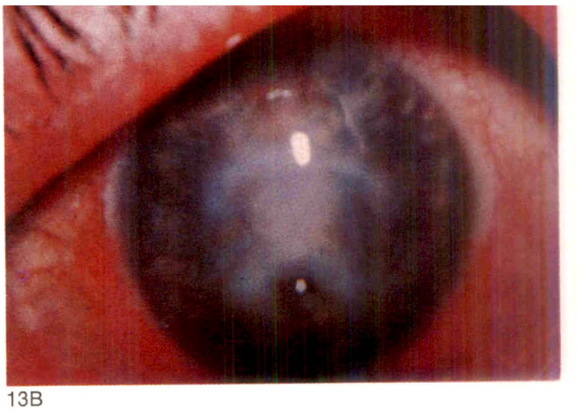
TABLE 20

INCIDENCE OF PATHOGENIC MICROBIAL DISEASE IN EARLY GRAFT PERIOD

| Entity | Cases | Successful Results | |
|---|---|---|---|
| | | No. | % |
| Bacterial | 4 | 4 | 100 |
| Viral | 2 | 0 | 0 |
| Total* | 6 | 4 | 67 |



* Of 163 patients, six demonstrated pathogenic microbial involvement, an incidence of <37%.



Viral infections were more difficult to diagnose during the early period. In two graft patients, a recurrent herpes simplex infection was demonstrated by electron microscopy in the donor graft during the early graft period. Both cases had progressed to early graft failure. In all, we have identified six microbial infections during the early graft period (Table 20). All bacterial cases were successfully treated, while known viral cases went on to graft failure.

The role of nonpathogenic indigenous microbes was evaluated because of the continued

TABLE 21

INFLAMMATION PRODUCED BY NONPATHOGENIC MICROBES FOLLOWING KERATOPLASTY

| Nylon Suture Pattern | No Reaction | Infiltrate | Neovascularization | Total Cases |
|---|---|---|---|---|
| Interrupted | 1 | 27 | 23 (45%) | 51 |
| Continuous | 6 | 7 | 4 (24%) | 17 |
| Total | 7 | 34 | 27 (40%) | 68 |

occurrence of suture tract infiltrates with occasional neovascularization in some patients sutured with interrupted nylon. This reaction did not have a direct effect on graft failure in the early period; however, it could have had a role in predisposing to delayed graft reactions. Such an indigenous bacterial reaction occurred in case 10; several sutures had to be removed to arrest formation of suture tract infiltrate and neovascularization.

### CASE REPORT

Patient 10, a 56-year-old Caucasian engineering executive, experienced continual inflammatory recurrence of his atopic keratitis during the past 34 years. In the last exacerbation, his visual acuity fell to less than 20/200 and did not improve after inactivation of the inflammatory episode. Morphologic classification was 3+. An 8.0 mm penetrating keratoplasty was performed, using a single running 10-0 Ethilon suture, and four Ethilon stay sutures. The stay sutures were removed at seven days. In the second postoperative week, there was a slight persistent wound leak at the temporal graft margin so that three interrupted Ethilon sutures were placed between 2:30 and four o'clock. The subsequent clinical course was so benign that dosage of the corticosteroid drops was reduced to two times a day. By the seventh postoperative week, an interesting phenomenon had occurred: The interrupted sutures showed inflammatory infiltrate in the area of the knot extending along the suture tract and new vessel formation leading up to these sutures. The continuous suture in the same area was entirely free of inflammatory signs (Fig. 9-E). A break in epithelium with pooling of fluorescein was noted adjacent to the interrupted suture knot; the continuous suture showed no evidence of staining along its course. Conjunctival culture revealed a prolific growth of Staph. epidermidis with an occasional diphtheroid, but no pathogenic bacteria were present. After the interrupted sutures were removed, the infiltrates disappeared and the new vessels involuted (Fig. 9-F). The continuous suture was removed at four months; the patient has achieved 20/20 visual acuity with a corneal contact lens.

The extremely low incidence of graft failure in nylon suture cases, whether interrupted or continuous, negated the usefulness of the "success-failure" criterion for evaluating this reaction. This necessitated the formulation of other criteria for determining indigenous bacterial toxicity. These are: (1) infiltrate and (2) neovascularization of the suture tract, as well as subjective patient response. These phenomena occurred more frequently when interrupted sutures were used (Table 21). As already noted in case 10, the reason for this difference can be readily demonstrated with fluorescein staining. An epithelial hole is made each time an interrupted suture is tied, while only a single epithelial defect is produced with continuous suture. These epithelial breaks appear to serve as "portals of entry" for toxic or im-

←

Fig. 14 (Moore and Aronson). Delayed graft reaction. (A) Patient 12, clear graft eight and one-half months following penetrating keratoplasty. (B) Same patient, now demonstrating traumatic delayed graft reaction following cataract extraction. (C) Same patient, subsequent clear graft after penetrating keratoplasty. (D) Patient 2, demonstrating exogenously induced delayed graft reaction (limbal type) 15 months after penetrating keratoplasty (clear graft is shown in Fig. 13-D). (E) Same patient, demonstrating severe corneal ulceration following secondary infection with Staph. aureus. (F) Same patient, demonstrating subsequent clear graft four and one-half months after surgery. (H) Same patient, demonstrating endogenously induced delayed graft reaction.

munogenic stimuli from the indigenous agent.

A distinct tissue incompatibility reaction proved extremely difficult to identify. We had only one case of graft failure in which we could rule out all other variables and speak specifically of tissue incompatibility. Theoretically, an incompatibility reaction of limbal origin would show a uniform reaction throughout the entire graft. A reaction of uveal origin would demonstrate a predominantly anterior chamber response involving primarily endothelial destruction.

Patient 11 has been included as an example of early graft reaction, even though the reaction was not identified until seven months after surgery. This outpatient failed to return for further follow-up after slightly over three months while his continuous nylon suture was still in position. He discontinued his coricosteroid medication approximately four and one-half months after surgery and first noted visual blurring shortly thereafter.* His graft failure occurred when corticosteroids were discontinued, which led us to conclude that his graft reaction originated in the early graft period. This reaction satisfies the postulated characteristics we believe a tissue incompatibility reaction should demonstrate during the early graft period; because of this we included his case history in this chapter.

* By definition, this case should be considered a delayed graft reaction and is so classified in appropriate tables.

### Case report

Patient 11, a 38-year-old Caucasian man, was an unemployed forger with history of a moderate alkali burn in his right eye two and one-half years before surgery, morphologic classification 3+. A 7.5 mm penetrating keratoplasty was secured with continuous nylon suture. The patient's postoperative course was relatively benign. When last seen, approximately 12 weeks postoperatively, he demonstrated a clear graft and was on corticosteroid drops two times a day.

When next seen, approximately seven months postoperatively, he demonstrated a markedly hazy graft throughout its entirety (Fig. 9-G). The central cornea was thickened by infiltrative edema. Of particular interest was the pattern of neovascularization of the cornea. Both superficial and deep vessels entered the cornea *between suture tracts* (Fig. 9-H), indicating that suture or exogenous toxicity did not produce this neovascularization.

On careful questioning, it was learned that the patient "had to leave the state" shortly after the 12th postoperative week "because the bunko squad was after me." He had continued using his corticosteroid drops until he ran out of them, approximately four and one-half months following surgery. Within 10 days of his discontinuance of topical corticosteroid drops, he noted photophobia and cloudy vision in the eye that was operated upon.

We started hourly topical corticosteroid drops and three times weekly subconjunctival corticosteroid injections in an attempt to see how much graft clearing would result. However, he again disappeared from follow-up.

## RESULTS

Several operative variables predominate in the early graft period which distinguish it from the remainder of the graft natural history. Perhaps the prevalent characteristic of each of these variables in this period is its acute inflammatory nature. Physiologic failure of the donor cornea is an acute process manifested within the first several weeks after surgery. The effects of surgery, whether mechanical or inflammatory, are clearly evident by the third postoperative week. Removal of the silk sutures 12 weeks after surgery mitigates this reaction. Microbes and the exogenous environment can exert their most devastating effects during this time, probably because the epithelium is incomplete and the wound not completely sealed. Finally, if tissue incompatibility is a crucial factor, the reaction is most likely to be acute during this period, as with other grafted organs.[1-3] Each of these acute reactions can operate separately or synergistically to produce graft failure. Because of this, the greatest number of graft failures occurs during the early period. With the passage of time, the ocular structure becomes normalized, and graft failure becomes less frequent.

Because of the high incidence of graft failure during the early period, we have emphasized intensive therapy during this time: corticosteroid to suppress inflammation, antibiotics to suppress exogenous microorganisms, nylon suture to prevent suture toxicity, and careful postoperative observation to ensure that irreversible graft damage does not occur. The early graft period terminates with removal of the sutures, so after this time follow-up care can be somewhat more relaxed.

*Primary donor failure*—This reflects, postoperatively, the limitations inherent in the selection of physiologically competent donor corneas. In general, we followed the precepts of Kaufman and others[4,5] in selecting donor corneas. By precluding the selection of corneas from donors over the age of 60, we hoped to have eliminated most endothelial problems related to aging.[6,7] Similarly, by using eyes as soon as possible after death, the effects of time and temperature should be reduced.[8,9] Corneal viability was evaluated preoperatively by biomicroscopic examination of the tissue. Obviously, evidence of edema, scarring, or endothelial change disqualified a donor cornea. There was one case of acute donor failure in 163 penetrating keratoplasties, an incidence of approximately 0.7%. This failure was recognized rapidly, and the patient was regrafted with relatively little morbidity in the second postoperative period (case 1). Ideally, this episode could have been avoided. However, the problem posed by such a donor failure is not particularly severe and, as in case 1, can be easily rectified. Although it would be preferable to have a more effective technique to evaluate the physiologic state of donor tissue, as has been suggested by others,[10,11] we believe that the relatively simple protocol followed in this series adequately eliminates nonviable donor corneal tissue. Less selective criteria (e.g., using eyes from patients of any age or for prolonged periods after death) would necessitate a more sensitive technique for evaluation of donor physiology.

To evaluate surgery as a variable, a single, standardized procedure had to be used in all cases until a series of adequate size was accumulated, after which any change in technique could be compared with the original procedure. To standardize this procedure, one of us (T.E.M., Jr.) either performed or assisted at the surgery in every case in the series and closely controlled postoperative management. This supervision ensured quality control throughout the course of the series. The comparative study between private and resident surgery reveals no significant difference in results (Table 15).

*Mechanical problems secondary to surgical inconsistency*—These problems occurred more frequently in the first chronologic surgical period (1965–67), became less frequent in the second period (1967–68), and were ex-

tremely infrequent with the adoption of nylon suture (Table 14). The rate of surgical complications closely parallels the graft success rate during these chronologic periods. In the first and second periods, while silk sutures were used, it seems likely that technical proficiency of the surgical team improved. However, the sharp increase in success rate when nylon suture was introduced implicates the suture as the more significant variable in these results.

The incidence of inflammation has been correlated with the extent of the surgical procedure performed (Tables 16 and 17). In general, the severity of the intraocular surgery had little effect on the outcome of the graft itself. (When limited to the nylon suture group, however, all three failures were in the group undergoing the most extensive surgery). When the type of procedure is compared with other ocular complications, the simple keratoplasty demonstrated the lowest number of non-corneal complications. However, overall visual acuity was approximately the same in the patients undergoing penetrating keratoplasty alone and those in whom the procedure was combined with cataract extraction (56 vs 61%). Of nine cases undergoing subsequent cataract extraction, three experienced some degree of endothelial disruption which led to graft failure. This observation, coupled with the high rate of success for the combined procedure, supports the contention that the combined procedure is preferable when cataract is present.[12,13]

There was a much higher incidence of complications when keratoplasty was combined with anterior chamber revision. These eyes frequently presented with severely altered internal and external structure and elevated intraocular pressure: eight of 17 eyes had vision-reducing disease. The high complication rate may be a manifestation of the initial disease—e.g., 12 eyes had suffered corneal perforations before surgery. Generally speaking, variation in surgical procedure had relatively little effect on the eventual outcome of the graft. However, eyes which had undergone extensive intraocular surgery demonstrated an increased incidence of intraocular complications.

*Suture toxicity*—Of all the variables evaluated within this series, suture toxicity appeared to be the most important single cause of graft failure. As noted in Table 19, when 10-0 Ethilon suture was used routinely, early success rates for all grafts improved from 81 to $> 95\%$. This change was not particularly pronounced in the cases with good prognosis, where success rates improved from 92 to 100%, but was markedly pronounced in the group with poor prognosis, where success rates increased from 73 to 93%.

Two individual cases demonstrate this difference in degree of suture toxicity, where interrupted 8-0 silk, 9-0 silk, and 10-0 nylon sutures were used alternately in suturing the donor button (Fig. 8-E and F). The reaction was considerably more severe to silk suture than to nylon. This type of experiment has been undertaken by other investigators[14,15] who reported similar results.

The emergence of suture toxicity as such an important factor in graft failure prompted us to determine the nature of suture toxicity. In a series of sequential in vivo studies,[16,17] we demonstrated the toxic nature of silk suture and the relatively inert characteristic of the nylon suture. In our initial experiments in rabbits, nylon suture appeared less toxic than the other sutures tested (8-0 silk, 9-0 silk, and 7-0 collagen); however, toxicity was noted with time. It appeared that the origin of this inflammatory reaction was the indigenous (nonpathogenic) bacteria of the conjunctival sac, with the suture tract providing an entrance to corneal stroma.

To confirm this inflammogenesis, the same experiment was repeated in germ-free guinea pigs. All sutures were tested again in guinea pig corneas, and this time there was no evidence of suture toxicity for 10-0 Ethilon.[17] However, some degree of toxicity was demonstrated in all other sutures.

Although silk suture toxicity was de-

quiescent, evidence for its past activity was sometimes hard to detect. Disagreement occurred most frequently in these groups.

Difficulty in separating 3 and 4+ cases led us to adopt a supraclassification which cancelled out the described error. Thus, morphologic groups were combined into good and poor prognosis categories. The good prognosis group (0, 1A, 1B, and 2+) at most demonstrated mild neovascularization and mild intraocular involvement. The poor prognosis group (3 and 4+) showed severe neovascularization and severe intraocular involvement. Classified in this fashion, overall early graft success rates were appreciably better in the good prognosis groups (95%) than in the poor prognosis groups (82%). This proved to be a very significant separation when statistically evaluated by discriminant function.

In summary, the clinical and morphologic classification appears to offer a relatively accurate severity gradient of structural alteration in the recipient cornea. By circumscribing other parameters which are difficult to grade (e.g., etiology), a high degree of reproducibility can be achieved. Correlation between morphologic group and prognosis proved to be extremely accurate.

Etiologic classification proved more difficult. Diagnosis was reasonably accurate for herpes simplex, herpes zoster, bacterial ulcers, aphakic bullous keratopathy, and keratoconus; however, such categories as idiopathic stromal keratitis and chemical or physical keratitis are markedly heterogeneous. This variation becomes particularly pronounced in evaluation of morphologic severity of the lesion. While most herpes simplex keratitis patients who go on to keratoplasty fall within the 3 or 4+ morphologic category (Table 3), patients with idiopathic stromal keratitis ranged from 2 to 4+ and those with chemical and physical injuries range from 1 to 4+. In our opinion, this classification does not adequately describe disease severity. Instead, these categories reflect the morphologic severity produced by a particular etiologic agent. In herpes simplex, seven of eight graft failures were in the 4+ category, while the eighth was in the 3+ category. Similarly, all interstitial stromal keratitis and chemical or physical trauma graft failures were in the 3 or 4+ groups. The 2+ cases with each of these diagnoses always resulted in successful grafts. Therefore, it would appear that the principal value of etiologic diagnosis for these groups lies in the morphologic severity which a particular etiologic agent has produced.

The question must be raised whether any etiologic category has usefulness as a subcategory within the morphologic scheme. Initially, aphakic bullous keratopathy was separated from the remainder of 1+ diagnoses because (1) distinct evidence of previous intraocular inflammation was identifiable, and (2) success rates seemed to be lower than in the 1A+ and 2+ categories. On close analysis, however, all early 1B+ graft failures occurred within the first surgical period (Table 14) in which silk suture was used. The most recent 21 cases have all resulted in early graft success, so that it seems likely that the 1B+ subdivision may not be justified.

A similar circumstance arises in chemical and physical keratitis. Generally, the prognoses given for the chemical keratitises have been poor, much worse than for any other category.[30,31] Overall, early graft results have not supported this (Table 9). If severe alkali cases are separated from the series, our results still do not bear this out. (In this circumstance, our results are six successes out of seven in the early period.) Pretreatment with heparin, which appears to revascularize ischemic zones, combined with high-dosage topical corticosteroid therapy, appears to enhance the chance for graft success. With time, however, alkali keratitis patients seem to be prone to delayed graft failure.

Although etiology is of less value than morphologic classification for graft prognosis, in the event of infectious etiology it is necessary for selection of appropriate, spec-

ific pre- and postoperative medication. As already noted, patients were treated specifically for each infectious agent identified during the early graft period. The antimicrobial agent is not discontinued until sutures have been removed and the epithelium is completely intact. The reason for this is culture evidence that certain individuals show a predilection for recurrence of specific bacteria or virus when antimicrobials are discontinued, e.g., herpes simplex, staphylococcus, and pseudomonas.[32-35] Also, corticosteroids probably allow enhancement of microbial proliferation.[36,37] This combination of events in the presence of altered structure could lead to a severe inflammatory response (as in patient 9).

Measurement of early IgG appeared to be particularly useful as a prognostic index to the severity of inflammation which could be anticipated in a forthcoming graft procedure. As Table 10 indicated, this correlation was more valuable in conjunction with the clinical and morphologic classification. Total IgG correlation with inflammatory response was less exact. Other immunologic factors were unrelated to graft-induced inflammation.

Since adopting early IgG as a therapeutic index for prospective graft patients, a group of selected patients have not been preoperatively treated with corticosteroid. The overall results in this selected group of patients are similar to those in the series that was treated prophylactically (Table 12). Statistical evaluation by discriminant function revealed prognostic significance for early IgG in silk suture cases during the early graft period (Table 22). When analysis is made on all cases (silk and nylon), prognostic value of early IgG during the early graft period is no longer statistically significant (Table 23). This is readily reflected by the number of early graft failures encountered when nylon suture is used; whereas 18 cases failed with 8-0 virgin silk, only three cases failed when nylon was used. Undoubtedly, the employment of nylon suture has allowed cases to succeed which would have failed with silk.

The exact function of early IgG is un-

known. At the time of our initial report,[38] we believed that IgA may also have been involved. Subsequent findings have indicated that only the early zone of IgG is related to graft prognosis.[39,40] In the past, we hypothesized that the early range of IgG may represent a measure of overall subclinical inflammation within the body, whereby in such persons, serum levels would be diminished because of molecular binding of the early IgG molecule at the site of inflammation. Currently, this is the only plausible explanation we have for the correlation between reduced early IgG and prospective graft-induced inflammation.

In conclusion, certain aspects of these studies have led to revision of our methods of procedure. While methods of patient selection and selection of donor corneas remain unchanged, several other factors have changed, and these are as follows:

*Selection of surgical procedure*—A penetrating keratoplasty is preferably between 7.0 and 8.0 mm in diameter. The extent of intraocular surgery is now dictated by the conditions encountered at surgery. If a cataract is also present, a combined procedure is undertaken.

*Sutures and suturing technique*—Four interrupted 10-0 nylon sutures are placed at three, six, nine, and 12 o'clock, and these are removed one week postoperatively. A continuous 10-0 nylon suture is tied in the 12 o'clock meridian, well away from the donor cornea and the cut ends are inserted either beneath bulbar conjunctiva or into corneal stroma and allowed to remain in position for 16 to 20 weeks.

*Corticosteroid therapy*—Prophylactic use of corticosteroid is determined by the immunomorphologic table (Table 4). The corticosteroid protocol remains unchanged.

Antibiotic therapy, the use of mydriatics, and postoperative care remain unchanged. Patients are given either a spectacle correction or a corneal contact lens,[41] and are followed according to the described postoperative schedule.

Once again, we should emphasize that while this is our current protocol, it is subject to change as we gain more experience with the penetrating keratoplasty.

As already noted, delayed graft reactions are divided into mechanical or inflammatory types. The mechanical reaction, related to surgery, requires a secondary event which interferes with the normal physiologic processes of the corneal endothelial cell. In our experience, cataract surgery has most often led to this phenomenon.

In our case 12, described below, the patient had a relatively uneventful postsurgical course. However, nine months after the initial keratoplasty, a lens extraction was performed. Following this, the patient developed epithelial edema superiorly which gradually went on to involve the entire visual axis (Fig. 14-A and C).

### Case report

Patient 12 was a 58-year-old Italian American man, first seen and treated for active herpes simplex stromal keratitis approximately four years earlier. An initial penetrating keratoplasty was performed after inactivation of the herpetic infection, and a clear corneal graft was achieved (Fig. 14-A). Nine months following this graft, an intracapsular cataract extraction was performed. At the time of surgery, the lens capsule forceps inadvertently rubbed the endothelial surface of the cornea. Following surgery, a zone of corneal edema was present which was not responsive to corticosteroid therapy. This localized area gradually progressed to involve the entire donor cornea; following this, secondary neovascularization occurred (Fig. 14-B). A subsequent penetrating keratoplasty was successful, and the patient achieved >20/25 visual acuity with a corneal contact lens (Fig. 14-C).

In reviewing this case, the pathogenetic sequence was traumatization of donor endothelium produced by entering the anterior chamber with capsule forceps. Surgery subsequent to keratoplasty must be extremely meticulous, with every effort being made to avoid contact with donor endothelium.

The inflammatory cases comprise two general types, either of which can progress to graft failure. Patient 2, already described, experienced a severe "cold" 15 months following keratoplasty; visual blurring occurred in the grafted eye, but the patient did not seek medical aid for nine days following this event. Despite high-dosage corticosteroid therapy, delayed graft failure could not be reversed (Fig. 14-D through F).

### Case report

Patient 2 retained a clear corneal graft for 15 months. A cataract was extracted at six months (Fig. 13-D). During the 15th month, he presented with loss of vision of approximately 10 days' duration. This occurred during the Asian flu ($A_2$) epidemic of 1968, and the patient complained of severe upper respiratory symptoms as well as "itchy" eyes.

On ocular examination, he demonstrated bilateral follicular conjunctivitis with acute congestive changes superimposed upon his bulbar conjunctiva. His cornea was markedly inflamed, showing engorgement of vessels in the host cornea and dense inflammatory infiltration of the donor cornea (Fig. 14-D). The opposite eye demonstrated follicular conjunctivitis and fine epithelial stippling of the cornea. The patient also demonstrated an acute pharyngitis. He was immediately hospitalized and started on hourly topical and daily subconjunctival corticosteroid injections. After one week of this therapy, he demonstrated some stromal clearing; however, he showed persistent epithelial edema, indicating endothelial destruction. The patient was continued on corticosteroid for another week, at the end of which time corticosteroid was discontinued and he was classified as a delayed graft failure.

When next seen (approximately eight months later), the graft had become secondarily infected with Staph. aureus, and he demonstrated severe inflammation with ulceration of donor graft tissue (Fig. 14-E). This was controlled with topical Neosporin and corticosteroid therapy. The patient was regrafted and maintained a clear graft for eight months following surgery (Fig. 14-F). He again reported to the clinic with severe opacification and neovascularization of both the donor and host corneas. On questioning, he stated that he first noted visual blurring two and one-half weeks earlier. He demonstrated a prolific growth of Staph. aureus on conjunctival culture. At present, he is receiving topical Neosporin and corticosteroid therapy.

This case followed the corneal pattern of inflammation—i.e., both in the central spreading of the limbal inflammation, and the presentation of the inflammation as keratoconjunctivitis.

The uveal pattern of inflammation is demonstrated in patient 13. The patient presented with an acute iritis in one grafted eye. The involved left eye was blind and served as an autograft donor to the opposite right eye; the left eye was simultaneously allo-

TABLE 24

TREATMENT SUCCESS IN DELAYED GRAFT REACTIONS

grafted. Because her blindness interfered with the recognition of symptoms, the patient did not present for therapy for several weeks after the corneal reaction started. By then, permanent endothelial change had occurred and could not be reversed with corticosteroid therapy (Fig. 14-G through H).

CASE REPORT

Patient 13 was a 51-year-old Caucasian woman with history of congenital cataract and blindness of more than 10 years' duration. Ocular examination revealed a blind left eye secondary to a retinal detachment with a clear cornea and a severely scarred right cornea. Both eyes demonstrated searching nystagmus.

Combined penetrating autograft (left to right cornea) and allograft (to left cornea) were performed using interrupted 8-0 virgin silk suture. Both grafts were successful (Fig. 14-G). The patient showed periodic bouts of inflammatory infiltrate into the inferonasal margin of the right autograft and was treated with topical corticosteroid. During one such period, she suffered a severe upper respiratory infection (URI). About two weeks after the onset of this attack, she noted that her blind left eye was injected and painful and she then presented for treatment. The left eye showed a marked papillofollicular reaction of the bulbar conjunctiva, ciliary injection, a hazy edematous cornea, and a 3+ iritis. Dense KP were noted on the posterior corneal surface (Fig. 14-H). The right conjunctiva demonstrated a fine follicular reaction; the cornea and anterior chamber remained free of inflammatory disease. The patient was using prednisolone acetate 1% drops four times a day in this eye. Hourly topical corticosteroid drops and daily subconjunctival corticosteroid injections were started to the left eye and continued for one week, the drops being continued for a second week. The iritis resolved rapidly, with disappearance of the KP. However, the endothelium must have been compromised, for epithelial and stromal edema remained. Since the eye was blind, a second keratoplasty was not contemplated. The patient was seen at regular intervals to prevent superinfection of this cornea.

Frequently, delayed graft reactions could be treated successfully (Table 24); 75% of delayed reactions were reversible with topical and subconjunctival corticosteroid therapy. Patient 14 demonstrates exogenous origin of disease in which the patient presented soon after the onset of ocular signs. Intensive corticosteroid therapy reversed his delayed reaction with a good visual result (Fig. 15-A through D).

CASE REPORT

Patient 14 was a 27-year-old Chilean man with a history of stromal keratitis following a thermal injury. Following a total lamellar keratectomy to remove a pseudopterygium, morphologic classification was 3+. A penetrating keratoplasty was performed using 8-0 virgin silk suture with a successful result. Visual acuity was 20/25 corrected with a corneal contact lens (Fig. 15-A).

Nine months after the keratoplasty, the patient presented complaining of blurred vision. He demonstrated an acute congestive conjunctivitis bilaterally. Culture revealed a prolific growth of Staph. epidermidis. The left eye showed marked vascular engorgement of the temporal vessels in the recipient cornea, with extension of infiltrate into the donor graft. The donor graft demonstrated inflammatory edema throughout (Fig. 15-B).

The patient was immediately started on topical and subconjunctival corticosteroid, the latter being given every other day for one week. After 11 days of hourly medication, he showed marked improvement (Fig. 15-C) and by three weeks the eye appeared clear; medication was then tapered to one drop a day. Four months after this episode, visual acuity returned to 20/25 (Fig. 15-D).

One year later he experienced another episode of blurring and immediately flew to San Francisco for evaluation. This time, he demonstrated an acute exudative conjunctivitis (left eye more severe than the right eye). Staph. aureus grew on culture. The corneal involvement was limited to the area adjacent to vascularization of the host cornea. Combined topical and subconjunctival corticosteroid resulted in a rapid remission. The area of vascular origin in the recipient and graft was attached to the palpebral conjunctiva by symblepharon. It was decided to sever this adhesion surgically with the expectation that the vessels in the host cornea would involute and no longer predispose the eye to delayed reactions.

Patient 15 provides an example of a grafted eye that had attacks of recurrent uveitis for several years. She presented with an acute iritis and marked graft edema secondary to KP which cleared rapidly on topical and subconjunctival corticosteroid therapy (Fig. 15-E through H).

### CASE REPORT

Patient 15 received a penetrating keratoplasty for severe herpes simplex stromal keratitis with perforation, morphologic classification 4+ (Fig. 15-E). Following surgery, she had a successful result with a clear donor graft (Fig. 15-F). However, because of a mature cataract, vision was unimproved.

Five months following her keratoplasty, she experienced pain and redness of her eye with a concomitant severe URI. Ocular examination revealed bilateral follicular conjunctivitis, more severe on the right side. The right eye demonstrated limbal injection and edema of the donor graft. A moderately severe iritis was noted in the anterior chamber with 2 to 3+ cellular reaction (Fig. 15-F). The opposite eye showed fine epithelial stippling of the cornea.

The patient was started on topical and subconjunctival corticosteroid for one week and demonstrated a dramatic improvement. The anterior uveitis cleared rapidly; in two to three weeks, the graft cleared completely (Fig. 15-H). Three months later, her lens was extracted; visual acuity was >20/30 with a corneal contact lens (Fig. 15-H).

The variable which principally influences success or failure in a delayed graft reaction is duration of inflammation prior to therapy (Table 25). If patients presented within 24 hours of inflammatory onset, delayed graft reactions could be routinely reversed, with good visual results. When presentation was within seven days of onset, in 94% the process was reversible; however, after inflammation had been present for more than a week, the prospects for reversal became extremely poor (50%). Of particular interest is the fact that in six patients who experienced two or more attacks, but who presented immediately after inflammatory onset, the process could be reversed. However, when treatment was delayed for one to two weeks, grafts went on to failure. It is difficult to determine exactly how long inflamma-

* Delayed graft reactions were demonstrated by 12 patients with herpes simplex; in only two of these patients could recurrence of herpes simplex virus be identified by electron microscopy.

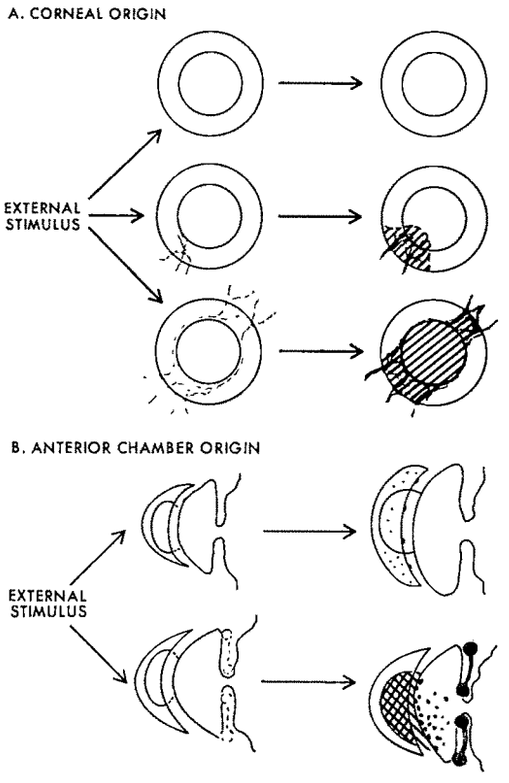

Fig. 16 (Moore and Aronson) Pathogenesis of the delayed graft reaction. (A) Corneal origin. (B) Anterior chamber origin.

tion can remain untreated without resulting in permanent endothelial decompensation. Undoubtedly, there is some degree of individual variation, but the critical time in this study was approximately seven days.

Factors which may predispose to delayed graft reactions are (1) an adequate stimulus, (2) variation in host response, and (3) severity of structural alteration.

In attempting to evaluate the origin and nature of the stimulus which provoked the recurrent inflammatory episode, we were able to identify a series of different etiologic agents (Table 26). The traumatic causes were easily classified into surgical (intraocular) and other (extraocular) trauma. The former produced graft failure, but the latter may not. The inflammatory delayed graft reactions have been divided into exogenous and endogenous stimulus pathways. The exogenous group again subdivided into bacterial (pathogenic and indigenous), viral (herpes simplex and upper respiratory infections, and nonreplicating topical allergens). Endogenous inflammations presented initially as uveitis; etiology for these attacks was seldom identified, although almost every episode followed a systemic illness. Finally, a small group of cases, apparently of exogenous onset and of unkown etiology, have been identified as idiopathic. All delayed graft failures in this group occurred in patients with chemical injuries. Strong criteria for diagnostic relationship were present

TABLE 27

ROLE OF STRUCTURE IN DELAYED GRAFT FAILURE

| Grand Total | 129 | 42 | 33 | 16 | 12 |

in all but the group in which history and other clinical evidence of upper respiratory disease served as bases for diagnosis. Five of the six patients in the idiopathic group demonstrated some degree of corneal vascular insufficiency, which probably explains the graft failure. In no case, however, were we able to demonstrate a delayed reaction solely attributable to tissue incompatibility.

Immunologically, patients with delayed graft reactions and delayed graft failures showed some increase in IgG, early IgG, and IgM, when compared with the nonreacting patients (Table 7). However, this increase could not be interpreted as a significant change. Similarly, protein electrophoresis and qualitative electrophoresis showed no particular abnormalities in patients with these groups. Since no hypogammaglobulinemic patients were identified in these groups, it would appear that immune competence is required in order to produce a delayed graft reaction.

or (3) generalized (Fig. 16). The degree of postoperative structural change roughly paralleled the preoperative morphologic classification, so that a preoperative 0+ patient will frequently show little or no neovascularization of the *host* cornea; naturally, a 4+ cornea always shows severe neovascularization of the host. Correlation of preoperative classification and occurrence of delayed graft reactions reveals that the majority of reactions occurred in the proper prognosis groups (3+ and 4+) (Table 27). When structural evaluation included the postoperative recipient cornea, delayed graft reactions correlated most closely with generalized recipient vascularity. This evaluation was more useful in groups with good prognosis, since initial corneal vascularization was either superficial or absent. Of the six patients who demonstrated delayed graft reations in the good prognosis groups, four demonstrated generalized vascularization of the recipient cornea; the other two showed segmental corneal vascularization, but had experienced many attacks of recurrent iritis (Table 28). Evidence of previous uveitis also predisposed such individuals to delayed reactions of the uveal pattern (Fig. 17).

The final variable studied was the relationship of socioeconomic status to delayed graft disease (Table 29). The overall recurrence rate in the indigent population (SFGH) substantially exceeded the recurrence rate in private and UC clinic patients, 88 to 23 to 30%. Similarly, graft failure as a result of delayed reactions occurred most frequently in the SFGH population (41 to 9 to 6%). This observation may be explained by the marked delay the SFGH patients exhibited in reporting their ocular symptoms (SFGH—11 days, UC—3.1 days, private patients—2.3 days).*

* This average of reporting time includes case 13, the patient with a blind grafted eye who came for treatment two weeks after the onset of symptoms, but excludes case 11, the criminal forger, who did not return for therapy.

(B) Same patient, demonstrating an exogenously induced delayed graft reaction nine months following surgery. (C) Same patient demonstrates corneal clearing after 11 days of corticosteroid therapy. (D) Same patient four months after inflammatory episode. The cornea has cleared and visual acuity has returned to the preinflammatory level (20/25). (E) Patient 15, preoperative photograph demonstrating central corneal perforation. (F) Same patient, postoperative photograph (six months) demonstrating clear penetrating graft (G) Same patient, nine months postsurgery, demonstrating a delayed graft reaction (uveal type). (H) Same patient after clearing of delayed graft reaction and subsequent lens extraction.

monstrable in vivo, the nature of the toxic reaction still remained obscure. In the past, we demonstrated a toxic corneal reaction to acacia extract[18] in which gamma globulin and complement were bound directly by the toxic agent but not by immunologic identification, leading to an acute inflammatory reaction. Using this as a model, we attempted to evaluate qualitative gamma globulin binding by silk and nylon sutures; strands of silk suture bound more than six times the amount of gamma globulin bound by the nylon.[19] This finding indicates that suture toxicity represents nonspecific binding of gamma globulin with subsequent complement binding, which in turn feeds into the acute inflammatory pathway.[19] The differences in toxicity between silk and nylon suture can readily explain the divergence in results obtained in our human graft series.

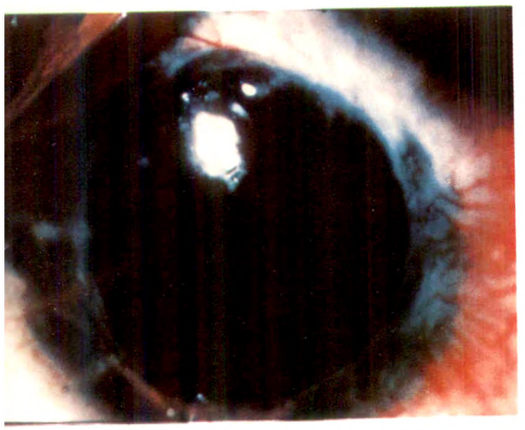
The potential hazard of the pathogenic microbe in corneal grafting has long been recognized[20,21] and probably accounts for routine saturation of the donor cornea with an antibiotic solution[22,23] as well as pre- and postoperative prophylactic antibiotic therapy.[24] The typical morphologic lesion, the suture tract abscess, correlates accurately with identification of pathogenic bacteria. It is interesting to note that this type of lesion occurs rather infrequently (in approximately 2.5% of cases) and, if recognized early, the pathologic process can be reversed with high-dosage topical antibiotic and corticosteroid therapy. As noted in our series, no cases of early graft failure could be attributed to pathogenic bacterial involvement.

The role of the virus in the early graft period is more difficult to evaluate, principally because of problems associated with primary virus isolations. In our series, primary virus isolation was attempted in only a few cases. Viral disease was usually diagnosed "after the fact" by electron microscope identification of the herpes simplex virus in failed donor or recipient tissue, or by a strongly presumptive diagnosis of herpetic endophthalmitis. (Since these were our critieria for diagnosis, it is not surprising to find that all cases with a positive virus diagnosis during the early graft period had failed.) By the criteria used, less than 8% of herpes simplex cases submitted to surgery demonstrated herpes simplex involvement during the early graft period. However, all cases suspected of this diagnosis preoperatively were treated in the postoperative period with topical IUDR and corticosteroid, and this could have suppressed virus proliferation. Evidence of other viral involvement was not present during the early graft period.

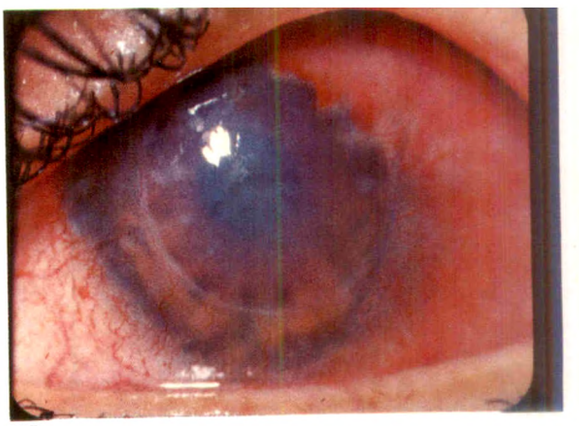
The role of indigenous (nonpathogenic) bacteria during the early graft period is of particular interest. Evidence for this toxicity reaction was based upon differences in the degree of morbidity between continuous and interrupted nylon suture cases (Table 21). The interrupted suture cases frequently demonstrated suture tract infiltrates as well as neovascularization, while the continuous suture cases showed only infiltrate at the site of the knot. This is exemplified in case 10, where both interrupted and continuous sutures were used but only the interrupted sutures demonstrated inflammogenesis. The microbes most frequently demonstrated on conjunctival culture were Staph. epidermidis and diphtheroids. We believe that the breaks in the epithelium caused by the suture serve as the "portal of entry" for bacterial or other stimuli.

This type of reaction has frequently been referred to in the literature as an irritation or irritative reaction.[25,26] The mechanism of toxicity is presumed to be the continuous movement or rubbing of the knot against the cornea. This mechanical stimulation produces corneal tissue necrosis, which sets up a subsequent inflammatory response. To refute this classic idea of irritation, we again returned to the germ-free guinea pig.[27] Animals were initially sutured with a single interrupted 10-0 nylon suture in a germ-free tank and allowed to remain in this condition for up to three months, during which time no inflammatory reaction occurred. Following this, the animals were infected with Staph. epidermidis. Within five days, severe

inflammatory signs occurred in the sutured eyes.

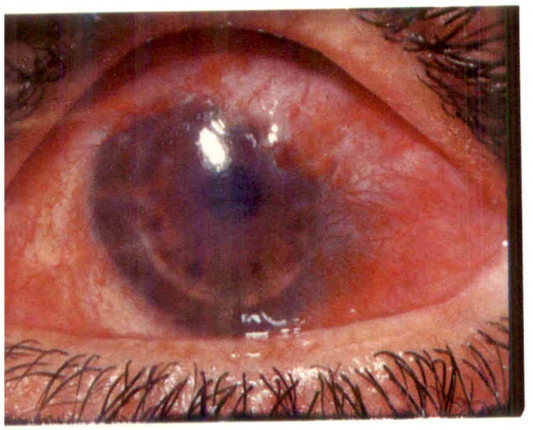


Animals' conjunctivae were recultured at this time and they demonstrated the presence of only the single nonpathogenic microbe. This experiment demonstrates the potential toxicity of indigenous bacteria under appropriate conditions of structural alteration. Indigenous bacterial toxicity, not mechanical irritation, is the most likely cause of inflammation when interrupted nylon sutures are used.

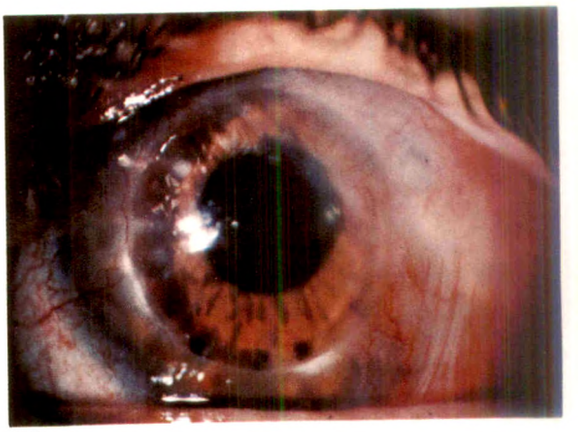


As noted earlier, we were able to identify a tissue incompatibility reaction in only one patient (patient 11). The pattern of inflammatory reaction satisfied the postulated criteria for a tissue incompatibility reaction, i.e., opacification of the cornea was relatively homogeneous and neovascularization appeared to be directed exclusively toward donor tissue. This pattern is not compatible with descriptions of other authors of the "maladie du greffon,[28]" or the homograft reaction.[29] These workers defined the earliest stages of the reaction as a cellular destruction of the endothelium with progressive edema of the cornea leading to neovascularization. This difference in interpretation is probably due to the original selection of patients in whom the pattern of graft reaction was evaluated. The homograft reaction has customarily been described in patients with nonvascularized corneas. Following penetrating keratoplasty, a majority of the inflammation is of uveal origin. Our studies have been designed to eliminate all variables before attempting to define the tissue incompatibility reaction. Since using nylon suture, we have not experienced a graft failure in a patient with a nonvascularized cornea. The tissue incompatibility reaction that we have described is for vascularized corneas where the limbus serves as the origin for the reaction.

It seems likely that we would have encountered tissue incompatibility had we not used an intensive corticosteroid regimen. Perhaps the question concerning the importance of tissue incompatibility in leading to graft failure will be clarified when we are able to identify more cases which apparently demonstrate this mechanism.



The systems of preoperative classification were designed as a measure of the degree of severity of structural change which was present in the cornea preoperatively. These severity gradients established only two morphologic signs as significant. These were: (1) neovascularization of the corneal stroma, and (2) evidence of intraocular inflammation. The latter parameter occurs only in the 1B+ and 4+ groups. The general severity gradient for vascularization is absent, superficial, and deep. Absent includes 0 and 1A+ stages, superficial is 2+, and deep is 3+ and 4+. Because vascularity was considered of principal importance when the two parameters were initially established, the possible history of intraocular structural change in the 1B+ group was overlooked and 1A and 1B were combined as a single category (cloudy cornea free of vascularization). However, subsequent studies indicated that prognosis for the 1B+ group was not as good as prognosis for the 1A or even 2+ group. This observation emphasizes the importance of previous intraocular disease. The 4+ category, the combination of severe corneal neovascularization and intraocular inflammation, is clearly the poorest prognostic group.



Reproducibility in patient classification was roughly tested by comparing the designations of each observer (the two authors). The 0+ and 1+ diagnoses were easily made and separated since one cornea was opacified and the other was free of opacity. The 1B+ was principally aphakic bullous keratopathy; in this case morphologic classification was aided by considering the patient's history. Separation between 2+ and 3+ was reasonably accurate since superficial neovascularization is easily distinguished from deep stromal vascularity. The separation between 3+ and 4+ was the most difficult. If corneal scarring and opacity were severe, the anterior chamber was frequently obscured. Similarly, if an anterior chamber reaction had become

## DISCUSSION

Our general classification divides the delayed graft reaction into two general groups, (1) inflammatory and (2) mechanical. The mechanical failure group includes principally patients who were returned to surgery after keratoplasty for a subsequent procedure, most often a cataract extraction. Within this group we had a total of four cases, all resulting in failure. In each case, donor endothelium was mechanically traumatized, giving rise to an intractable bullous keratopathy. This may have resulted from either direct instrument contact with the endothelium or manipulation of the cornea during cataract delivery. It would appear to be a factor which can be controlled by improved surgical technique. In this series, there have been no delayed failures due to trauma during the past two and one-half years, even though a greater number of postkeratoplasty lens extractions were performed (11 lens extractions, 1967–69 vs seven, 1964–67). Mechanical failure is included in this dicussion for completeness. Technical refinements should eventually eliminate mechanical failures as a cause of the delayed graft reaction.

The inflammatory delayed reactions exemplify a syndrome which has frequently been interpreted as a delayed-onset allograft reaction. Case reports in the ophthalmic literature have often analogized this reaction to the second-set reaction.[1,2] An example is the reaction which occurs in an initially grafted eye, following subsequent keratoplasty on the patient's second eye.[3] The interpretation is that the patient, who had been immunized to allogeneic corneal tissue during the initial graft, develops an anamnestic response to the corneal donor button in the second eye. The antibody so produced reacts with the initial donor cornea. (In our 12 patients with bilateral surgery this reaction has not been seen.)

Characterization of the delayed graft reaction is somewhat vague.[4,5] Most authors emphasize that only the donor cornea is involved in the inflammatory reaction, based on the fact that it alone becomes opaque. Our experience differs somewhat. The course of the reaction we saw has already been described. We shall present the pathogenetic events in sequence. There are two clinical patterns of delayed reaction: the corneal pattern predominates, accounting for over 75% of reactions. The uveal pattern, though less frequent, can also lead to graft failure. In the corneal sequence, the initial, presenting lesion is a totally inflamed cornea (Fig. 5) in which inflammatory infiltrate occurs in both donor and host, and dormant ghost vessels of the host become markedly engorged. The pattern changes if the inflammation is allowed to proceed to graft failure. Inflammation still prevails in the donor and host, but the donor cornea now demonstrates predominantly edema, an indication that the inflammatory process has involved the endothelium. At this stage the reaction is difficult to reverse; the donor cornea subsequently progresses to bullous keratopathy. Once the inflammation has resolved, either spontaneously or following corticosteroid medication, the cornea demonstrates a classically de-

Fig. 21 (Moore and Aronson). Factors leading to early graft failure in rabbits. (A) Wound dehiscence eight days following surgery. (B) Same animal with prolapse of intraocular contents 35 days following surgery. (C) Silk suture toxicity 13 days after penetrating keratoplasty. (D) Graft failure secondary to silk suture toxicity, 60 days after surgery. (E) Nylon suture free of reaction 13 days after surgery. (F) Clear graft 60 days postsurgery in which interrupted nylon sutures were used. (G) Staph. aureus abscess in a suture tract, nine days after grafting. (H) A probable tissue incompatibility reaction (pigmented donor to albino host) in which other causes of graft failure had been eliminated.

scribed delayed graft reaction, i.e., an opaque donor cornea with clear surrounding host tissue.

The clinical course of the uveal pattern parallels the corneal picture, except that the degree of corneal and limbal inflammation is greatly reduced. In the early course of this disease, the patient demonstrates a rather severe anterior chamber reaction with approximately 2 to 3+ cells and flare. KP are noted on both the donor and inferior host endothelium. As the disease progresses, the donor cornea undergoes edematous changes which may lead to bullous keratopathy. Again, the classic picture of resolution is an opaque, bullous donor cornea with old KP on its endothelial surface and a clear host. Combined corneal and uveal patterns occur frequently with a predictable, relatively ominous outcome.

The pathogenetic sequence followed by the delayed graft reaction is initially that of a severe inflammation which can destroy parenchymal cells. Theoretically, the episode is always self-limited, so that if donor tissue can survive the reaction, a good result will follow spontaneously. However, the endothelial cells of the donor cornea appear to be much more vulnerable than those of the host; these cells must be protected from the ravages of the inflammatory response. Graft failure, a physiologic failure of the cornea produced by an inflammatory reaction, occurs when endothelial cells are destroyed.

Our experience supports the contention that treatment of delayed graft reactions should be successful if the patient is seen early in the course of his inflammatory reaction. If patients are seen within an adequate time of inflammatory onset, the reaction can be reversed. The most critical aspect in therapy is suppression of the inflammatory response without regard to the etiologic agent. In our protocol, patients are immediately started on topical corticosteroid. If epithelial edema is also detected, the patient receives simultaneous subconjunctival corticosteroid therapy until inflammatory signs resolve. Inflammatory signs can be reversed even in delayed graft failures, although endothelial damage may produce bullous keratopathy.

We have treated specific bacterial or viral (herpes simplex) diagnoses simultaneously with the anti-inflammatory regimen. Following specific evidence of etiology, specific antimicrobial therapy is started and continued until cultures are negative (bacterial) or corticosteroids are discontinued (herpes simplex). This combined therapy has been effective in controlling the specific agent, but rapid resolution of the inflammation by high-dosage corticosteroid must be emphasized as the critical therapeutic objective.

Identifiable exogenous stimuli played a significant role in delayed graft reactions. Of 42 cases with inflammatory delayed graft reactions, 32 were related causally to exogenous stimuli (Table 26). The prevalent cause of graft failure was pathogenic bacteria. Each of these patients presented long after functional changes of the donor cornea had occurred.

Several categories, e.g., indigenous bacteria and upper respiratory infection virus, are questionable in relation to a defined pathogenic agent. For example, indigenous bacteria comprised diphtheroids and Staph. epidermidis, which were demonstrated in abundance on culture and have been related to disease in the past.[6,7] Undoubtedly, such microbes take advantage of structurally altered ocular vascular permeability and produce an immunogenic reaction and consequent corneal inflammation.

The URI group is diagnosed by history. The patient either demonstrates signs of upper respiratory disease or relates a history of such experience. One patient with a long history of acute spondylitis and iritis in both eyes following upper respiratory infections experienced delayed graft reactions of the uveal type during two URI episodes. The pathogenetic agent in these reactions could have been introduced either exogenously or endogenously. In exogenous disease, the vi-

rus proliferates in the conjunctiva, producing a conjunctivitis. In the structurally altered graft eye, this leads to engorgement of blood vessels in the host cornea, which increases the amount of antiviral antibody in both the donor and host corneas. Combined viral antigen and antibody produce an immunogenic inflammatory reaction. Experimentally, in eyes where the uveal structure has been altered, this immunogenic reaction may present as a uveitis. In the endogenous reaction, antigen-antibody complexes precipitate out in the uvea and provoke an immunogenic uveitis.[9,10] In this instance, the enhanced uveal vascular permeability produced by previous uveitis sufficiently increases ocular blood flow to allow systemic antigen-antibody complexes to enter the eye in adequate concentration to produce an inflammatory response.

The possibility that these reactions represent late tissue incompatibility reactions should be considered. None of the six idiopathic cases demonstrated an inflammatory stimulus, yet all showed delayed reactions, three of which proceeded to graft failure. Each of these cases demonstrated extremely heavy vascularization of the host cornea (four chemical keratitises), a circumstance which should theoretically favor a tissue incompatibility reaction.

In general terms, if tissue incompatibility were to play a role in the graft reaction, it should be during the early graft period. Those antigens which are most accessible to the host immune system—that is, the soluble antigens—should disappear rapidly in this early period. Disappearance of these antigens has been demonstrated in heterologous renal grafts and skin homografts.[11,12] It can be assumed that the donor cornea is free of soluble antigenicity in the delayed graft period. (As already noted, this type of reaction in our series has been suppressed by the corticosteroid therapy.)

In the delayed graft period, fixed antigens must be the source for antigenicity of the donor cornea, i.e., relatively insoluble antigenic loci. Such antigens probably are immunochemically related to the soluble antigens of the cornea and can cross-react with antibody to soluble antigen. Antibody or immune competent cells must now come to the donor cornea to react with the fixed antigen contained within the donor graft. This means that a second stimulus must initiate the inflammatory reaction which secondarily activates the tissue noncompatibility reaction. In theory, the experimental second-set reaction produces an anticorneal antibody which will react with donor corneal tissue. In order to gain access to fixed antigenicity, the antibody must be humoral in a clear donor cornea.

Four of the idiopathic cases have demonstrated almost continuous inflammatory reactivity throughout the course of their graft history and have required almost continuous corticosteroid therapy. Each of these cases demonstrated severe vascularization of the host cornea and may represent an example of a delayed tissue incompatibility reaction.

The other examples of delayed graft reaction have almost always demonstrated the presence of a second stimulus, e.g., exogenous microbes. We believe that these stimuli produce the inflammatory reaction which leads to delayed graft failure. However, it is possible that such exogenous reactions can ignite a tissue incompatibility reaction which in turn leads to graft failure. Differentiation of this reaction into such components is an extremely difficulty undertaking.

The significance of host responsivity was determined by a series of immunologic tests. The overall pattern in the delayed graft reaction group indicates a relatively normal distribution curve for all values tested. It is particularly interesting to note that all patients fell within two standard deviations of the normal range for all tests. The immune distribution curve was unusually tight for this population, indicating that an individual must be able to produce an adequate immune response if a delayed graft reaction is to occur.

Altered structure emerges as the most significant single variable studied in this series (Tables 27 and 28). In general, the highly vascularized host cornea or the uvea which had experienced previous inflammation apparently predisposed to a delayed graft reaction. No graft which demonstrated a delayed reaction was free of a moderate amount of structural change. The substantial correlation between pre- and postoperative corneal structural change is hardly surprising; obviously, the cornea which has once demonstrated neovascularization will demonstrate this change in the postoperative period.

The dynamic pathway by which structural change predisposes to recurrent inflammation merits comment. In rabbit corneal graft experiments,[8] grafts were allowed to subside for three months postoperatively. At the end of this period, a severity gradient of corneal structural change was established. Corneal change was classified as mild, moderate, and severe: (1) mild—only ghost vessels in the host, (2) moderate—active vessels in the host, and (3) severe—active vessels in both the host and donor. A normal cornea was one in which no surgery had been performed. Radiotagged HSA($^{131}$I) or HGG ($^{125}$I) was administered intravenously and allowed to equilibrate—the corneas were then counted for accumulated plasma. All the donors were appreciably above the normal. The moderately changed host cornea, which compares most accurately to the human cornea undergoing a delayed graft reaction, showed a marked increase in ocular vascular permeability compared with the mildly changed cornea. Subsequently, rabbits were immunized and topically challenged with several antigens. The same criteria for corneal classification were applied. The moderately reacting host corneas showed severe inflammatory reactions and progressed to delayed graft failure. The animals with mildly reacting corneas showed much less severe reactions; none progressed to graft failure.

These experiments demonstrate the interplay between exogenous stimulus and structural alteration. The vascular changes in the host cornea increase corneal vascular permeability. On challenge with a topical antigen, as in the topical immune model, an immunogenic delayed graft reaction is produced.

The role of socioeconomic factors (patient failure) in predisposing to delayed graft reaction and delayed graft failure is probably a secondary operative variable. The lowest socioeconomic group, the indigent SFGH patients, demonstrated the highest incidence of delayed graft reactions and also the highest incidence of delayed graft failure (Table 29). To avoid speculation (which may be extremely important), evaluation has been limited to quantitative factors. Of the 15 SFGH patients with delayed graft reactions, nine were known alcoholics. Few UC or private patients with reactions had a documented history of alcoholism. The sustained physiopathologic effect of alcohol on blood vessels in the host cornea leads to a prolonged vasodilation. Such a reaction has been well described. In this "morning after" response, the individual demonstrates vasodilation of conjunctival vessels—"bloodshot" eyes. Undoubtedly, such vasodilatation leads to enhanced vascular permeability, which in turn intensifies the host response to exogenous stimuli. Of the cases mentioned, five patients demonstrated bacteria in both conjunctival sacs, but only the graft eye showed corneal inflammation.

As noted earlier, the incidence of delayed graft failure is directly related to the delay in time of presentation of patients after the onset of symptoms. The percentage of graft failures during the early period was not appreciably different in the three series (Table 15). However, when patients were left to their own recognizance, graft failure occurred frequently in SFGH patients. The SFGH patients were extremely tardy in appearing for treatment following the onset of a delayed graft reaction.

When delayed graft failure occurred in

the private series, an extenuating circumstance could usually be identified, such as the failure to recognize a graft reaction in her blind eye by patient 13.

Undoubtedly, factors other than socioeconomic played a role in this predisposition toward delayed graft reaction, but such an evaluation is beyond the scope of this paper.[13]

Summarizing our discussion on the early graft reaction, we described our ideal protocol for corneal graft management during the early graft period. In theory, once sutures have been removed, the grafted eye should rapidly reach a homeostasis and remain free of active inflammation. In our ideal graft, there is only minimal structural change in the host cornea (as well as the donor), the patient is free of symptoms, and no longer requires therapy.

During long-term management of grafts, our principal goal is prophylactic: to prevent delayed graft reactions. As noted, delayed graft reactions can be predicted with some degree of accuracy by evaluating the structural status of the host cornea once it has stabilized. On this basis, patients with relatively severe structural changes are seen at closer intervals than those with minimal host vascularization. As a general rule, we attempt to see patients at monthly intervals (following suture removal) between the third and the sixth month, at trimonthly intervals between six and 18 months, and at semiannual intervals thereafter. If there is evidence of progressive structural change, they are started on a short course of corticosteroids (two to three weeks). This includes Prednefrin Forte 1% hourly between six A.M. and 10 P.M., plus a specific antimicrobial daily if indicated. As active inflammation resolves, corticosteroids are rapidly reduced, then discontinued. During active therapy, the patient is seen one to three times a week. After medication is withdrawn, the patient is followed according to the described schedule.

A small group of patients have required continuous corticosteroid therapy following keratoplasty. Dosage ranges from once a day to one drop weekly. If corticosteroid is discontinued, these patients develop inflammatory reactivity within several days. This group of patients is followed at weekly to monthly intervals to ensure that no complications have occurred. Naturally, maximal therapy is resumed should inflammation exacerbate.

Finally, it is possible for structural alteration to modify with the passage of time. For example, a patient with herpes keratitis experienced two delayed graft reactions within the first 18 months of grafting, but the eye has been completely quiet for the past two years, demonstrating marked attenuation of vessels in the host cornea. At present, we still consider such an individual to be a potential reactor. In general, all patients who have had penetrating keratoplasty have some degree of altered structure. Such patients must be impressed with the possibility that they may have a delayed reaction in the future and, to avoid delayed graft failure, they should alert us immediately to (1) blurred vision or (2) redness or pain in their eyes. If the patient is a referral from a distance, we ask the referring ophthalmologist to keep us advised of the onset and progression of the delayed graft reaction. We emphasize that any uncertainty necessitates sending the patient to us for therapy. This rigid follow-up regimen is designed to avoid delayed graft failures.

## LONG-TERM RESULTS IN MAN

A long-term graft success is defined as a corneal graft which has remained clear for nine months or longer. The longest period of follow-up in this series is just under five years, but the total long-term series is comprised of 146 cases, 129 eyes, and 121 patients (Table 30). This represents more than 95% of all patients who were operated upon; only six patients were lost to follow-up.

Long-term success was usually designated on the basis of personal observation of the patient by one of us in order to validate that the graft had remained clear. An alternative to this procedure for patients who could not return to San Francisco for long-term evaluation was a photograph (preferably slit lamp) of the clear donor button and a record of the patient's final visual acuity. Long-term failures included any cornea which became clouded or opaque.

Variables evaluated on a long-term basis included the preoperative morphologic, etiologic, and immunologic classifying criteria. Other evaluations were the degree of success achieved in regard to visual acuity; the occurrence of ocular complications, whether or not they were cornea-related; long-term effects of suture toxicity; and long-term effects of socioeconomic status on graft results.

The overall distribution of graft failures showed a definitely higher rate in the first three months, or early graft period (Fig. 17). Twenty-one of 40 failures (52.5%) occurred during this early period. The incidence of failure diminished with time. Thirteen of 19 (68%) delayed graft failures occurred between three months and one year. Only six grafts failed after the first year.

Preoperative classifying criteria have been extended to the long-term series.

Morphologic evaluation (Table 30) revealed overall success of $> 72\%$ in all cases. Broken down into subgroups, success rates were as follows: 1A and 2+: 100%, 0+: $> 96\%$, 1B+ : 71%, and 3 to 4+ : just over 60%. It is interesting to note that when cases with poor prognosis were divided into primary and multiple graft groups (Table 31), no appreciable difference in long-term success could be noted. Success improves markedly when evaluated by eyes: overall: 81%, 1B+: 100%, 3+: 69%, and 4+: 73%, respectively. Results are approximately the same for patient evaluation.

By etiologic classification, 100% success was achieved in all cases of keratoconus, familial corneal dystrophy, corneal trauma, and herpes zoster keratitis (Table 32); aphakic bullous cases: 79% success, which when corrected for eye and patient, improved to 95%;

* This includes 29 regrafted eyes, of which 21 (72%) have had successful results.

† Thirteen eyes had perforated prior to keratoplasty; eight (62%) have had successful results.

herpes simplex: 62% for cases and 72% for eyes and patients. This percentage was extremely close to idiopathic stromal keratitis, where 68% of cases and 75% of eyes and patients were successful. Bacterial ulcers and other diagnoses, both small series, demonstrated over 80% success for eyes and patients. The poorest results were in the physical or chemical agent category. Only 38% of cases were successful, a figure which remained unchanged for eyes and patients.

Immunologic evaluation for the overall series would indicate no significant difference for any of the tests evaluated (Table 33). Parameters that were useful in the early graft period were not pertinent during the delayed graft period. Added together, overall significance was lost.

The overall functional results are expressed in Table 34. Degree of success is described as symptomatic relief, some visual improvement. such as visual acuity of 20/40. Almost every patient demonstrated symptomatic improvement—for example, a perforated cornea was reconstituted and the eye was saved. More than 54% of all grafted eyes attained a visual acuity of > 20/40. On the basis of preoperative morphologic classification, the best visual results were obtained in the good prognosis categories (76%). However, a reasonably significant percentage of eyes in the poor prognosis categories (41%) also attained visual acuity of > 20/40.

As already noted, complications are divided into two general categories, those related to the penetrating keratoplasty—for example, secondary glaucoma—and those not related to the graft but occurring in eyes with corneal disease. Significant complications which have persisted as long-term ocular problems are listed in Table 18. Glau-

coma was the most frequent single complication, occurring in 13% of eyes. Other complications were less frequently seen and were relatively evenly divided. It is especially interesting to note that only five eyes (3.5%) showed long-term deterioration, intractable glaucoma, or phthisis bulbi, three finally requiring enucleation. These complications occurred most frequently in the poor prognosis categories (Table 35). As best we can determine, a vast majority of these complications were unrelated to corneal surgery, but reflect intraocular involvement simultaneous with the corneal disease process.

Long-term comparison of silk and nylon suture cases may be premature at this time because only 55 nylon cases have been followed for one year or longer. However, at

* Includes one case of graft failure secondary to subsequent surgery in each group.

the present time, only three delayed graft failures have occurred in nylon suture cases. Comparative long-term results for silk and nylon suture reveal a dramatic difference in overall success rate, 89 nylon vs 69% silk (Table 36), when cases have been comparably followed for the first year after surgery.

The final factor which should be considered in long-term results is the overall effect of socioeconomic factors on success. The incredibly high incidence of delayed graft reactions in the indigent group (SFGH) prompted us to chart long-term success rates in each patient series (Table 37). The long-term success rate for SFGH cases is 50%, as compared to 74% for private patients, and 82% for UC cases.

## DISCUSSION

Evaluation of long-term graft results should focus on accumulating data which will permit accurate preoperative prognosis. One inherent drawback to such data is the heterogeneity in time for the series. It may take a single center five to 10 years to accumulate sufficient data for a significant prospective series.

The long-term data within this report manifest the usual shortcomings of a single-center project—that is, a lack of homogeneity of the series since a majority of patients have been followed for a much shorter time interval than the longest period reported. These data merit presentation, however, because they demonstrate changes in the rate of success which occur over prolonged time intervals related to control of graft variables. We should emphasize that many larger series have been reported in which patients have been followed for a longer period of time,[1-3] but these series frequently included lamellar keratoplasty.

The criteria which we have considered over the long term include: (1) temporal occurrence of graft failure after the early graft period; the incidence of failed grafts in (2) morphologic, (3) etiologic, and (4) immunologic groups; functional aspects of long-term grafted eyes, including (5) visual acuity and (6) incidence of noncorneal complications; and finally, the effect of (7) suture and (8) socioeconomic factors were evaluated.

The distribution of graft failure with time is presented in Figure 17. A majority of cases fail in the early graft period. The number of subsequent failures appears to diminish with the passage of time. The reason for this change in rate of failure probably represents normalization of enhanced ocular vascular permeability (OVP) with time. During the early graft period a number of inflammogenic variables are operative which produce a marked increase in OVP, indicated by the redness of the eye during this period. As time passes, OVP normalizes and the rate of delayed graft reactions and failures diminishes. This is particularly evident in the patient who experienced two delayed graft reactions within the first 18 months, but has been free of recurrent inflammation for the past two years, although he was presumably exposed to the same stimuli. Apparently, neovascularized channels tend to become inactive with time, allowing OVP to return to normal, after which predisposition toward recurrent inflammation diminishes considerably.

Other factors undoubtedly play secondary roles in inflammatory recurrence. A patient is usually exposed to a stimulating agent, as in the case of Staph. aureus and herpes simplex, the patient apparently is chronically infected with the agent. (However, in this series herpes reinfection of the cornea after grafting occurred infrequently). Obviously, the degree of host response also plays a role, since no individuals below the series mean demonstrated a reaction during the delayed period. Similarly, individuals within the indigent socioeconomic class showed a predisposition to delayed reactions and failure. Each of these variables must play a role in producing inflammatory recurrence; however, they would seem to be subordinate to OVP, as expressed through structural alteration.[4]

The evaluation of long-term surgical results by preoperative classifying criteria yielded results similar to those for the early graft period. As in the early graft period, the morphologic classification was the most pertinent. Cases with poor prognosis (3 and 4+) demonstrated much poorer long-term success than those with good prognosis. This was also true for eyes. It is particularly interesting that a majority of delayed graft failures as well as early graft failures occurred in the 3+ and 4+ groups, so that long-term prognosis for these cases was decidedly worse than early results (62 vs 82%).

Results were similar in the etiologic classification system. The cases with poor progno-

sis in the etiologic classifications of chemical and physical agents, herpes simplex, and idiopathic stromal keratitis, demonstrated a higher incidence of delayed graft failure than did those with good prognoses. Once again, this was markedly improved for eyes over cases. (As already noted, the similarity between morphologic and etiologic results probably stems from the considerable overlap of the two classifying sytems.)

Preoperative immunologic classification proved to be much more meaningful in the early graft period than in the delayed graft period. Early IgG evaluation was significant in predicting graft success during the early period; however, when applied to long-term results, it did not offer prognostic utility. The reason for this loss of prognostic relevance has been partially analyzed in this discussion. It is probably related to the effect of increased OVP on the level of host inflammatory response to a given stimulus. The acute or early graft reaction represents a relatively high level of inflammatory reactivity to a stimulus which is present for a reasonably long interval. The individual who is prone to inflammation, as identified by early IgG estimation, demonstrates this proclivity for graft failure. The delayed graft reaction is a relatively short inflammatory episode in which graft failure occurs when donor endothelium has decompensated. Since the patient is not being actively treated at the time of onset, the reaction can progress to failure before treatment is instituted. It seems likely that the immunologic testing procedures are not sufficiently sensitive to prognosticate the potential reaction.

The roles of suture and socioeconomic status were evaluated because they appear to have substantial influence on long-term graft results. The suture toxicity in the long-term period may be explained by the severity of the graft reaction during the early graft period. In general, in the early graft period silk-sutured cases demonstrated more severe structural alterations than nylon-sutured cases. This observation is compatible with the demonstrated toxicity of silk suture and the markedly greater number of silk-sutured graft failures in the early period. Evidently, a certain number of cases which succeeded in the early period incurred sufficiently severe structural change to predispose them to a delayed graft reaction.

The role of socioeconomic factors in predisposing to delayed graft failure was clarified by studies of the indigent patients (SFGH), who showed an extremely high rate of failure. This observation is particularly interesting because early graft failure rates in the indigent group were virtually identical with the private and UC clinic (fixed or minimal fee) groups. On his own recognizance, the indigent patient showed virtually no concern for the care and outcome of his graft. This is evidenced by (1) the high incidence of external disease in these patients' eyes after grafting, and (2) the prolonged delay in presenting for treatment displayed by these patients despite their awareness of active ocular disease.

The inordinately high rate of delayed graft failure in this group compelled us to evaluate whether keratoplasty is justified in such a group of individuals. Although penetrating keratoplasty is an excellent therapeutic measure in a responsible individual, it represents a liability to the patient who pays no attention to protecting it. In the last analysis, such a patient is better served by a treatment which requires no patient cooperation; this usually means a conjunctival flap or, in other words, no positive effort to restore vision.

The last point of discussion will be the functional quality of the grafted eye. Overall, the corneal graft appears to offer an excellent functional prognosis. Our results (Table 34), as those of others, would indicate that in a high percentage of grafted patients excellent visual acuity ($> 20/40$) will be achieved. In cases with good prognosis, the rate of excellent visual acuity is better than 75%. Even in cases with poor prognosis, in a meaningful percentage (41%) this

level of visual acuity is achieved. The reason for this is that corneal disease cases are frequently free of other intraocular complications (Tables 18 and 35). When a complication does occur, it is usually in the anterior eye (glaucoma) and responds favorably to medical or surgical control. Altogether, only 20 eyes demonstrated intractable or incurable posterior ocular diseases such as senile macular degeneration or optic atrophy. In some cases, e.g., those with retinal detachment, excellent results were achieved following retinal surgery; in other cases—those with optic atrophy secondary to glaucoma, for example—good results would have been achieved except for the fact that there was pre-existing damage.

In general, long-term results show a decline in the rate of graft failures with time as with most surgical procedures. Two of the principal causes of delayed graft failure—suture toxicity and socioeconomic predilection—can be rectified. If this transpires, long-term graft results should reach the level of results in the early graft period.

## STATISTICAL EVALUATION

The data on penetrating keratoplasties sutured with 8-0 virgin silk and 10-0 Ethilon were analyzed by discriminant function. Details of the coding are given in Table 38. Linear discriminant analysis (as used in this study) is a mathematical method of assigning a case to one of two outcome categories on the basis of various characteristics. Categories are computed from data where the outcome is known, in order to evaluate the importance of the various characteristics in the outcome or to predict the outcome of future similar cases. In this study, the outcome under evaluation was success or failure of the transplant; early and late outcomes were evaluated separately. The other characteristics are listed in Table 38.

Discriminant analysis is based on the fact that the mean values of each characteristic are likely to differ between the two outcome groups. Analyzing the characteristics compositely, their predictive ability may be stronger than any one alone would be. The linear discriminant equation is of the form:

$$Z = a_1 x_1 + a_2 x_2 + \ldots + a_2 x_1$$

where each $x_1$ is one of the discriminating characteristics and each $a_1$ is a constant. The $a_1$ categories are selected in such a way as to maximize the difference in Z values for cases in the two groups. For each case, a Z value is computed from the x values for that case and the constant a values. If the function worked ideally, there would be no overlap in the Z values for the cases in the two groups. For example, all Z values in the first group might be between 5 to 10, while all values for the second group might be between 20 and 29 (Fig. 18).

The initial study on corneal transplants su-

tured with 8-0 virgin silk was evaluated for early and late outcome (Table 22). Only cases in which outcome data were available have been included in this study. (Where other characteristics were unknown, mean values were used as estimates.) A second study has been made on all suture cases and this study has been evaluated similarly (Table 23).

The characteristics which contributed strongly to prediction in silk-sutured cases were morphologic classification and the wound. Other significant variables included secondary membrane formation and early IgG in early results (Table 23). Significant characteristics in silk-plus-nylon sutured cases included morphologic classification, the wound, secondary membrane formation, and the type of suture used, that is, silk or nylon. Unrelated variables appeared to be significant in late outcome cases (Table 22).

The discriminant function was statistically significant at $p \leq 0.01$ for all groups—that is, the separation in the Z values for the two groups is greater than would be expected purely by chance (Table 39). Translated into percent of failures which have been misclassified, approximately 25% of failures have been missed for early outcome and 20% for late outcome. The reverse of this—that is, success misclassified as failure—has occurred much less often.

* Cases with Z values above this point would be classified as failures, below this point as successes.

## METHODS

Experimental studies in the rabbit were designed to evaluate both the early and the delayed graft reaction, as in the patient series. The significant variables in the early graft period are: (1) the surgical procedure, (2) the suture, (3) the exogenous microbial environment, and (4) tissue incompatibility reactions. Since tissue was taken immediately from young donor animals, primary donor failure did not occur. Experiments were designed so that each variable could be studied separately, then related subsequently to the other variables.

A delayed graft reaction has been defined as an inflammatory reaction involving the donor graft which occurs after the 75th postoperative day. The delayed graft reaction in the rabbit, as the reaction in man, appears to be principally related to exogenous stimuli, i.e., infection by a pathogenic bacterium. To evaluate further the role of exogenous stimuli in producting delayed graft reactions, a group of successfully grafted animals was topically challenged with immunogenic stimuli and experimental delayed reactions were produced.

The subsequent report describes the early graft reaction and the spontaneous and experimental delayed graft reaction in rabbits.

*Selection of animals*—Rabbits were selected from two breeding strains. The first, designated Horton's New Zealand White, was composed of a closed population of New Zealand White animals started in 1957 as 400 breeding pairs; no outside breeding stock was added thereafter. These animals, designated herein as albinos, were operated on when they weighed between 2500 and 3000 g. The second group, or Horton's Dutch, was purchased from a show farm and started as 200 breeding pairs in 1958. Since then, outside breeders have been added periodically, but these additions have been limited to pigmented rabbits that have characteristic "Dutch" traits, such as similar coat markings and dark eye pigmentation. These animals will be referred to as pigmented. They were operated on between 1500 and 2000 g in weight.

The total number of animals used in these experiments was considerable, probably numbering more than 350 animals. They were divided into seven experimental recipient groups as outlined in Table 40.

*Selection of donor grafts (allografts)*—The donor rabbit, whether albino or pigmented, was killed immediately before surgery. We attempted to use a single donor for two recipient allografts. No longer than two hours elapsed before the corneas were used. Donor corneas were selected from eyes free of corneal disease as determined by microscopic examination.

*Autografts*—Rotational autografts (180°) were performed on the second eye of each animal to serve as tissue histocompatibility control.

*The surgical procedure*—The first 100 animals were anesthetized with pentobarbital (about 15 mg/kg for induction). Since each animal underwent two surgical procedures, an indwelling venous catheter was used to facilitate periodic injection of anesthesia. Despite this precaution, more than 25% of the animals died in the immediate postoperative period. A gas inhalant (Metafane) was adopted for anesthetizing the remaining animals in a closed gas recycling system, so that the depth of anesthesia could be better controlled than it had been with pentobarbital. Refinement of the inhalation technique almost eliminated anesthetic deaths. All surgery was performed by one of us (TEM, Jr.). During a fellowship year in London prior to this project, the surgeon had performed more than 150 rabbit penetrating keratoplasties. Thus the surgical technique was standardized and a high degree of reproducibility had been achieved. All keratoplasties were performed under the Zeiss diploscope.

The procedure consisted of the placement

of a 5.0 mm penetrating corneal button with 12 direct appositional interrupted sutures. After the animal was anesthetized, the eyelids and the eye were retracted with stay sutures. A 5.0 mm trephine button was outlined in the center of the host rabbit cornea. A donor button was then cut from the eye of a rabbit killed immediately before surgery. A 5.0 mm donor button was prepared with trephine and scissors. The recipeint button was prepared in similar fasion. Following this, the donor button was positioned in the recipient eye and stay sutures were placed (8-0 virgin silk or 10-0 Ethilon) in the three, six, nine, and 12 o'clock meridians. Two additional interrupted sutures were then placed in each quadrant. If fibrin-clotted aqueous presented in the wound, it was removed with forceps or a sponge (heparin was not used to prevent clotting). The chamber was allowed to reform spontaneously. If a chamber did not reform, sutures in the area of the leak were replaced. Following the allograft, most animals received a rotational autograft in the opposite eye, with the same procedure used throughout, except that the donor button, after being cut, was rotated through 180°. At the end of the second procedure, the animal was cycled on oxygen until he was conscious. One drop of phenylephrine HCl 10%, polymyxin B, and cylclopentolate was placed in each eye and the animal was returned to its cage.

*Postoperative treatment and evaluation*—After surgery, animals received topical polymyxin B to each eye twice daily for two days, after which no further medication was given. They were observed twice weekly until the sutures were removed (at approximately 14 days); they were seen daily for three days after removal of the sutures and thereafter at weekly intervals. All examinations were made by slit lamp microscopy. Slit lamp evaluation is imperative during the first 17 postoperative days because the cause of graft failure usually can be diagnosed during this period.

*The early graft reaction*—In the rabbit, the early graft reaction may begin as soon as the second postoperative day and may continue until the 60th day. Because of this range, and because sutures must be removed sooner in the rabbit (about 14 days) than in man, the early graft period has been delineated arbitrarily as lasting until the 75th day. The maximal reaction seems to occur between the seventh and 21st day, much earlier than in man. Degree of reaction among animals varied markedly (Fig. 19). The clinical course of these reactions has been defined as mild, moderate, severe, and permanent donor opacity. In mild reactions, the inflammatory response was limited to the donor-host junction. When neovascularization occurred, it rarely extended beyond the recipient margin. The central cornea remained free of inflammation (Fig. 19-A and 20-A). In moderate reactions, inflammatory edema extended throughout the recipient and donor cornea; neovascularization extended into the peripheral donor cornea, but not into the central donor. With quiescence, most of the donor cornea is clear (Fig. 19-B and 20-C).

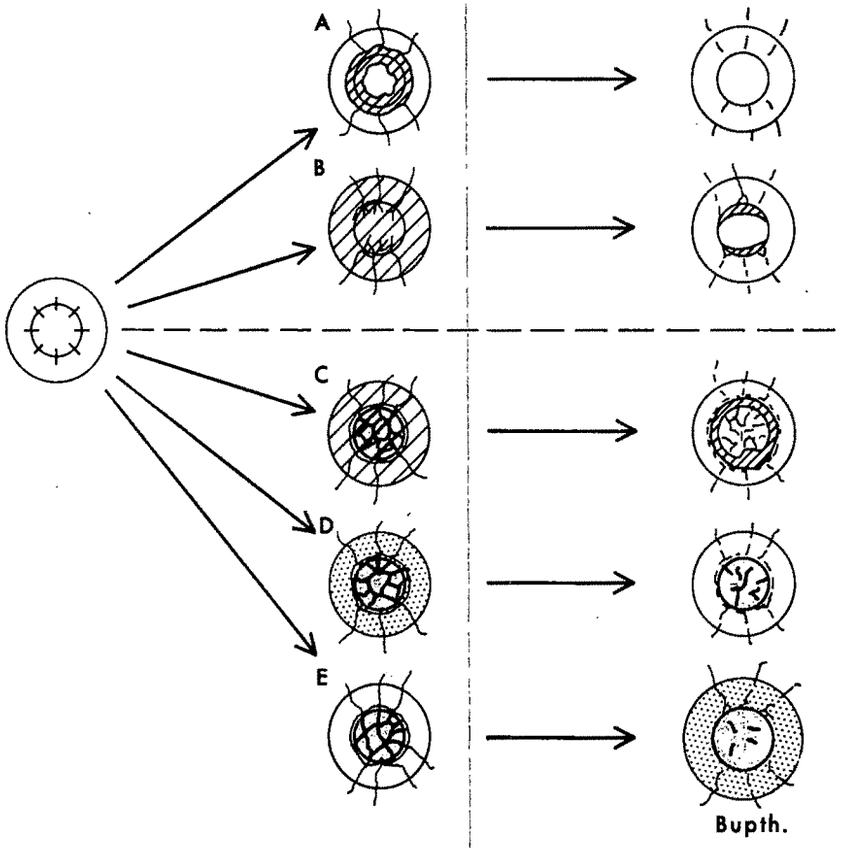

Fig. 19 (Moore and Aronson). Clinical patterns of graft reaction in the rabbit. (A) Mild reaction with minimal structural change. (B) Moderate reaction in which some degree of structural change occurs in the peripheral donor cornea. (C) Severe reaction in which the donor cornea clears following resolution of active inflammation. (D) Severe reaction in which residual scarring and atrophy of the donor cornea are present. (E) Severe reaction in which buphthalmos has occurred.

In severe reactions, both inflammatory opacity and neovascularization pervade the recipient and donor corneas. If the central area of the donor cornea clears when inflammation subsides, it often gives the impression of being transparent (Fig. 19-C and 20-E); however, slit lamp examination will reveal scarring and ghost vessel formation. If the donor cornea does not clear when inflammation subsides, it has incurred permanent opacification. As a rule, the donor cornea is a shrunken, atrophic graft (Fig. 19-D) or it is thinned in a buphthalmic eye (Fig. 19-E and 20-G). Histologic evaluation of mild reactions revealed scarring at the donor-host junction (Fig. 20-B). Neovascularization extending through the host cornea and involving the donor-host junction was observed in moderate reactions (Fig. 20-D). In severe reactions, distinct evidence of neovascularization and scarring in the donor graft was seen (Fig. 20-E). In atrophic grafts, a small, heavily scarred button was present. In buphthalmos, the principal characteristic was marked scarring accompanied by severe active inflammation (Fig. 20-H).

We have defined a successful graft in the rabbit according to that classification in man —i.e., one that is entirely clear with the exception of the suture tracts. The mild and moderate graft reactions yield successful grafts. The severe and opaque graft reactions are classified as failures, although the

(H) Histology of the same eye (×25). Note severe inflammatory response throughout the donor cornea.

severe reaction eventually clears and presents an apparently clear donor graft. This eventual clearing results from the unique regenerative property of the rabbit endothelium.[1,2] While rabbit donor endothelium is destroyed in the course of a severe graft reaction, unlike human endothelium,[3] it regenerates from the host cornea following inflammatory resolution with clearing of the donor graft. For purposes of analogy, in the rabbit experiments, a severe reaction has been classified as an early graft failure.

### Causes of graft failure

Earlier in this report, we identified five potential causes of early graft failure in man. The first four, namely, primary donor failure, surgical trauma, suture toxicity, and microbial toxicity, were identified by a specific clinical and morphologic picture or a culture. The last, tissue incompatibility, was identified only after the other causes of graft failure could be excluded. A simultaneous autograft in each animal provided a concurrent histocompatibility control for evaluating this reaction. Only animals demonstrating a clear autograft and failed allograft were considered to manifest tissue incompatibility reactions.

*Surgical failure*—This presented a typical clinical picture. During the first several days after surgery, some derangement of the anterior chamber was evident. This included an absent chamber, fibrin hypopyon or hyphema in the chamber, and intrusion of the lens or iris into the wound. By the seventh to 10th day, intraocular pressure increase could be identified by haziness of the donor cornea on slit lamp examination, tautness of sutures with evidence of cutting into donor and recipient tissue, and firmness of the eye on tactile evaluation. Wound dehiscences began to appear by the 14th day (Fig. 21-A). If, according to protocol, sutures were removed at this time, the incidence of wound dehiscence markedly increased and prolapse of intraocular contents occurred (Fig. 21-B). If sutures were not removed, buphthalmos appeared about the 21st day, and occurred in almost every failure by the 50th day.

*Suture toxicity*—Toxicity to 8-0 silk suture was discernible as early as the fourth postoperative day. It presented initially as a dense white infiltrate throughout the suture tract. This rapidly progressed (at seven to 10 days) to neovascularization of the suture tract (Fig. 21-C), frequently extending into the central cornea and leading to graft failure (Fig. 21-D). When 10-0 Ethilon suture was used, the degree of infiltrate formation was markedly reduced (Fig. 21-E); however, superimposition of indigenous bacterial flora along the suture tract occasionally led to neovascularization of the tract but rarely caused graft failures.

*Bacterial infection*—This category is divided into pathogenic and indigenous subgroups. Conjunctivae were cultured routinely before surgery and at the time of sacrifice. Animals demonstrating a suspected bacterial lesion were cultured at the time of such identification. All cultures were plated on blood and chocolate agar and read at 24 hours.

A pathogenic microbial infection presented clinically as a suture tract abscess (Fig. 21-G). If the abscessed suture was removed early in the course of inflammation, graft failure usually could be prevented. Pathogenic microbes identified as causative inflammatory agents in this study include Staph. aureus, beta hemolytic streptococcus, and Pseudomonas aerugenosa.

Reactions caused by indigenous bacterial toxicity could be diagnosed only in nylon-sutured rabbits since the reaction is identical to that caused by silk suture toxicity. This reaction appears about the eighth postoperative day and is indicated initially by infiltrates surrounding the suture tracts. Suture tracts rapidly vascularize. In our series, such a reaction did not progress to total corneal neovascularization, probably because sutures were removed by the 14th day. Epithelial closing of the suture tract prevents bacterial entry, thereby halting progression of the inflammation. The predominant microbes re-

sponsible for this reaction were Hauch mimae and Moraxella nonliquefaciens.

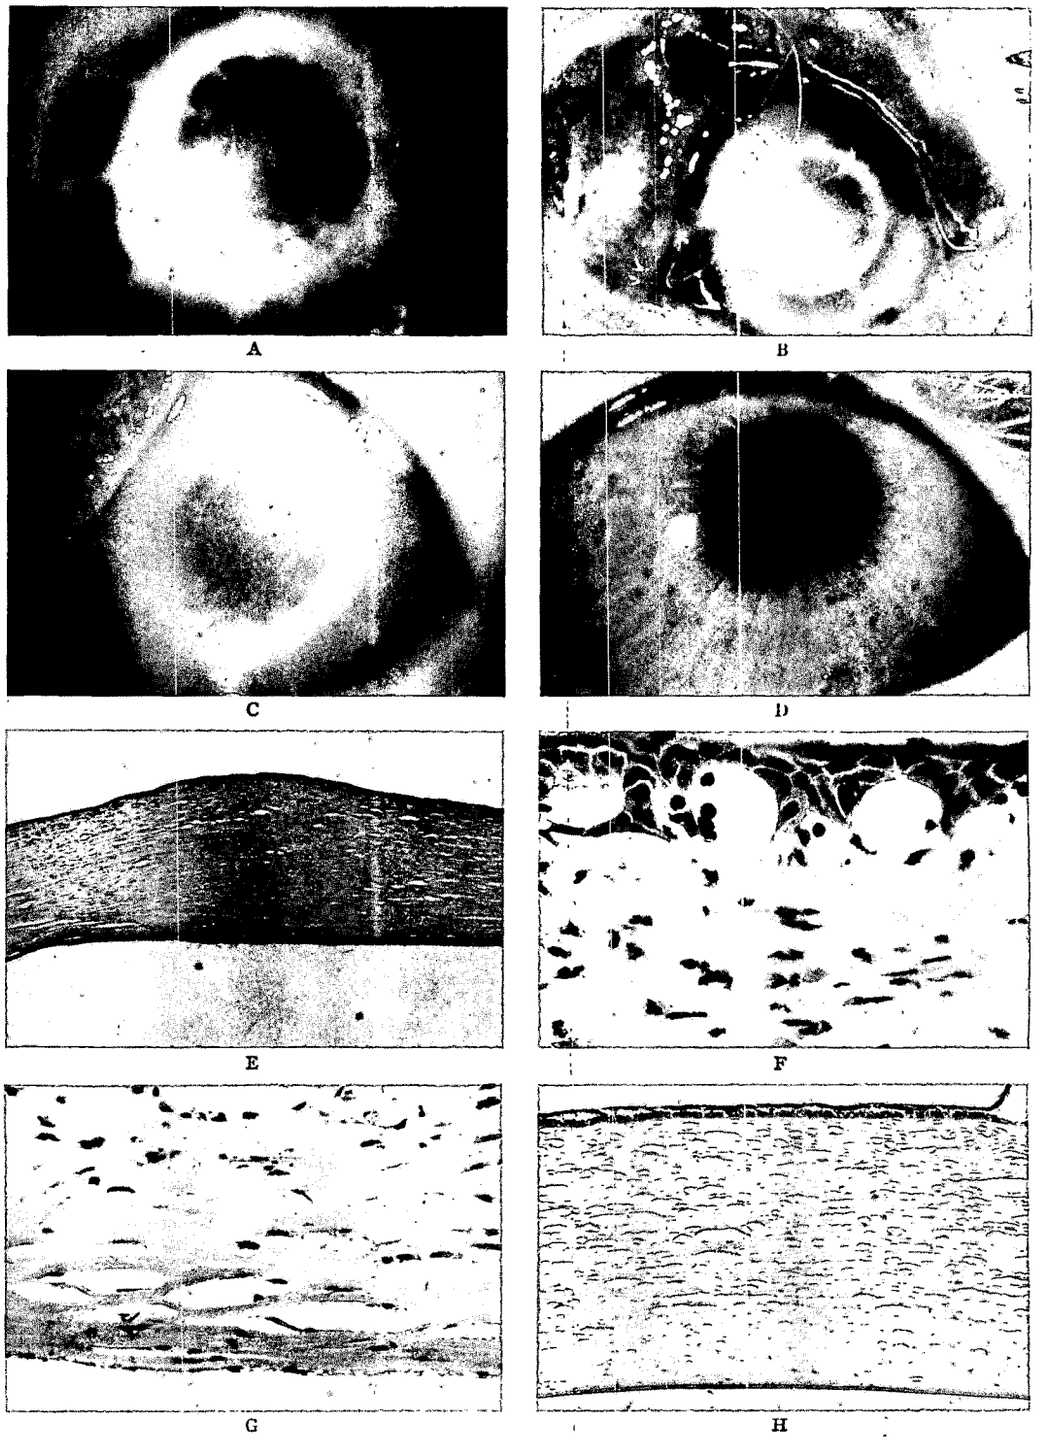
*Tissue incompatibility*—Our previous discussion has indicated that tissue incompatibility could be diagnosed only after the other variables were controlled; thus, it could be identified only in nylon-sutured animals without evidence of surgical failure or microbial toxicity. The reactivity of indigenous bacteria delays precise identification of the reaction until the sutures are removed. We have limited the identification to animals with a simultaneous autograft which remained nonreactive. The earliest detectable onset of this reaction is between two and one-half and three weeks after surgery. The reaction is characterized by infiltrate formation, first in the periphery, then extending throughout the corneal stroma. The reaction appears to originate in the limbus, since the anterior chamber is relatively quiet. As the reaction progresses, extensive neovascularization extends first into the peripheral donor cornea and then throughout the corneal stroma. These reactions usually progress to a severely shrunken, scarred cornea or to buphthalmos (Fig. 21-H). Occasionally, a cornea will demonstrate involuted blood vessels and clearing of the corneal stroma until a clear donor graft is achieved.

Corneal histopathology has been exceptionally well characterized for the graft reaction in the rabbit.[4-6] In no circumstance, however, can types of graft failure be differentiated by histopathologic configuration. Although histologic changes were studied in numerous eyes in this series, they did not prove as useful as sequential clinical and morphologic evaluations.

*Delayed graft reaction*—In the rabbit, this refers to inflammatory reactions of the donor cornea which occur any time after 75 days (the end of the early graft period). A delayed graft reaction is one that occurs in a previously quiet eye. Onset of the active stage features injection of the recipient vessels and extension of inflammatory edema into the donor cornea. With progression to the severe stage, neovascularization of the donor cornea occurs. In delayed graft failure, this stage invariably proceeds to buphthalmos. In a certain number of animals, the graft cleared spontaneously after the delayed graft reaction became inactive.

TABLE 41

GRAFTED EYES EVALUATED FOR SPONTANEOUS DELAYED GRAFT REACTIONS



| Follow-up Time | Allograft Eyes | Autograft Eyes | Total Eyes |
|---|---|---|---|
| One month or less | 5 | 3 | 8 |
| One to two months | 8 | 9 | 17 |
| Two to three months | 15 | 10 | 25 |
| Three to four months | 6 | 0 | 6 |
| Four to five months | 12 | 12 | 24 |
| Five to six months | 4 | 2 | 6 |
| Six months or more | 8 | 5 | 13 |
| Total eyes | 58 | 41 | 99* |

* This number of grafts was performed in 73 animals.

Two types of study of the delayed graft reaction were undertaken. The first study evaluated the total number of delayed graft reactions which occurred spontaneously in animals with successful grafts in the early period. In the second study, animals whose grafts were successful throughout the early period were immunized systemically and then challenged by conjunctival instillation of the immunizing antigen.

*Spontaneous inflammation*—In the first study, which dealt with spontaneous inflammation, 73 animals (99 eyes) were followed for seven months after the end of the early graft period (Table 41). During this period, gross cage inspection was made weekly and slit lamp examinations were made biweekly. When a delayed graft reaction was detected, the animal was monitored by slit lamp examination every other day throughout the course of active inflammation. If the reaction had not cleared by the end of the eighth week, the animal was classified as a delayed graft failure (Fig. 22-A and B).

Animals with delayed reactions were cul-

tured for bacteria when the reaction was first identified. Swab cultures were taken from the inferior conjunctival fornix of both eyes and plated on blood and chocolate agars. Cultures were read and identified at 24 hours.

Histologic changes in the delayed graft reaction were difficult to differentiate from those in the immediate reaction. The acute phase of inflammation demonstrated a diffuse polymorphonuclear (PMN) leukocyte reaction throughout the corneal stroma. Other findings included marked engorgement of blood vessels and a moderate anterior chamber inflammatory response. As inflammation subsided and buphthalmos developed, thinning and scarring of the donor cornea with epithelial edema became apparent.

Some variables which may be operative in predisposing to delayed graft reactions were evaluated in the spontaneous reaction group. The stimulus was evaluated by conjunctival culture. Host response was evaluated by comparing the number of pigmented and albino animals which manifested reactions. The effect of structural change in predisposing to subsequent inflammation was evaluated by classifying the degree of neovascularization in the recipient cornea. The classifications were: (1) absent, (2) mild (in which a single vascular branch extended into the host cornea), and (3) moderate (in which a network of vessels extended into the host cornea and encircled the donor graft). This classification closely paralleled that already described for the postoperative graft in the patient series.

The effect of particular variables in the early graft reaction was also evaluated in the spontaneous reaction group. These variables included suture toxicity and tissue incompatibility. The former was a comparison of silk and nylon sutures, the latter a comparison of allo- and autografts.

*Exogenous stimulation*—These experiments were performed in 30 rabbits which had survived the period of observation for spontaneous inflammation without evidence of a delayed graft reaction. Animals were selected on the basis of degree of structural change and neovascularization in the host cornea. They were divided into groups according to whether these reactions were: (1) absent, (2) minimal, or (3) moderate. A similar number of allo- and autograft corneas were divided into the three structural groups (Table 42).

Animals were systemically immunized to bovine serum albumin (BSA) by weekly injections of 0.1 ml (10 mg BSA in Freund's adjuvant, equal parts) into four intradermal sites. Following the fourth injection, all animals were titered for anti-BSA by reverse radial diffusion.[7] They were subsequently challenged by the topical instillation of BSA (100 mg/ml, 4 drops, 5 mg per drop) into each conjunctival sac every two hours at eight-hour intervals for 10-day periods. Animals were examined daily throughout this challenge period by slit lamp microscopy. The earliest discernible change was limbal injection and infiltrative clouding of the host cornea. This progressed to involve the donor cornea first by focal infiltrates, and later by

TABLE 42

SELECTION OF ANIMALS FOR EXOGENOUS IMMUNOGENIC STIMULATION

| Structural Group | Allograft | Autograft | Total Eyes |
|---|---|---|---|
| No host neovascularization | 10 | 9 | 19 |
| Mild neovascularization | 8 | 7 | 15 |
| Moderate neovascularization | 7 | 19 | 26 |
| Total eyes | 25 | 35 | 60 |

diffuse stromal clouding. Most animals were killed and their eyes enucleated by the end of the 10-day period. However, two animals (one allograft, one autograft) that demonstrated relatively severe stromal inflammation were continued on topical medication as described above for 15 additional days. Both animals developed buphthalmos.

Histologic observations on the corneas of these animals were much the same as in the spontaneous delayed graft reaction group. In the early stages, a marked lymphoid hyperplasia was noted around the limbal vasculature. PMN proliferation occurred throughout the host cornea, entering minimally into the donor cornea. In more severe reactions, PMN's were diffused throughout the corneal stroma; distinct endothelial involvement was also present. The animals which had been allowed to develop buphthalmos demonstrated the severe changes described above as characteristic of buphthalmic eyes.

A second experiment was designed to demonstrate differences between the reactions of grafted and nongrafted eyes to topical immunogenic stimulation. Fourteen animals with monocular grafts were divided into two groups: nine with no changes and five with mild changes. They were immunized systemically to bovine gamma globulin (BGG) in Fruend's adjuvant, in a dosage and schedule similar to the previous experiment. BGG was selected because it does not produce corneal stromal disease in a nontraumatized eye.[8] Following immunization, all animals were challenged bilaterally with topical BGG (100 mg/ml) and followed by slit lamp as described previously for the BSA model.

Changes in the grafted eye were similar to those described in the BSA experiment. Corneal infiltrates and severe corneal clouding occurred (Fig. 22-C). The nongrafted eye demonstrated only limbal hyperemia; there was no evidence of corneal inflammatory disease (Fig. 22-D).

At the end of the 10th day, animals were killed, the eyes enucleated and prepared for histology. Histologic evaluation revealed corneal changes which conformed to the described clinical picture. The focal infiltrates appeared as discrete clumps of PMNs. A diffuse PMN reaction was noted in severe stromal disease (Fig. 22-E). PMNs extended into donor epithelium (Fig. 22-F) and endothelium (Fig. 22-G), leading ultimately to delayed graft failure. The nongrafted cornea was free of a PMN response (Fig. 22-H).

These experiments were undertaken to demonstrate that an exogenous immunogenic challenge can produce a delayed graft reaction. This reaction has been compared to (1) the degree of immune response and (2) the amount of structural change exhibited by the challenged animals.

Overall results during the early graft period have been expressed in Table 43. The difference between autograft and allograft success is 9%. When only simultaneous auto-allograft animals are counted, the difference is 12%. In a single-variable experiment, this difference (9 to 12%) would account for tissue incompatibility failures; however, the remaining 45% of graft failures must be accounted for. Analysis of an individual variable required that each variable be controlled independently.

*Silk suture toxicity*—This appeared to account for a majority of all graft failures. When silk and nylon suture groups (all autografts) are compared, success rates for the two sutures are 32 vs 76%, respectively. (Table 44). If the silk–nylon comparison is limited to all allografts, the difference is pronounced: 18 vs 69%. However, if the most reactive group (group IV, albino donor, pigmented recipient) is evaluated, the divergence is dramatic: 92% clear nylon vs 23% silk for autografts, and 43% nylon vs 0% silk for allografts. Since the choice of suture material so strongly affected the degree of graft success, it was obvious that subsequent variables could be evaluated only in nylon-sutured grafts.

*Surgical trauma*—Evaluation of surgical trauma as the cause of graft failure indicates that 55% of allograft failures and 100% of autograft failures can be attributed to a surgical cause (Table 45). This category includes cases with a persistently flat chamber, early wound dehiscence, or early-onset buphthalmos. In general, evidence for surgical failure was identifiable between the second and seventh postoperative day.

*Pathogenic bacteria*—Staph. aureus and beta hemolytic streptococcus produced suture tract abscesses which resulted in one opaque graft and one severe graft reaction and accounted for 10% of failed grafts.

*Nonpathogenic bacteria*—These were not identified as the primary cause of any graft failure in this series. However, a number of nylon-sutured cases demonstrated neovascularization of the suture tracts. When sutures were removed, the inflammatory reaction ceased and vessels involuted. Prolific growths of indigenous bacteria (H. mimae, moraxella) were cultured from the conjunctival sac of each of these animals.

*Tissue incompatibility*—As it was in the patient series, tissue incompatibility was diagnosed by exclusion. In this series, following elimination of silk-sutured cases, 35% of all graft failures were most likely due to tissue incompatibility factors. However, when evaluating the most reactive experimental group (group IV), the percentage of failures is increased to 75%. A tissue incompatibility graft failure also occurred in group II. Within-strain grafting (groups I and III) demonstrated no evidence of tissue incompatibility.

Table 46 presents an approximation of the incidence of graft failure attributable to each variable in this penetrating keratoplasty se-

* Evaluation limited to Ethilon suture series.

ries. As mentioned, silk suture was the prevalent cause of failure, producing 61% failure in the allograft series. (These data were obtained by calculating the difference between success rates in the silk and nylon suture series. This assumes that the only difference in these two series was the suture material. Other suture-related variables may play a role in this extraordinary difference.)

Surgery, pathogenic bacteria, and tissue incompatibility were evaluated only in the nylon suture series. Surgical failure occurred in 22% of allografts. Pathogenic bacteria were responsible for graft failure in 4% of cases. And tissue incompatibility occurred in approximately 13% of allografts. As noted, we did not feel that the role of nonpathogenic bacteria could be evaluated accurately in this study. In descending order the ratio of failure is suture toxicity—61%, surgical trauma—22%, tissue incompatibility —13%, and bacterial infection—4%.

## RESULTS

The use of the rabbit as an experimental model for penetrating keratoplasty is not entirely satisfactory. Several factors complicate surgical technique in the rabbit: corneal thinness, a relatively shallow anterior chamber, and rapid fibrin clotting in the aqueous during surgery. Inflammatory reactivity is considerably greater in the postoperative period; wound healing is markedly faster. The normal rabbit eye is often bacteriologically sterile but once inflammation occurs, bacterial contamination by indigenous microbes develops. The incidence of pathogenic bacteria is much greater in the rabbit series than in the human. Finally, unlike the human cornea, the endothelium of the rabbit host cornea regenerates following inflammation, a characteristic which can render an opaque graft apparently clear.

These properties limit the applicability of findings in rabbit experiments to problems in the human graft. First, distinctly defined criteria for the course of postoperative inflammation are essential to determining the success or failure rate of keratoplasties. The mild or moderate clinical course produces a successful graft. The mild reaction is characterized by inflammation adjacent to the wound margin only; it is analogous to mild or moderate graft reactions in man. The moderate reaction shows haze throughout the donor cornea. Centrally, the reaction is in the anterior corneal stroma. Peripheral neovascularization extends to the central margin of donor sutures, but never into the central donor cornea. This reaction is analogous to a severe inflammatory reaction in man. As noted earlier, a successful human graft can be achieved if the endothelium is protected from severe central inflammation. For purposes of this study, a mild or moderate reaction is classified as a successful graft.

Aspects of graft failure in the rabbit do not satisfactorily compare to the clinical graft experience. Obviously, the opaque donor corneas and buphthalmos are acceptable as failures. However, a severe reaction in a clear donor graft is designated as a graft failure in man. The course of this reaction features a severe inflammatory response throughout the entire donor cornea; neovascularization extends throughout the central cornea; endothelial involvement by the inflammatory process is uniform. At this stage the donor cornea is completely opaque. Such a reaction invariably goes on to donor failure in man. In the rabbit, however, such a reaction can go on to graft failure or it can eventually clear with the disappearance of active inflammatory signs. Central blood vessels involute and become ghost vessels. The donor endothelium can regenerate with host cells and a viable graft can result. Because this kind of reaction does not occur in man, we have considered this group of cases to represent graft failure.

*Variables*—Suture toxicity was considered a supravariable in this series, since the experiments could not be completed until silk suture toxicity had been controlled and overcome. As noted in Table 44, this proved to be especially true in group IV animals (albino donor, pigmented recipient) where all allografts sutured with silk resulted in failure. Obviously, other variables could not be evaluated in such a circumstance. The distinct features of suture toxicity have been evaluated at length in previous studies.[1-3] With adoption of nylon suture, suture toxicity was eliminated as a significant variable in this series.

Of the other variables evaluated in nylon-sutured animals, the surgical procedure appeared to be the most important in graft success. To evaluate the significance of the surgical procedure, we attempted to simulate the clinical procedure as closely as possible. To avoid introducing another variable to our multiple variable analysis, we did not use anticoagulants or other agents that could have altered the reproducibility of the original procedure. This may explain the relatively high incidence of surgical failure in contrast to other reported series.[4,5]

A surgical failure could be identified with considerable precision. The signs of surgically induced inflammation appeared very early as anterior chamber fibrin, hemorrhage, inflammation, or wound problems. Sequelae to these early signs followed rapidly, almost always manifested by an increase in intraocular pressure (donor haze or wound rupture). As noted, these invariably led to buphthalmos. We believe that this pattern of events could not be related to any of the other variables, principally because of the rapid onset following keratoplasty.

The role of infection by pathogenic bacteria was clearly distinguishable. The corneal lesion appears as a suture tract infection which spreads to envelop the entire cornea. The lesion in the rabbit is identical to the lesion in the human.[6] Its incidence was minimal, 4% in this series. The source of infection was identified by culture.

Indigenous bacteria were implicated earlier as a more significant factor in enhancing corneal graft reactions. In interrupted nylon suture grafts, this lesion appeared as infiltrate and as neovascularization of suture tracts and necessitated early removal of sutures. H. mimae was the prevalent agent involved; prolific numbers of organisms were noted in animals with the above described reactions. A distinct graft failure which is directly attributable to such organisms is extremely difficult to demonstrate, insofar as similar changes occur in the early tissue incompatibility reaction. Rather, we have considered indigenous bacteria to be a secondary modifier, which tends to heighten or precipitate the overall graft reaction, but probably in itself does not produce graft failure.

Tissue incompatibility as a factor in graft failure was evaluated by two methods. The first was an overall series comparison between allo- and autografts in the same animals, yielding a 12% difference in allograft failure (Table 42). The second was identification of tissue incompatibility reactions in the nylon-sutured allograft series. In this case, 13% of grafts failed because of this factor (Table 45). (It should be reiterated that the tissue incompatibility reaction was principally a diagnosis of exclusion, and identification was made only after the other known variables were ruled out.) The close approximation of 12 to 13% tissue incompatibility reaction, derived from two different techniques of evaluation, strongly supports this figure as the incidence of tissue incompatibility in these rabbit penetrating keratoplasty experiments.

Of particular interest is the identification of the onset of a tissue incompatibility reaction. By selecting distinctly different strains of rabbits, we were able to heighten the level of graft failure due to tissue incompatibility. In allografts done within a strain (i.e., group I, albino donor–albino recipient, and group III, pigmented donor–pigmented recipient) no tissue incompatibility reactions were identifiable. However, they were identified in cross-strain allografts. In group IV, albino donor–pigmented recipient, 43% of grafts failed because of this factor, while in group II, pigmented donor–albino recipient, 11% failed because of it. It seems probable that genetic factors play a major role in producing ocular tissue incompatibility reactions as in kidney and heart transplants.[7-9] The cross-strain grafts reacted more severely than the in-strain grafts, the former resembling cross-grafting reactions in heterologous species[10,11] and the latter much like isologous strains.[12,13]

As already noted, these rabbit strains were selected because of their extensive inbreeding over a period of years. In previous experiments,[14,15] we reported the increased immunogenic inflammatory reactivity demonstrated by the pigmented rabbit in contrast to the albino when challenged with pure protein antigens. In these experiments, the pigmented animal demonstrated extreme reactivity to silk suture. It seems likely that the higher incidence of tissue incompatibility reactions in pigmented animals accounts for the increased inflammatory reactivity which seems characteristic of this strain. This does

not rule out the remote possibility that the reaction in pigmented animals is due to increased antigenicity of the albino donor cornea.

Primary donor failure, described as a cause of human graft failure, does not pertain to these experiments since donor tissue was taken from relatively young animals and used immediately after death.

The disparity between our keratoplasty failure rates in the rabbit and those of other authors[4-6] probably results from the experimental goals of the different groups. Our objective was to evaluate the role of all variables in graft failure. Other groups focused on the tissue incompatibility reaction, setting up techniques purposely to exclude other variables. Also, to the best of our knowledge all other groups did in-strain grafting (many employing lamellar keratoplasties), most frequently albino-to-albino. Perhaps our results would comply with those of other reports had we not attempted to exclude these biases from our series.

A majority of spontaneous delayed graft reactions (16 of 20) occurred in the initial two-month period (Table 47). Only four reactions occurred after the second month. (However, most animals were observed in the initial early graft period.) When corrected for percentage of occurrence (percent failure in all animals), the incidence of spontaneous delayed reactions gradually diminishes with time. A rate of 13% for the first month after the early graft period had ended decreased to an average of 2% for the following two-month intervals.

The principal variable relating to occurrence of the delayed graft reaction was bacterial infection (Tables 48 and 49). Sixty percent of reactions (66% of failures) demonstrated a pathogenic bacterium on culture. The predominant aggravating microbe was Staph. aureus. Florid cultures of nonpathogenic bacteria were recovered from all but one of the remaining eyes. In this case, moraxella was the predominant organism. (We describe moraxella as a nonpathogen in the rabbit because active inflammation is seldom seen in the rabbit cornea although cultures are positive.)

The role of suture toxicity in predisposing to the delayed graft reaction was again evaluated (Table 50). A preponderance of delayed graft reactions occurred in animals with silk-sutured (8-0 virgin silk) grafts. Only 9% of nylon-sutured grafts demonstrated a delayed reaction and none of these went on to failure.

The effect of silk suture in predisposing to delayed failure is probably related to the degree of altered host structure still present at

TABLE 50

OCCURRENCE OF DELAYED GRAFT REACTIONS, SILK VS NYLON SUTURE

| Suture Group | Total Animals | Reaction | | Failure | |
|---|---|---|---|---|---|
| | | No. | % | No. | % |
| Silk | 52 | 16 | 31 | 9 | 17 |
| Nylon | 47 | 4 | 9 | 0 | 0 |

the end of the early graft period. Four of the nine grafts which failed spontaneously had experienced a severe early graft course. The other five had a moderately severe course. Of the 11 graft reactions, one had a severe course, six moderate, and four mild. In general, the clinical course of silk-sutured grafts is much more severe in the early graft period than that of the nylon-sutured grafts (Table 44).

The incidence of delayed reactions was somewhat greater in autografts than allografts, 29 vs 14% (Table 51). Similarly, delayed failure rate was higher in autografts. (Neither of these differences is significant.) This observation would mediate against the relationship of tissue incompatibility to the delayed graft reaction.

When grafted groups of rabbits are compared (Table 52), there is no appreciable difference between the in-strain and the cross-strain groups. (Group I vs II, and III vs IV are compatible.)

TABLE 51

COMPARISON OF THE INCIDENCE OF DELAYED GRAFT REACTIONS, ALLOGRAFTS VS AUTOGRAFTS

| Graft Group | No. Animals | Delayed Reactions | | Delayed Failures | |
|---|---|---|---|---|---|
| | | No. | % | No. | % |
| Allograft | 58 | 8 | 14 | 2 | 3 |
| Autograft | 41 | 12 | 29 | 7 | 17 |
| Total | 99 | 20 | 20 | 9 | 9 |

Of particular interest is the predominance of delayed graft reactions in albino rabbits, a ratio of 32 vs 3%. This ratio correlates closely with the abundance of both pathogenic and nonpathogenic bacteria on conjunctival culture of the albino rabbit in contrast to that of the pigmented rabbit. Likewise, the albino animal almost always demonstrates the nonpathogenic H. mimae and, frequently, moraxella, while the pigmented animal is virtually free of all bacteria.

In summary, of the variables evaluated in spontaneous delayed graft reactions, severity of structural change and prevalence of pathogenic and nonpathogenic bacteria appear to be significant, while tissue incompatibility appears to be unrelated to the reaction.

The exogenous stimulation experiments were designed to demonstrate that: (1) an exogenous stimulus can produce graft failure, (2) the degree of structural alteration

* One totally opaque allograft and one autograft developed buphthalmos following continuous topical BGG challenge.

of the host cornea will determine the severity of the inflammatory response, and (3) the host must demonstrate an adequate immune response to the challenging antigens for graft failure to occur.

In the initial experiment, the severity of the delayed graft reaction following topical BSA challenge was related to the degree of structural change within the host cornea (Table 53). Fifty-seven percent of allografts and 67% of autografts with severe structural change developed complete donor opacity following exogenous BSA challenge. Corneas demonstrating mild or absent neovascularization of the host rarely went on to complete opacification. Buphthalmos occurred following chronic exogenous stimulation. In this reaction, it would appear that an adequately prolonged iritis and trabeculitis must be produced before outflow channels are blocked and buphthalmos results. There was no apparent difference between allografts and autografts in their reaction to the exogenous stimulus.

TABLE 54

ANTI-BSA TITERS RELATED TO SEVERITY OF IMMUNOGENIC INFLAMMATION IN THE DONOR CORNEA

| | Antibody Titer Expressed in Diameter of Diffusion | | | | | |
|---|---|---|---|---|---|---|
| | 4 mm | 6 mm | 8 mm | 10 mm | 12 mm | 14 mm |
| Absent host vascularity | | | | | | |

| Total opacity | | | | | 1 | 1 |
| Severe neovascularization | | | | | | |
| Infiltrative change | 1 | | | | | |
| Partial opacity | 2 | 2 | | 1 | | |
| Total opacity | | 1 | 3 | 4 | 1 | 1 |

TABLE 55

EFFECT OF BGG CHALLENGE ON NORMAL AND GRAFTED EYES

| Structural Change | Total Animals | Limbal Hyperemia | Corneal Infiltrate | Partial Opacity |
|---|---|---|---|---|
| Normal | 14 | 14 | | |
| Absent neovascularization | 9 | 3 | 5 | 1 |
| Mild neovascularization | 5 | 1 | 3 | 1 |

In addition to structural alteration, reaction severity also depends upon the host ability to respond to an exogenous stimulus. In Table 54, antibody titers are compared with the severity of the donor response. In cases with absent or mild neovascularization of the host cornea, total opacification was producible only in animals demonstrating very high antibody titers (12 or 14 mm ID), while in severe disease, total opacity could be produced despite much lower titers.

The second group of exogenous stimulation experiments attempted to differentiate between structural predisposition of corneas with absent or mild host vascularity and a normal cornea. On BGG challenge, this group of grafted animals showed signs of clinical inflammation, corneal infiltrates, and anterior opacity. Normal eyes demonstrated only signs of conjunctival and limbal disease (Table 55).

This experiment serves to emphasize the effect of structural change on the predisposition to corneal inflammatory disease, since BGG is too large a molecule to produce change in the normal cornea.

## RESULTS

The delayed graft reaction in the rabbit, in contrast to that in man, originates exogenously and develops the corneal pattern of disease. Pathogenic or indigenous bacteria were recovered in every spontaneous reaction. However, immunogenic stimuli can also ignite the reaction, as the exogenous stimulation model demonstrated. However, with inflammatory resolution the rabbit donor cornea either clears or goes on to buphthalmos.

A majority of spontaneous delayed graft reactions occurred in the first two months following the end of the early graft period (between 75 and 135 days following surgery). As noted in the patient series, this period proximal to the early graft reaction exhibits the greatest degree of active structural alteration. OVP is increased in this period, while it tends to normalize with the passage of time. This is readily demonstrated clinically by the progressive involution of blood vessels in the host cornea with time.

Significant factors evaluated in the spontaneous delayed graft reaction included: (1) exogenous bacterial stimulation, (2) tissue incompatibility, and (3) the early graft variable, suture toxicity.

When pathogenic or indigenous bacteria were identified in delayed graft reactions, many more microbes were identified in the inflamed eye. This was particularly true in the case of indigenous bacteria, indicating a causal relationship.

The role of host response in the delayed graft reaction was demonstrated in the exogenous challenge experiments. If structure was normal, an animal required more immunity to produce a reaction. It seems likely that an adequate immune response must be present for a reaction to occur.

The potential role of tissue incompatibility as a factor in the experimental delayed graft reaction has been eliminated. As noted: (1) bacteria have been identified in the presence of spontaneous reactions, and (2) the incidence of delayed reactions is about the same in allografts and autografts (Table 52). The classic hypothesis that this reaction represents a delayed-onset tissue incompatibility reaction[1,2] was principally built upon analogy to vascular organ transplants such as the kidney, heart, and lung,[3-5] or to the second-set reaction.[6,7] In the former, inflammatory reactions frequently occur at intervals long after surgery and respond to immunosuppression.[8,9] In the latter, grafting of tissue at a later time from the original donor will produce a corneal reaction. Neither appears to apply in this case.

The cornea is unique in its dual characteristics of minimal antigenicity and avascularity, a combination which makes tissue incompatibility a minor factor in the early graft period and of questionable significance in the delayed reaction.

Suture toxicity, the most important factor in the early period, plays an indirect role in the delayed reaction. By producing a severe inflammatory response during the early period, suture toxicity results in severe structural changes which predisposes the eye to a delayed graft reaction. The degree of structural change produced by silk sutures was considerably greater than that demonstrated by nylon. Similarly, the occurrence of delayed reactions in silk-sutured animals was much greater than in nylon-sutured animals.

The role of structural alteration is extremely well demonstrated in the immunogenic stimulation model. With increasing severity of structural alteration, delayed graft reactions could be produced in animals with relatively low antibody titer. The pathogenesis of structural alteration allows for a much greater number of gamma globulin molecules to enter the cornea. Even though specific antibody titer is low, the total number of antibody molecules entering the cornea is adequate to effect an immunogenic inflammatory response.

In summary, the delayed graft reaction in the rabbit appears to be composed of: (1) stimuli in the exogenous environment, (2) an adequate host response, and (3) adequate

structural alteration in the host cornea. The effect of the early graft reaction on predisposition to subsequent delayed disease is mediated through structural alteration. Intrinsic tissue incompatibility plays no identifiable role in this reaction.

## SUMMARY

These studies evaluate several factors which influence the outcome of a penetrating corneal graft. These factors include preoperative patient classification based on a combined clinical and morphologic system, preoperative protocols, donor cornea selection, the surgical procedure, the choice of suture, and postoperative management during the early and delayed graft reaction periods.

The long-term outcome for penetrating keratoplasty is promising. Our overall success rate for clear grafts is 72%. Including multiple procedures per eye, the success rate becomes 81%. With the optimal procedure, long-term success increases to 89% for cases and 91% for eyes.

Of greater importance is the functional result achieved in grafted eyes. We designated a visual acuity of $> 20/40$, usually with a corneal contact lens, as a good visual result. In more than 54% of all eyes treated, this result was achieved. Excluding cases with poor prognosis, more than 76% of eyes attained this level of visual acuity.

These studies illustrate that the penetrating keratoplasty is a practical restorative procedure for almost every vision-decreasing corneal problem.

## GLOSSARY

1. *Corneal graft (transplantation, keratoplasty)*—Replacement of diseased corneal tissue with viable nondiseased corneal tissue. In this study all grafting procedures were performed as penetrating keratoplasties utilizing allogeneic (homologous) donor corneal tissue.

2. *Corneal autograft*—A graft for which the donor cornea is taken from the patient's opposite eye.

3. *Corneal graft reaction*—An inflammatory reaction occurring in the host or donor cornea, or both, following corneal grafting and caused by a single inflammogenic stimulus or a combination of stimuli, e.g., suture toxicity, microbial toxicity.

4. *Corneal graft failure*—Nonclearing opacification of the donor cornea for any reason, e.g., inflammatory sequela, primary donor failure, tissue incompatibility reaction.

5. *Early graft reaction*—Corneal graft reaction occurring within the first 12 postoperative weeks in silk-sutured patients or 16 to 18 weeks in nylon-sutured patients.

6. *Delayed graft reaction*—Corneal graft reaction occurring after removal of sutures, approximately 12 to 16 weeks postoperatively.

7. *Inflammatory failure*—Opacification of the donor cornea resulting from effects of inflammation.

8. *Primary donor failure*—Immediate nonclearing opacification of the donor cornea after surgery resulting from nonviable or damaged donor endothelium.

9. *Clinical and morphologic classification of the host eye*—The system by which the host eye was evaluated preoperatively for varying degrees of structural change; the primary bases for this classification were presence or absence of corneal neovascularization and evidence of intraocular inflammation.

10. *Etiologic classification of the host eye*—Clinical diagnosis or identification of a specific causative agent.

11. *Suture toxicity*—A progressive inflammatory reaction presenting as suture tract infiltrate which is rapidly succeeded by neovascularization which in turn can culminate in graft failure. Suture toxicity was found to be a highly significant variable in this series.

12. *Microbial toxicity*—An inflammatory reaction which may be produced by pathogenic or indigenous (nonpathogenic) bacteria. The characteristic reaction produced by pathogenic bacteria presents as a suture tract abscess (Figs. 13-C, 21-G). Indigenous bacterial involvement presents as infiltrate along nlyon suture tracts. Viral infections (e.g., herpes simplex) occur as epithelial dendrites. Identification was by culture or by electron microscopy.

13. *Host immunologic classification*—Evaluation of host ability to respond to exogenous stimuli. Tests performed included: (1) protein electrophoresis, (2) qualitative immunoelectrophoresis, (3) quantitative IgG, IgA, IgM, and early IgG determination, and (4) $B_1C/B_1A$ evaluation.

14. *Tissue incompatibility (homograft) reaction*—An immunogenic host response to allogeneic donor corneal tissue. Identification of this reaction was achieved by exclusion of other inflammogenic variables. The reaction is characterized by a relatively uniform infiltration and neovascularization of donor tissue. It seems likely that the endothelial reaction described by Paufique and associates (Corneal Grafting. Paris, Masson, 1948) has been suppressed in our series by the use of corticosteroid.

15. *Successful graft*—A clear donor cornea throughout its entirety except suture tracts.

16. *Dependent noncorneal variables*—Introacular changes that have resulted from the keratoplasty procedure, e.g., glaucoma, retinal detachment.

17. *Independent noncorneal variables*—Intraocular changes that are unrelated to the

penetrating keratoplasty and most likely were pre-existing, e.g., macular degeneration, glaucoma.

18. *Long-term graft results*—Evaluation of graft success or failure after nine months or longer by morphologic, etiologic, and immunologic criteria.

19. *Case*—A single penetrating keratoplasty, e.g., one eye in this series received three keratoplasties and thereby is three *cases*.

20. *Eyes*—The number of individual eyes on which surgery was performed.

21. *Patients*—The number of individual patients on whom surgery was performed (12 patients had bilateral surgery).

22. *Structural alteration*—The permanent changes in tissue or in cellular function which result from adequately severe or prolonged inflammation and characterized by scarring and neovascularization. Eyes which demonstrate such changes show a marked predisposition to inflammatory recurrence.

23. *Socioeconomic factors*—The combined characteristics of an individual's social behavior, personal habits, and environment.

## ACKNOWLEDGMENTS

The publication of this study was made possible by a gift from the Ethicon Foundation. We wish to acknowledge the support given this project by The Dawn Society, The Odd Fellows, the Clinical Laboratories San Francisco General Hospital, the Biometry Section NINDS National Institutes of Health.

We also wish to thank the individuals who participated actively in major aspects of this study: M. A. Coon, K. M. Sugai, F. B. Brescia, B. Goldfeller, M. R. Sucec, G. Fujimoto, K. E. Jones, D. Longenacker, and 27 University of California eye residents who have rotated through the several eye services during the course of this work.

All electron microscopy identifications in this study were performed by C. R. Dawson, M.D. All bacteriologic identifications were performed by W. K. Hadley, M.D. Statistical evaluation was conducted throughout these studies by William Weiss (Chief), Jerome Deutschberger (deceased), and Eileen Jackson of the Office of Biometry, National Institute of Neurological Diseases and Stroke, Bethesda, Maryland.

## THE PRECISION MICROSCOPE THAT'S AS MANEUVERABLE AS YOU ARE

Your delicate movements during surgery require you to **move about freely.** So you've passed up table or floor mounted microscopes to retain your mobility.

Now, the XONIX STEREOSCOPE* — the quality binocular microscope **you control like a loupe.** To bring a subject into focus, you merely move your head. A glance below the oculars gives you an unobstructed, unmagnified view of the field. **Your hands are completely free** — no fiddling with adjustments during surgery.

**Self-contained coaxial light system** pinpoints the subject with 1500 foot-candles of **cool illumination,** which you'll find particularly useful when operating in cavities.

Interchangeable oculars provide various magnifications, such as 6X, with exceptional optical clarity and resolution. The optical system was **computer-designed** specifically for this instrument.

Comfortable headpiece is **chamois-lined** to absorb moisture and **foam-padded** to provide a soft cushion. You can even wear the XONIX STEREOSCOPE **with your regular glasses** without sacrificing field size.

**THE XONIX STEREOSCOPE — DESIGNED FOR THE SURGEON WHO WANTS THE SAME MANEUVERABILITY WITH HIS MICROSCOPE AS HE HAS WITH HIS HANDS.**

## GENERAL

Address manuscripts and other scientific communications to Frank W. Newell, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Manuscripts must be original material submitted solely to the AMERICAN JOURNAL OF OPHTHALMOLOGY. Two original typed copies must be submitted. The entire manuscript, including case reports, footnotes and references, must be typed in double space, with wide margins, on 8½ by 11-inch heavy white bond paper. See Suggestions to Authors (Am. J. Ophth. **70**: Advertising pages 85–88, December, 1970).

Author's proofs must be corrected and returned with 48 hours to Manuscript Editor, 160 East Grand Avenue, Chicago, Illinois 60611.

Fifty reprints of each article will be supplied to the senior author without charge. Additional reprints may be obtained from Ophthalmic Publishing Company, 160 East Grand Avenue, Chicago, Illinois 60611, if ordered at the time proofs are returned.

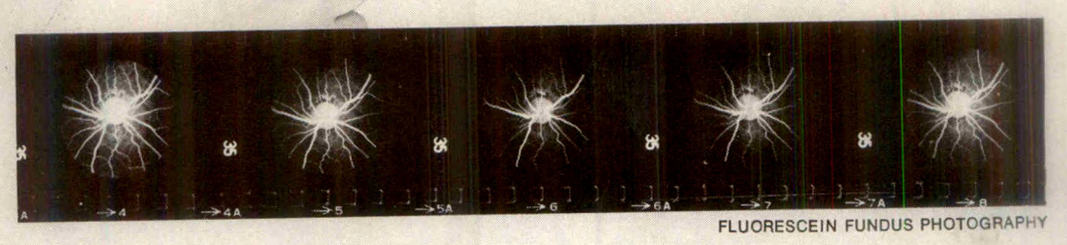
Address news items and society proceedings to Thomas Chalkley, M.D., 700 North Michigan Avenue, Chicago, Illinois 60611.

Exchange copies of medical journals should be sent to David Shoch, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Subscriptions, requests for single issues, notices of changes of addresses, advertising, and other communications should be sent to 160 East Grand Avenue, Chicago, Illinois 60611.

Change of address notices must be received at least 60 days in advance and must include both old and new addresses.

Claims for copies lost in the mail must be received within 60 days from the date of issue.



Advertisement insertion orders and copy must be received before the first day of the preceding month for which the advertisement is scheduled.

# Kowa RC-2

## fundus camera

*The simple approach to fundus and fluorescein photography.*

FLUORESCEIN FUNDUS PHOTOGRAPHY

To be fully meaningful to the medical profession, all instrumentation must function as an extension of the user's eyes, hands, and mind. The Kowa RC-2 fundus camera fully embodies this principle.

• *Fundus and External Photography* The basic RC-2 incorporates every conceivable advance in optics, mechanics, and electronics. Standard are built-in flash, 2X magnifying lens, automatic frame numbering for patient coding, and more. It will produce impeccable 35mm results even for inexperienced users.

• *Fluorescein Photography* By simply adding an auto-wind back, filters, and a quick-cycling power unit, the RC-2 becomes a flawless fluorescein photographic instrument.

• *Polaroid® Photography* An attachment gives you 60-second fundus photographs.

To see why the *total systems approach* has made Kowa's RC-2 the standard by which all others are measured, contact the representative in your area.

# It's been helping to save sight for a long time

And DIAMOX does not interfere with other forms of glaucoma therapy which influence the outflow mechanism. In fact, a complementary effect may be obtained when DIAMOX is used in conjunction with miotics.

Treatment with DIAMOX may retard progress of glaucoma by reducing secretion of aqueous humor and thus intraocular pressure. With DIAMOX SEQUELS, acetazolamide is slowly released, and concentrations peak at 8 to 12 hours. A single dose may provide a therapeutic effect for as long as 18 to 24 hours. It is thus possible to maintain the inhibitory effect on aqueous humor formation with a twice-daily regimen . . . an important consideration for the patient's rest and for minimization of side effects.

**DIAMOX®**
ACETAZOLAMIDE
**SEQUELS®** 500 mg
Sustained Release Capsules

**Contraindications**—Situations in which sodium and/or potassium serum levels are depressed, in kidney and liver disease or dysfunction, suprarenal gland failure and hyperchloremic acidosis. Long-term administration is contraindicated in chronic noncongestive angle closure glaucoma.

**Warning**—Although teratogenic and embryocidal effects demonstrated in mice at more than ten times the equivalent therapeutic doses have not been evidenced in humans, DIAMOX Acetazolamide should not be used in pregnancy, especially during the first trimester, unless the expected benefits outweigh these potential adverse effects.

**Precautions**—Increasing the dose may increase drowsiness and paresthesia and decrease diuresis. Reactions common to sulfonamides may occur: fever, rash, crystalluria, renal calculus, bone marrow depression, thrombocytopenic purpura, hemolytic anemia, leukopenia, pancytopenia, agranulocytosis. If such occur, discontinue drug and institute appropriate therapy.

**Side Effects**—During short-term therapy: paresthesias, loss of appetite, polyuria, drowsiness, confusion. In long-term therapy an acidotic state may supervene. Transient myopia has been reported. Other occasional reactions: urticaria, melena, hematuria, glycosuria, hepatic insufficiency, flaccid paralysis, convulsions.

Cryophake®
Firm grip
with a
light touch

# Cryophake®

Sterile/Disposable Cryoextractor

Developed by R. David Sudarsky, M.D.

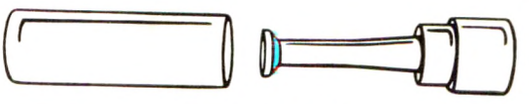
## for a firm grip with a light touch

### All the advantages of cryoextraction with Cryophake

Reduces incidence of capsule rupture[1-5]
Facilitates intracapsular extraction[2,3,4,5]
Reduces likelihood of vitreous loss[1,2,5]
Reduces trauma and postoperative complications[1-5]
Permits a wide variety of surgical techniques[3]

### All these surgical benefits with Cryophake

Selective defrosting . . . accidental adhesions easily freed without loosening bond on lens
Ready for immediate use, self contained, easily activated
Compact, hand-contoured design for 'in use' comfort
Lightweight and maneuverable
Small tip for maximum visualization
Pre-sterilized to minimize chance of infection
Disposable and inexpensive



**Cryophake** . . . for all your cataract surgery

**PHONE: (614) 452-4787**

Specific for
Herpes Simplex Keratitis

**STOXIL®**
**brand of IDOXURIDINE**

the only brand of IDU
available in two forms:
Solution—Ointment

Both now available in Canada

# The choice is yours

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.

**Description: 'Stoxil' Ophthalmic Solution** contains idoxuridine (5-iodo-2'-deoxyuridine) **0.1% (1 mg./cc.)** in distilled water. Preserved with thimerosal, 1:50,000. **'Stoxil' Ophthalmic Ointment** contains idoxuridine **0.5% (5 mg./Gm.)** in a petrolatum base. (White petrolatum and liquid petrolatum are inactive ingredients.)

**Contraindications:** Contraindicated in patients with known or suspected hypersensitivity to any of its components.

**Precautions:** Some strains of herpes simplex appear to be resistant. If there is no response in *epithelial infections* after 7 or 8 days of treatment, other forms of therapy should be considered.

The recommended frequency and duration of administration should not be exceeded.

'Stoxil' is not effective in corneal inflammations in which the virus is not present.

Corticosteroids are usually contraindicated in herpes simplex keratitis.

Boric acid should not be used during the course of the therapy.

'Stoxil' Ophthalmic Solution should not be mixed with other medications.

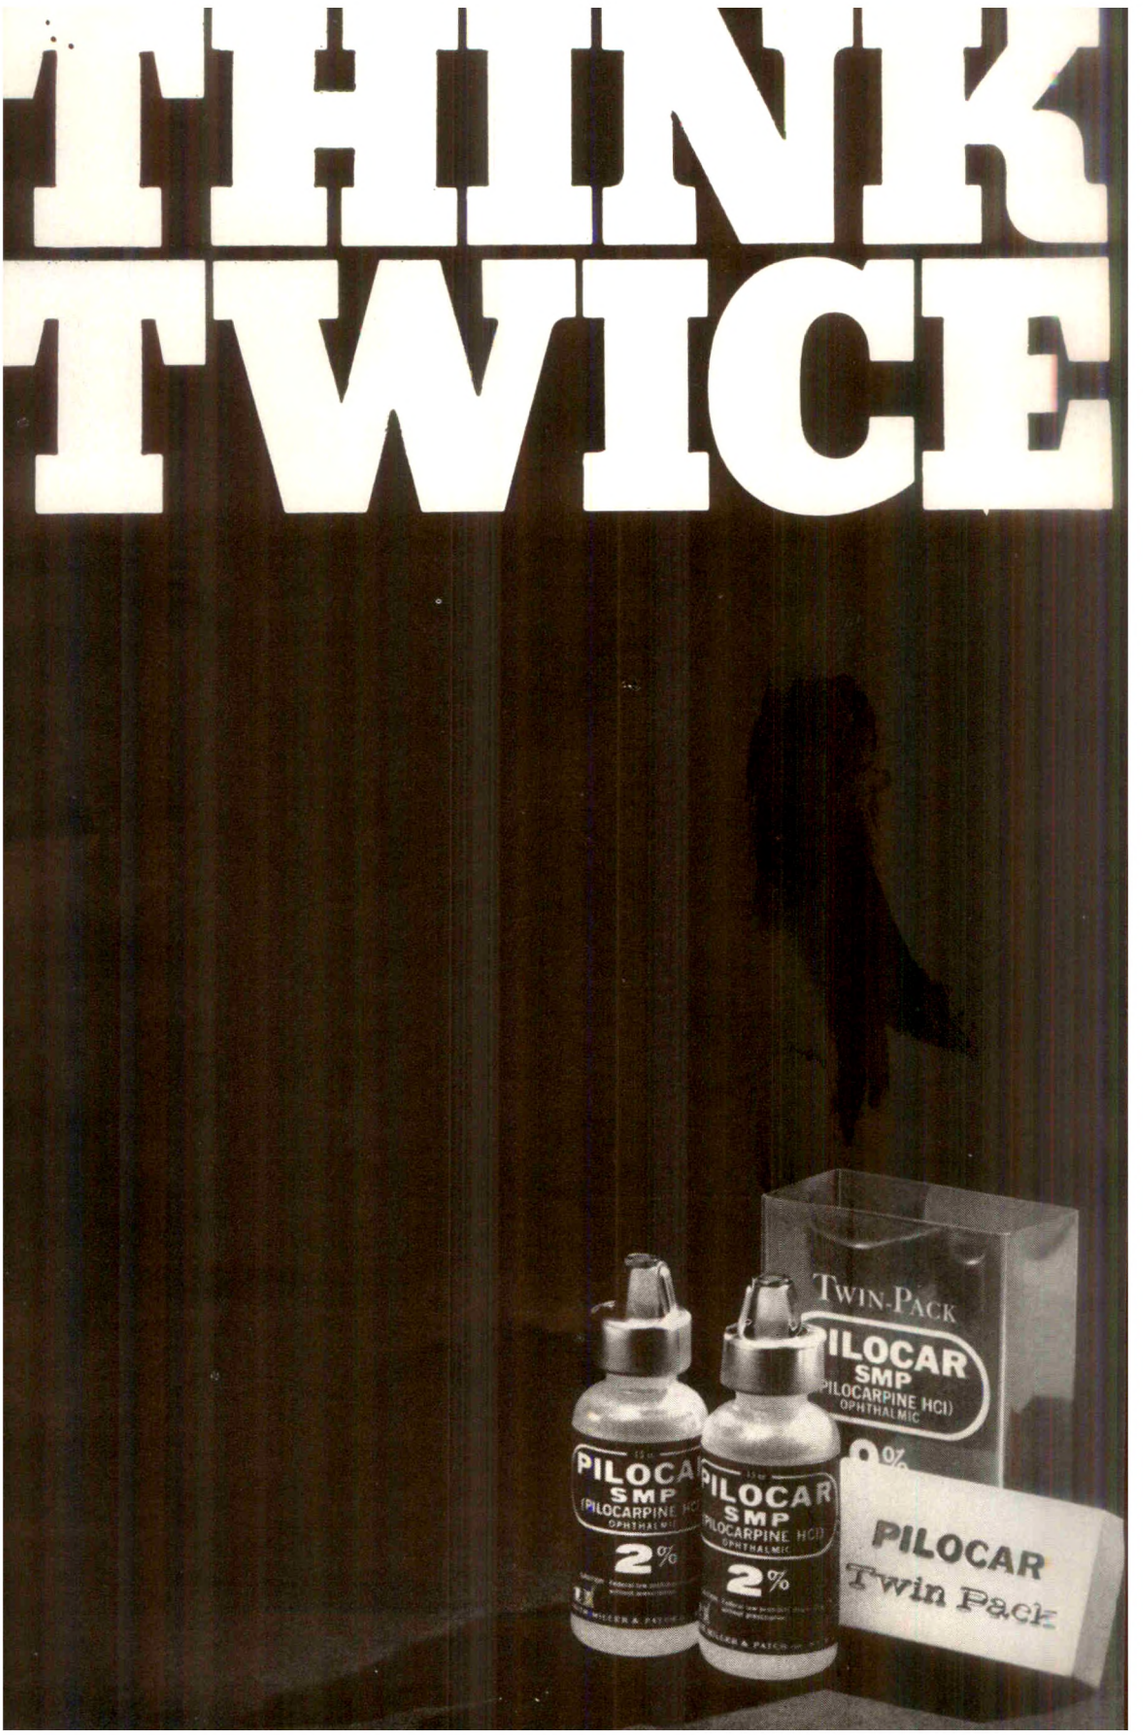
**Adverse Reactions:** Occasionally, irritation, pain, pruritus, inflammation, edema of eye or lids and, rarely, allergic reactions have been reported. Photophobia has occurred. Occasionally corneal clouding, stippling and small punctate defects in the corneal epithelium have been observed. The punctate lesions may be a manifestation of the infection.

**How Supplied:** 0.1% Ophthalmic Solution (1 mg./cc.), in 15 cc. bottles with dropper; 0.5% Ophthalmic Ointment (5 mg./Gm.) in 4 Gm. tubes.

**Stability:** The Ophthalmic Solution should be stored in refrigerator until dispensed. 'Stoxil' Ophthalmic Ointment does not require refrigeration.

SK&F Smith Kline & French Laboratories

# A single control...



# for streak focus and rotation.

This AO Ful-Vue® Streak Retinoscope features new fingertip control for faster, easier streak retinoscopy. The streak is easily controlled, can be rotated continuously, focused over a wide range (covering convex to concave mirror effects), and varied in width. All in one single motion. Thanks to the full-aperture high-reflection mirror, the streak is always clear, always correct. There's no distortion. No disturbing "central shadow." Ask your authorized AO instrument distributor or AO sales representative for a demonstration of the AO Ful-Vue Streak Retinoscope.

# At her age, she's entitled to see.

One of the most tragic infirmities of age is that of failing vision. It is a precious gift to an oldster when the services of ophthalmologist and dispenser can be combined to enable her to read once again . . . to sew, perhaps . . . to see the faces of her family and friends.

Here, the dispensing optician serves a vital function, for the ophthalmologist's prescription must be perfectly interpreted in order to provide the patient with as much vision as possible.

The Guild Optician, by the very nature of his excellent capabilities in this area, is well qualified to handle subnormal vision cases. If he didn't have these capabilities, he wouldn't be a Guildmember.

This is one of the reasons we believe a Guild Optician is best qualified to serve the ophthalmologists' dispensing needs.

# There is still nothing like it.

The superb Donaldson* Stereo-Camera is still the standard of quality that all others try to match. None has yet.

And quality means more than precision construction. The Donaldson is simple to use — you concentrate on the subject, not on complicated controls. It is versatile — you can use it for close-up photography as you would an ordinary 35mm camera. It is a complete system — with an available drum viewer, strip viewer, and single slide viewer.

As for processing, we simplify that too — both developing and mounting if you wish. And last but not least, the Donaldson Stereo-System is now available without delay. Write today for a full description and ordering information. Mentor Division, Codman & Shurtleff, Inc., Randolph, Massachusetts 02368.

## BRITISH JOURNAL OF OPHTHALMOLOGY

This Journal publishes original articles on every aspect of the ophthalmological sciences by practising ophthalmologists and research workers all over the world. While welcoming reports on experimental work, the editors nevertheless pay special attention to the practical problems of eye disorders and their treatment, to give as much help as possible to ophthalmic surgeons and all concerned with clinical ophthalmology. All articles are in English and carry summaries wherever appropriate.
Book reviews, shorter notes, and correspondence also appear at frequent intervals.

*Published Monthly* *Annual Subscription $26.50*

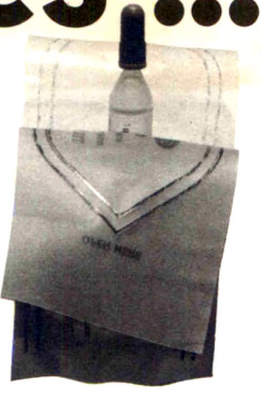
## OPHTHALMIC LITERATURE

OPHTHALMIC LITERATURE is the key to virtually all published information on ophthalmology. Each issue consists of carefully prepared, informative abstracts in English of relevant articles in medical and scientific journals throughout the world; each abstract is classified under one of forty specific headings, with cross references where necessary. Summaries of new books and new editions on the subject are included under the appropriate headings. An author index is also included in each issue.

In its comprehensiveness OPHTHALMIC LITERATURE is unique among abstracting journals in the world.

*Six issues a year, plus index* *Annual Subscription $26.50*

*These two world famous ophthalmic journals can be ordered at the special combined subscription rate of: $45.50*



**Subscriptions in the United States can be ordered through the BRITISH MEDICAL JOURNAL, 80 Brighton Avenue, Boston, Mass., 02134.** Subscriptions for all other countries should be ordered direct from the Subscription Manager.

Cooper COOPER LABORATORIES, INC. WAYNE, NEW JERSEY 07470

**Composition:**

**Inflamase**

*Prednisolone Sodium Phosphate .....0.125%
(Equivalent to Prednisolone 0.1%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

**Inflamase Forte**

*Prednisolone Sodium Phosphate 1.0%
(Equivalent to Prednisolone 0.8%)
Benzalkonium chloride .....0.01%

In an aqueous buffered isotonic solution containing disodium ethylenediaminetetraacetate, mono and dibasic sodium phosphate, and sodium chloride.

Prednisolone Sodium Phosphate is a water soluble inorganic ester of prednisolone. It is approximately 2,000 times as soluble in water at 25°C. as is hydrocortisone.

*Licensed under patent #3,134,718.

**Indications:** Inflamase and Inflamase Forte ophthalmic solutions may be used effectively in the following conditions of the anterior segment of the eye: superficial keratitis, including punctate epithelial lesions (Thygeson type), phlyctenular keratoconjunctivitis, and Sjogren's keratoconjunctivitis (with systemic steroids); deep keratitis, including interstitial or parenchymatous keratitis, acne rosacea, sclerosing keratitis; herpes zoster opthalmicus (do not use in herpes simplex); non-purulent conjunctivitis, including vernal, allergic, catarrhal; iridocyclitis; acute iritis; recurrent marginal ulceration, whether endogenous or due to atopic or contact allergies, or microbial allergy; corneal injuries, such as aseptic thermal, radiation, or chemical burns and corneal injuries following surgery or the penetration of foreign bodies; lid allergy; and non-purulent blepheritis, including catarrhal and allergic.

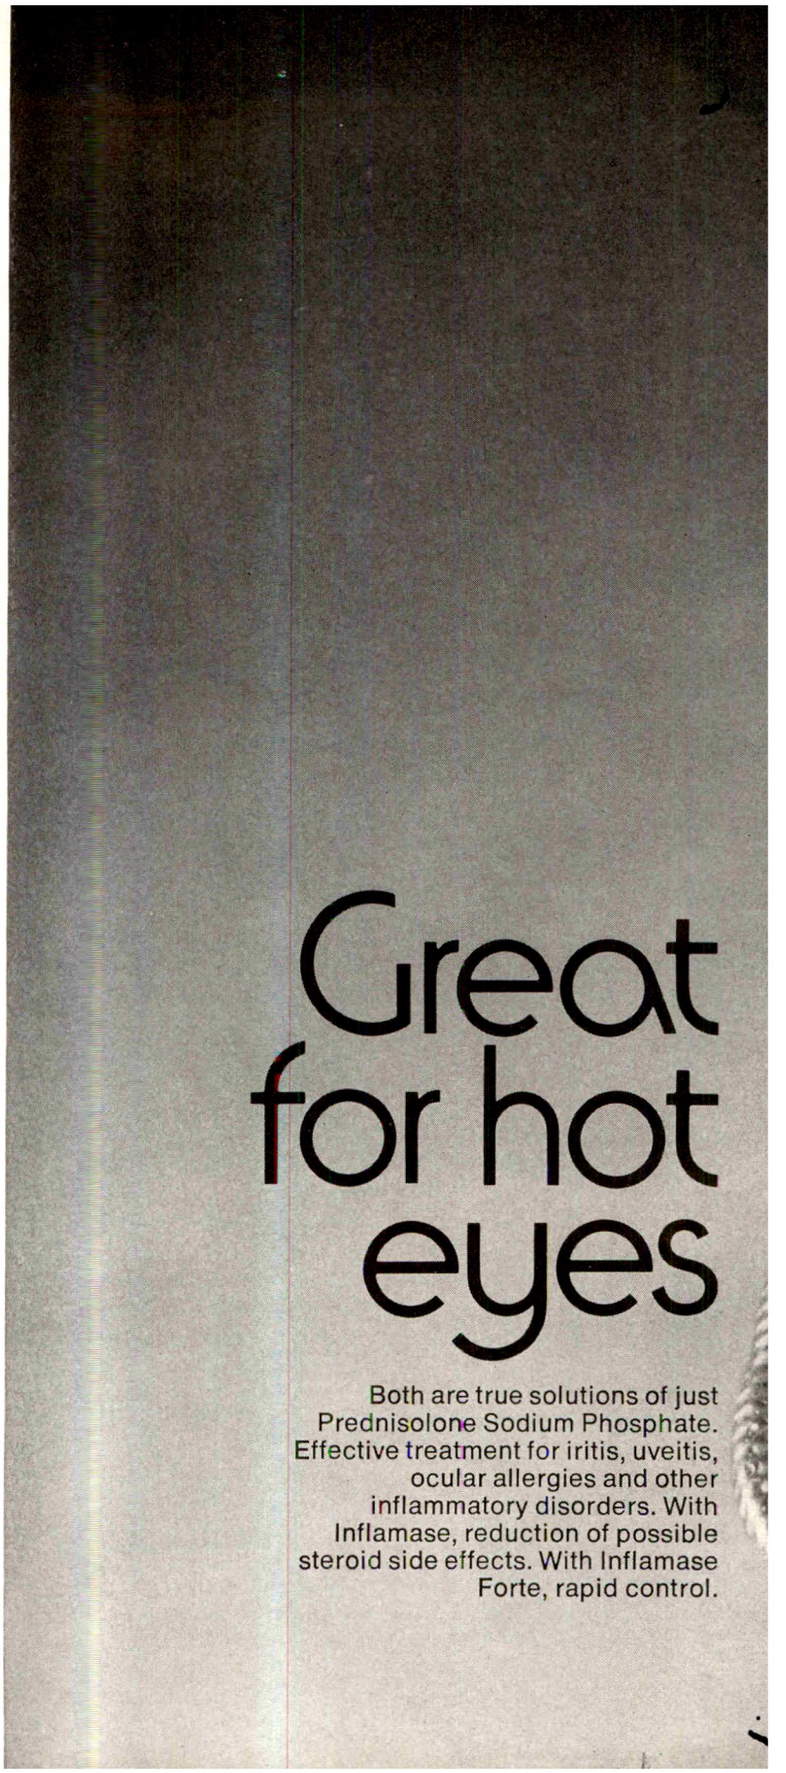
Inflamase and Inflamase Forte ophthalmic solutions have their principal effect on the anterior segment of the eye (cornea and the anterior uvea), with acute disorders responding more favorably than chronic disorders. Inflamase Forte 1% solution is recommended for moderate to severe inflammations particularly when rapid control is desired. In stubborn cases of anterior segment eye disease, systemic adrenocortical hormone therapy may be required. When the deeper ocular structures are involved, systemic therapy is necessary.

**Dosage:** Initially, 1 or 2 drops placed in conjunctival sac every hour during day and every 2 hours during night until improvement occurs. Thereafter, 1 or 2 drops 2 to 4 times daily.

**Contraindications:** Contraindicated in acute herpes simplex, ocular tuberculosis, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva; fungal diseases of the eye. Purulent conjunctivitis, purulent blepharitis, and infectious conditions are contraindications to the use of steroids.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.

**Warning:** If irritation persists or develops, patient should be advised to discontinue use and consult prescribing physician.



**How Supplied:** 5 cc plastic squeeze bottle with dropper tip. These products are sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area, or other areas with the dropper tip of the bottle. Keep bottle tightly closed when not in use.

Store in cool place. Protect from light.

**Caution:** Federal law prohibits dispensing without prescription.

**Smith, Miller & Patch, Inc.**

401 Joyce Kilmer Avenue
New Brunswick, N.J. 08903

# Great for hot eyes

Both are true solutions of just Prednisolone Sodium Phosphate. Effective treatment for iritis, uveitis, ocular allergies and other inflammatory disorders. With Inflamase, reduction of possible steroid side effects. With Inflamase Forte, rapid control.

**Inflamase**
for most inflammations.

**Inflamase Forte**
for the tough ones.

# COVELLI CRYOEXTRACTOR

FOR CATARACTS

*Now available...*

## NO MORE ACCIDENTAL ADHESIONS!

ONCE YOU GRASP THE LENS, AT NO TIME DOES THE IRIS OR ANY OTHER TISSUE ADHERE TO THE PROBE, EVEN WHEN THERE IS DIRECT CONTACT!. THIS EXCEPTIONAL ADVANTAGE IS DUE TO ITS SPECIALLY DESIGNED TIP.

OTHER IMPORTANT ADVANTAGES:

- Thin tip (2.75 mm.) with special shape for better visibility.
- Light weight (11 g.) Just like your ball pen.
- Heat - resistant, so it can be autoclaved repeatedly.
- Durable, it can be used a great number of times.
- Rechargeable, uses gas *"FREON" 12; commercially available.
- Low price.

# Neosporin®

## Ophthalmic Solution, Sterile

polymyxin B–neomycin–gramicidin

Each cc. contains: Aerosporin® brand Polymyxin B Sulfate 5000 units; Neomycin Sulfate 2.5 mg. (equivalent to 1.75 mg. of neomycin base); Gramicidin 0.025 mg., in aqueous saline solution isotonic with tears, containing the inactive ingredients alcohol (0.5%), propylene glycol, polyoxyethylene polyoxypropylene compound, sodium chloride, and purified water (preservative: thimerosal 0.001%). Bottles of 10 cc. with sterile dropper.

## eradicates bacterial conjunctivitis and other eye infections due to susceptible organisms–

- highly effective against almost all pathogens which invade the eye, including *Pseudomonas* and *Staphylococcus aureus*
- bacterial resistance rarely develops on repeated or prolonged use
- low allergenicity
- also available: Neosporin® Ophthalmic Ointment—Each gram contains: Aerosporin® brand Polymyxin B Sulfate 5000 units; Zinc Bacitracin 400 units; Neomycin Sulfate 5 mg. (equivalent to 3.5 mg. neomycin base) in special white petrolatum q.s. In ⅛ oz. tubes with ophthalmic tip.

*Precaution:* As with other antibiotic preparations, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs. Articles in the current medical literature indicate an increase in the prevalence of persons allergic to neomycin. The possibility of such a reaction should be borne in mind.

*Contraindications:* This product is contraindicated for subconjunctival or intraocular injection, or for irrigation of fistulous tracts. This product is also contraindicated in those individuals who have shown hypersensitivity to any of its components.

Complete literature available on request from Professional Services Dept. PML.

Wellcome

**Burroughs Wellcome Co.**
Research Triangle Park

*THE TISSUE-FRIENDLY*

# SUPRAMID EXTRA®

**SUTURE.** Polyfilament but neither braided nor twisted. New cable-type construction with several strands enclosed in a perfectly smooth cover of the same material, gives great pliability and superior strength. Strong as steel wire, handles as silk. No stitch irritation, no growth of tissue into suture. Sizes 10-0 to 8.

**SPECIAL NEEDLES:** Our CT needle for cataracts (wire size 0.30mm, length 9mm), CA needle for corneal work (wire size 0.30mm, length 6mm), and EX needle for special keratoplasties (wire size 0.2mm, length 5mm), a flattened reverse cutting needle to prevent "leaking wounds," equal to the smallest hand made eyed needles No. 82F, **and finally the smallest spatula needle on the market, length 5 millimeters, wire size 0.2mm, double armed with 10-0, 9-0 and 8-0 black Supramid Extra. Code Nos. 2SC-100, 2SC-90 and 2SC-80.**

**A NEW PRODUCT:** Implants—Sleeves (Tubes) for preventing adhesions in Eye Muscle Surgery. Method development by Edward A. Dunlap, M.D. Reference: Dunlap, Edward A.: Plastic Implants in Muscle Surgery, Archives of Ophthalmology, 80: 249-257, August 1968.

**TUBING.** *Fully inert because it is made of the same material as the suture;
* Thinnest walls of any surgical tubing, fully transparent and can be *repeatedly* autoclaved;
* Most economical. It is in your interest to compare prices and quality.

**FOIL.** Excellent results with our suture created the demand for Foil for plastic and reconstructive surgery in such cases as orbital fractures, lid reconstruction, etc. Foil is chemically identical with the sutures, thus just as inert when buried in the tissue.

Available in thickness from 0.05mm to 2.00mm, in sheets 15 x 20cm.

Can be steam-autoclaved, cut to size, and carved to shapes and forms.

E. WILLIAM TILLYER

## Aspheric Cataract Lenses

Of all the work done in optics for the betterment of vision, perhaps the most spectacular is the development of aspheric cataract lenses. Nowhere can I recall such dramatic improvement in the quality of vision as that which occurs when properly developed aspheric curves are used in place of spherical curves in the aphakic patient's prescription.

The patient's reaction, of course, is the ultimate criterion. But the advantages of the aspheric curves can be proved mathematically.

For instance, a +14.00 sphere, if made up in a spherical curve with a —3.00 D inside curve, has the following Rx at 15mm away from the center of lens:

$$+14.16 = +2.14$$

The aspheric lens of the same power has an Rx at 15mm away from the center of:

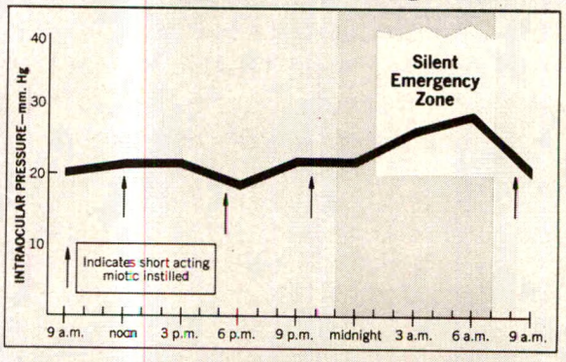
$$+14.31 = -.75$$

This is quite a dramatic reduction in the marginal error. It is no wonder so many patients are extremely pleased with their new aspheric lenses!

But just being an aspheric lens does not make all the difference. One cannot use the same aspheric curve for all Rx's and still get these same results. The marginal effects of each power of sphere combined with each cylinder must be computed. Then a determination can be reached of the best aspheric curves for the individual power required.

We use 29 different base curves in the range from plus 8.00 D to plus 20.00 D. Only with this minimum can we achieve what we consider the ultimate results.

This seems like a lot of changes—more than one for every half diopter change in Rx power. But it gives the patient better vision every time.



There are other areas where improvements have been made in lens design which are extremely important. But I, personally, still believe that none are as dramatic as the vision given the aphakic patient—by the use of a true aspheric series of cataract lenses.

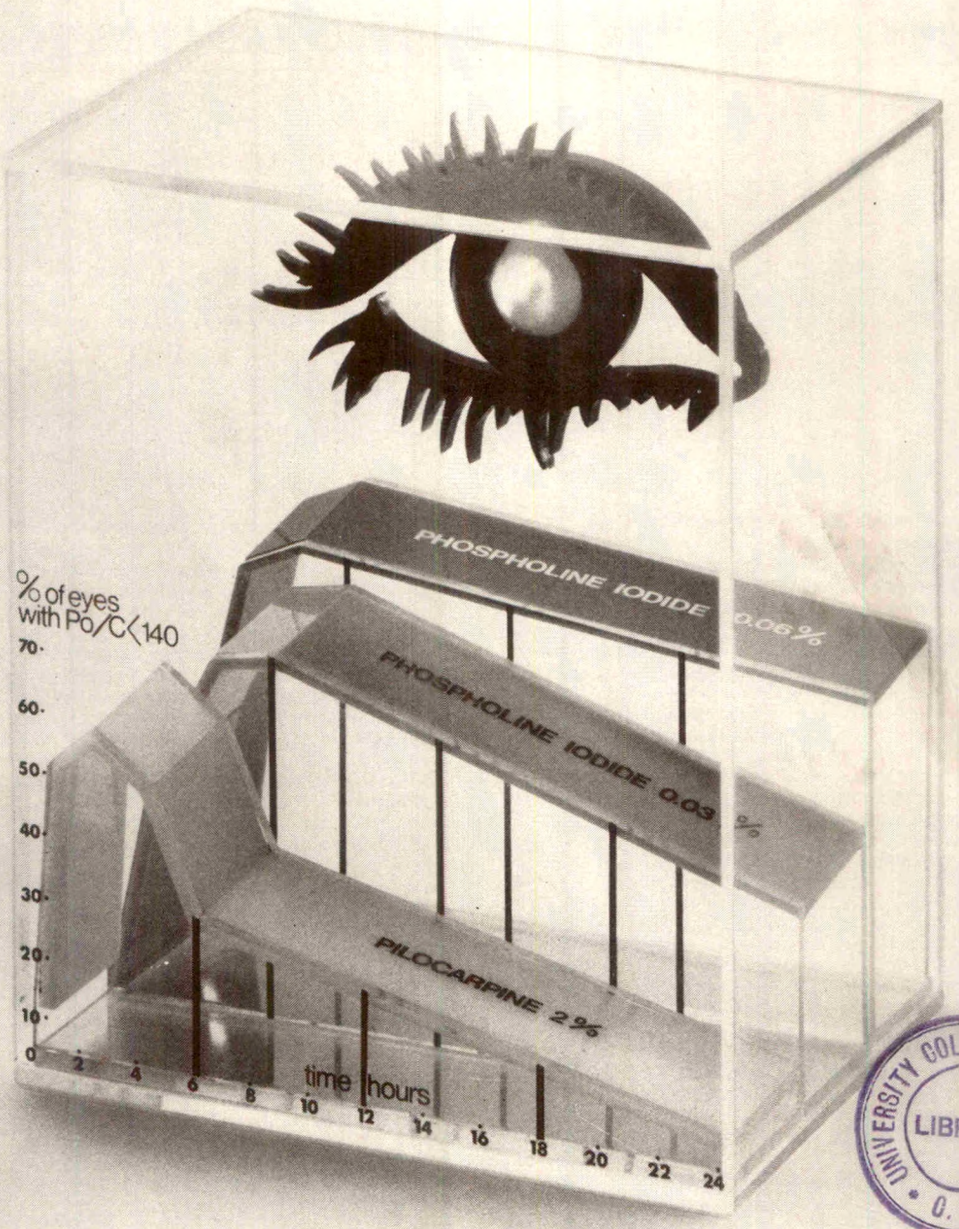
# Not more potent, but longer acting*...

PHOSPHOLINE IODIDE 0.03% and 0.06% were compared with pilocarpine 2% in a study of the time course of changes in outflow facility and intraocular pressure after single dose administration in patients with open-angle glaucoma. While Phospholine Iodide 0.06% showed little diminution in effect on intraocular pressure after 24 hours, the effect of pilocarpine 2% declined markedly in the first few hours, and was almost completely dissipated after 24 hours. The action of Phospholine Iodide 0.03% was intermediate between that of pilocarpine 2% and Phospholine Iodide 0.06%.

## An important consideration in the management of glaucoma



When treated with short acting miotics, the patient with open-angle glaucoma runs the risk of an undetected intraocular pressure buildup during the night—a "silent emergency."

The longer acting Phospholine Iodide® (echothiophate iodide) may protect against this nightly insult. A single instillation of the 0.03% or 0.06% strength before retiring will act through the critical hours, and is especially recommended when you have found pilocarpine to be inadequate.

When initiating therapy... Phospholine Iodide 0.03% can often maintain 24 hour control of intraocular pressure with a single instillation at bedtime. It provides a smooth transition to the higher strengths—0.06%, 0.125%, 0.25% —when necessary. When indicated, epinephrine or carbonic anhydrase inhibitors may be prescribed with any strength of Phospholine Iodide.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide for ophthalmic solution)

UNIVERSITY COLLEGE OF MEDICINE
LIBRARY
O. U.

Effect of Phospholine Iodide and pilocarpine on intraocular pressure control.

*Adapted from Barsam, P. C., Boston U. School of Med.: Time Curves of the Effect of Miotics on Intraocular Pressure and Outflow Facility, Scientific Exhibit, Annual Convention, American Academy of Ophthalmology and Otolaryngology, Las Vegas, Oct. 5-9, 1970.

See next page for Brief Summary of prescribing information.

# PHOSPHOLINE IODIDE®
## (echothiophate iodide)

for 24 hour control in chronic simple (open-angle) glaucoma and glaucoma secondary to aphakia

just 1 or 2 instillations a day
- for long lasting effect on ocular tension—
helps protect against a "silent emergency" at night
- may be substituted for the bedtime dose of a short acting miotic
that controls intraocular pressure by day, but
fails to provide adequate control during the night and early morning
- choice of four strengths for individualized therapy—
may be used alone or as a complementary agent

**BRIEF SUMMARY (for full prescribing information, consult package circular)**
**Phospholine Iodide® (echothiophate iodide)**
**In Management of Chronic Simple (Noncongestive) and Aphakic Glaucoma/Concomitant Esotropia**

**Contraindications:** This medication is contraindicated in acute (congestive) angle closure glaucoma, but may be useful in the subacute or chronic stages after iridectomy or where surgery is refused or contraindicated. It is also contraindicated in glaucoma associated with iridocyclitis. It should be prescribed only after consultation with the patient's internist or surgeon in the presence of bronchial asthma, gastrointestinal spasm, urinary tract obstruction, vascular hypertension, myocardial infarction, and Parkinson's disease.

**Warnings:** Therapy should be temporarily discontinued if (otherwise unexplainable) persistent diarrhea, profuse sweating, or muscle weakness occurs. Succinylcholine should not be used concomitantly. In patients with myasthenia gravis, only specialists who are aware of the likelihood of drug interactions should employ PHOSPHOLINE IODIDE (echothiophate iodide) concomitantly with neostigmine, ambenonium, pyridostigmine, or edrophonium.

**Use in pregnancy:** Not established is safe use in pregnancy, nor absence of adverse effects on fetus or on respiration of neonate. Administration in pregnancy requires weighing potential benefits against potential hazards.

**Precautions:** Patients regularly exposed to pesticides of the organophosphate or carbamate class should be cautioned to observe all protective measures recommended in their handling.

**Minor side effects** *(patient to be alerted):* Initially, brow-ache, dimness of vision, blurring, or ciliary and conjunctival injection may occur, but usually disappear after 5 to 10 days of treatment.

**Other side effects:** *(local)* Iris cysts occur occasionally in adults, but fairly frequently in children. Pigmented cysts of the ciliary epithelium have been noted. Retinal detachment has occurred, and the medication should be used with extreme caution, if at all, if there is a history of this disorder. It may cause or activate acute iritis. Posterior synechiae may develop. Recent controlled clinical studies have shown that PHOSPHOLINE IODIDE (echothiophate iodide) therapy may be a causative factor in the development of lens opacities in adult glaucoma patients. This phenomenon is apparently (a) *dose-related,* since it has not been observed with 0.03%, but only with the higher strengths; (b) *selective in character,* since some patients have tolerated many years of treatment with the highest strength of the drug without lens changes; (c) *age-related,* since lens opacities associated with this medication are virtually unknown in children; and (d) *species specific,* since attempts to produce comparable effects in experimental animals have been unsuccessful. Pupillary block may develop due to intense miosis together with vascular congestion, especially in eyes with narrow angles.

Resistance to the medication may appear in some patients after many months of therapy; usually the response can be restored by changing to another medication for a short time.

*(systemic)* Rarely, systemic effects may appear such as gastrointestinal spasm, nausea, vomiting, diarrhea, increased secretion of lacrimal, salivary or sweat glands, tightness in the chest, bradycardia, etc. Muscle weakness and one case of localized paresthesias have been reported. Lowering of blood cholinesterase level frequently occurs during long term therapy and is an indication of systemic absorption, not an adverse side effect.

**Antidotes:** Atropine, 2 mg. parenterally; PROTOPAM® CHLORIDE (pralidoxime chloride), 25 mg./Kg., I.V.; artificial respiration, if necessary.

**Supplied:** 1.5 mg. package for dispensing 0.03% solution; 3.0 mg. package for 0.06% solution; 6.25 mg. package for 0.125% solution; 12.5 mg. package for 0.25% solution. [Also contains potassium acetate (sodium hydroxide or acetic acid may have been incorporated to adjust pH during manufacturing), chlorobutanol (chloral derivative), mannitol, boric acid, and exsiccated sodium phosphate.]

# MUROCOLL EPINEPHRINE 1%

**As (L-Epinephrine Bitartrate 1.82%)** **PRODUCT #29½**

- Effective in maintaining lowered intraocular pressure in certain cases of open angle glaucoma by reducing the rate of aqueous formation.
- Improves the facility of outflow after prolonged therapy in more than 50% of eyes with open angle glaucoma.*
- Aids in breaking posterior synechiae in uveitis.

Murocoll Epinephrine 1% (as Bitartrate 1.82%) with Chlorobutanol 0.5% as a preservative and bacteriostatic agent is also available as Murocoll Epinephrine 2% (as Bitartrate 3.64%), Product #29.

Both solutions also have Sodium Bisulfite as preservative; Sodium Chloride and distilled water as inactive ingredients.

Above solutions are contraindicated in narrow angle glaucoma. Use with caution in presence of hypertension.

Available: 7.5 cc. glass bottle with plastic dropper. ℞ only

Patient does not have to refrigerate above solutions.

# THE 10 MOS
# QUESTIONS ABOU

## THE QUESTIONS

1. What makes PHOTOGRAY lenses work?
2. How fast do PHOTOGRAY lenses change?
3. Will the darkening-fading process wear out?
4. Do PHOTOGRAY lenses need breaking in?
5. Can PHOTOGRAY lenses be hardened or toughened?
6. How do PHOTOGRAY lenses work in a car?
7. In what types of lenses is PHOTOGRAY glass available?
8. Is the darkening-fading process comfortable to the wearer?
9. Do PHOTOGRAY glasses have a residual tint indoors?
10. Will PHOTOGRAY glass be available in a darker sunglass version?

**Note:** If you get asked other questions by your patients about PHOTOGRAY glasses that you think would be of broad interest, please send them to us. When we get enough new ones, we'll answer them in another ad.

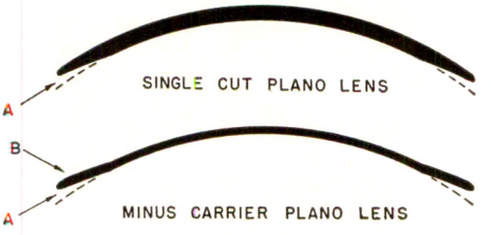
If you'd like complete technical information on PHOTOGRAY lenses, just write to: Corning Optical Products Dept., Corning, New York 14830.

# FTEN ASKED
# HOTOGRAY® LENSES.

## THE ANSWERS

1. PHOTOGRAY lenses are photochromic: sensitive to ultraviolet light. When sunlight strikes them, invisible microcrystals of silver halide become darkened. When the light is removed, the crystals clear again.
2. Quite rapidly. In 60 seconds the lens is 75% darkened by sunlight and virtually fully darkened in 5 minutes. Removed from sunlight the lens clears half way in 5 minutes and 75% in 20 minutes. At their darkest, PHOTOGRAY lenses have a light transmittance of 45%. When clearest they have a light transmittance of 85%.
3. No. The photochromic reaction is locked into the composition of the glass and is completely reversible. It will keep performing for a lifetime without changing its characteristics.
4. Yes. Several complete darken-fade cycles are needed to bring PHOTOGRAY lenses up to their normal operating performance.
5. Yes, Most definitely. PHOTOGRAY lenses can be heat-treated or tempered. The tempering time is slightly different from that needed for clear lenses. Corning publishes heat-treating tables that give settings for the more popular units available.
6. Not too well. The window glass will screen out a lot of the ultraviolet light which activates the photochromic property of the lenses. This keeps the glass from darkening as fully as when it is exposed to direct sunlight.
7. PHOTOGRAY lenses come in a full range of sizes—in both single-vision and 1 piece multi-focal types.
8. Yes. The process, while quite rapid, is gradual enough to be imperceptible to the wearer. This, combined with the protection given by the darkened glass, is why PHOTOGRAY is known as the "comfort glass".
9. Yes. It's a very light, hardly noticeable tint.
10. Yes. Corning is currently in the final stages of developing a sunglass companion to PHOTOGRAY glass. Called PHOTOSUN™ glass, it's a true variable sunglass. PHOTOSUN lenses will be ready for introduction shortly.

CORNING
OPTICAL PRODUCTS



# THE ULTRA-THIN MINUS CARRIER CONTACT LENS

A vexing fitting problem is the low-riding lens which does not move enough as the patient blinks, resulting in tear stasis and edema under the lens apex. This problem is more prevalent with the use of small thin lenses today, since there is less lid action exerted on them; thus less movement. It is most common with plus and low-minus (under −3.00) single-cut lenses, since their thickness and consequent weight pulls them down. Also, the steep outside radius minimizes the upward pull of the lids. The partial blinking patient has the greatest problem with such low-riding lenses, since his lids may not come down far enough to move the lenses, or may make just enough contact to force the lenses down even farther.

Past solutions to the problem have been: (1) "Blink training"; (2) Larger lens diameter, so that the lens edge would be held up under the upper lid, so that even slight blink action would give more lens movement and tear interchange. However, often neither measure was successful and lens wear was curtailed or discontinued.

The *ultra-thin MINUS CARRIER LENS* offers new hope for these patients. It can be made *thinner* than single-cut lenses, since plastic removed from the posterior surface by peripheral curves at "A", which requires increased center thickness in a single-cut lens, is instead replaced at the anterior periphery of the MINUS CARRIER LENS at "B" by using a *flat carrier curve* which is parallel to or even flatter than the posterior peripheral curve. Thus, *no increase* in center thickness is needed.

The MINUS CARRIER LENS attacks the problem of low riding in two ways: (1) Being *thinner and lighter,* there is less gravitational pull and better centering; (2) The *flat anterior periphery* provides more upward lid pull and lens movement.

This lens can be fitted using the small thin lens technique, or as a larger diameter lens. As it is thinner and tends to be tighter, the preferred fit is as a small (7.8 to 8.8 mm) intra-palpebral fissure lens, free of the upper lid except during the blink. Due to its *flat anterior periphery,* even a partial blink will pick up the lens if the lid comes down several millimeters over the lens edge. If it still rides too low, or if the blink is too slight to pick up the lens, a larger diameter MINUS CARRIER LENS that positions under the upper lid at all times should provide sufficient tear interchange, even with minimal blink action.

Most ophthalmic solutions start out sterile. But the OCUMETER® helps this one stay that way.
OCUMETER helps steroid solution stay sterile by eliminating a major cause of contamination —the eye dropper. Sterile, highly stable
Ophthalmic Solution
DECADRON®
Phosphate
(Dexamethasone Sodium Phosphate|MSD)
0.1% Dexamethasone Phosphate Equivalent
for mild acute iritis and nonpurulent conjunctivitis
For prescribing information, please see next page.

## for mild acute iritis and nonpurulent conjunctivitis

Not all steroid ophthalmic solutions stay sterile during the days and weeks of therapy. But this one is more apt to—Ophthalmic Solution DECADRON Phosphate (Dexamethasone Sodium Phosphate, MSD) in the OCUMETER® eliminates a common source of contamination—the eye dropper.

*Uniform dosage, drop after drop*

Each drop of Ophthalmic Solution DECADRON Phosphate contains the same dosage of steroid. And, with a gentle squeeze, the OCUMETER measures out one drop at a time. So your patient can conveniently get the steroid dose you want her to have, wherever she is.

Each cc. contains dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate. Also available as DECADRON® Phosphate Ophthalmic Ointment (0.05%); and as NeoDECADRON® Ophthalmic Solution containing dexamethasone sodium phosphate equivalent to 1 mg. (0.1%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base in each cc.; and NeoDECADRON® Ophthalmic Ointment, containing dexamethasone sodium phosphate equivalent to 0.5 mg. (0.05%) dexamethasone phosphate and neomycin sulfate equivalent to 3.5 mg. neomycin base per gram.

Sterile, highly stable
Ophthalmic Solution
**DECADRON®** Phosphate
(Dexamethasone Sodium
Phosphate|MSD)

CONTRAINDICATIONS: DECADRON and NeoDECADRON should not be used in the presence of infectious tuberculous lesions of the eye, chickenpox, early acute herpes simplex, vaccinia, the early acute stages of most viral diseases of the cornea and conjunctiva, acute purulent untreated infections of the conjunctiva and lids, suspected ocular or aural fungal infection, perforated ear drum. Sensitivity to components is also a contraindication.

PRECAUTIONS: DECADRON: Like all adrenal corticosteroids, may sometimes mask, activate, or enhance incipient infection. Whenever possibility of infection exists, suitable antibiotic agents or a steroid-antibiotic preparation (such as NeoDECADRON) should be considered. If infections do not respond promptly, therapy should be discontinued until the infection has been adequately controlled by other measures.

Systemic side effects may occur with extensive use of steroids. Rarely, ocular herpes simplex has been reported in patients receiving adrenocortical steroids systemically or locally in the eye for other conditions.

As with other corticosteroids, increased intraocular tension can follow extended local use (1-2 weeks or more) of dexamethasone sodium phosphate. Since increased intraocular tension can lead to loss of vision, this possibility should be kept in mind and topical administration used only under adequate tonometric supervision, particularly in patients known to have glaucoma, or whose family history includes glaucoma.

In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids. Reports in the literature indicate that, rarely, protracted use of topical corticosteroids in the eye may be associated with the development of posterior subcapsular cataracts. Hereditary and degenerative eye diseases in general do not show any response to treatment with these preparations.

Stubborn cases of anterior segment eye disease may require systemic adrenocortical hormone therapy. When the deeper ocular structures are involved, systemic therapy is necessary.

NeoDECADRON: A few individuals may be sensitive to one or more of the components of NeoDECADRON. If any reaction indicating sensitivity is observed, discontinue use. Sensitivity to neomycin may occasionally develop, especially when it is applied to abraded skin. Some reports in the current literature point to an increase in the number of persons sensitive to neomycin.

Use of any antibiotic agent may result in overgrowth of fungi or other organisms not susceptible to the antibiotic, necessitating prompt medical attention for such new infections.

As the safety of topical steroids during pregnancy has not been confirmed, they should not be used for extended periods during pregnancy.

**For more detailed information, consult your MSD Representative or see the Direction Circular. Merck Sharp & Dohme Division of Merck & Co., Inc., West Point, Pa. 19486**

**MSD** MERCK SHARP & DOHME

# BY ALL MEANS!

Armorlite originated the world's first hard resin lenses in 1947, and has been perfecting them ever since. We make more types of these modern lenses than any one else, and they have a reputation for unsurpassed quality. We make only hard resin lenses and we do it in earnest; they are not a side-line with us.

When you think patient care and protection, think Armorlites, by all means.

**ARMORLITE, INC.**

**Indications:** Relief and management of nonpurulent Blepharitis and Conjunctivitis.

**Dosage:** Initially, 1 or 2 drops placed in the conjunctival sac every hour until improvement occurs.

Thereafter, 1 or 2 drops 2 to 4 times daily.

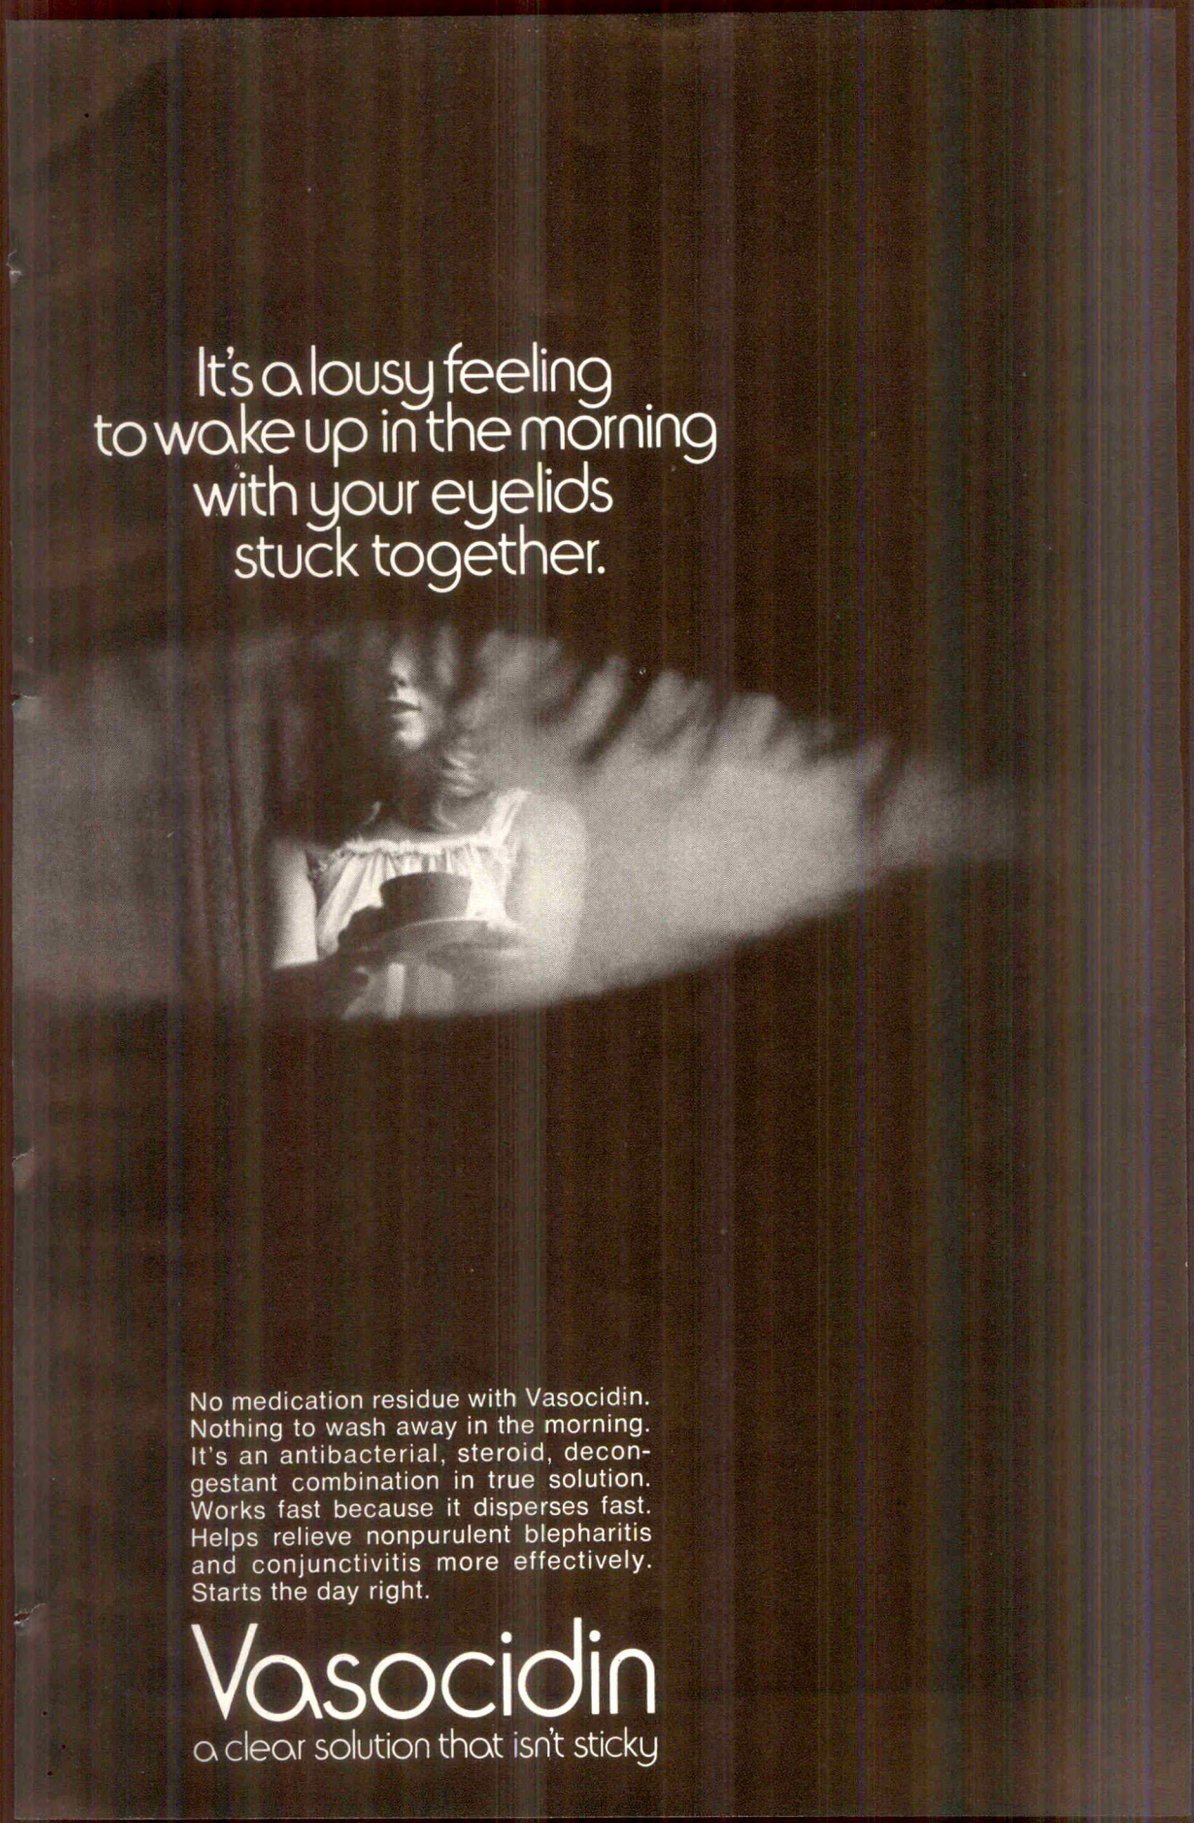
**Composition:**

Prednisolone-21-phosphate sodium .....0.25%
(Equivalent to Prednisolone 0.2%)
Sulfacetamide sodium ....10.0%
Phenylephrine HCl .....0.125%
Methylparaben .....0.02%
Propylparaben .....0.005%

In a stabilized aqueous solution containing sodium thiosulfate and *SMP-68 (a combination of polyoxypropylene compound and polysorbate 80).

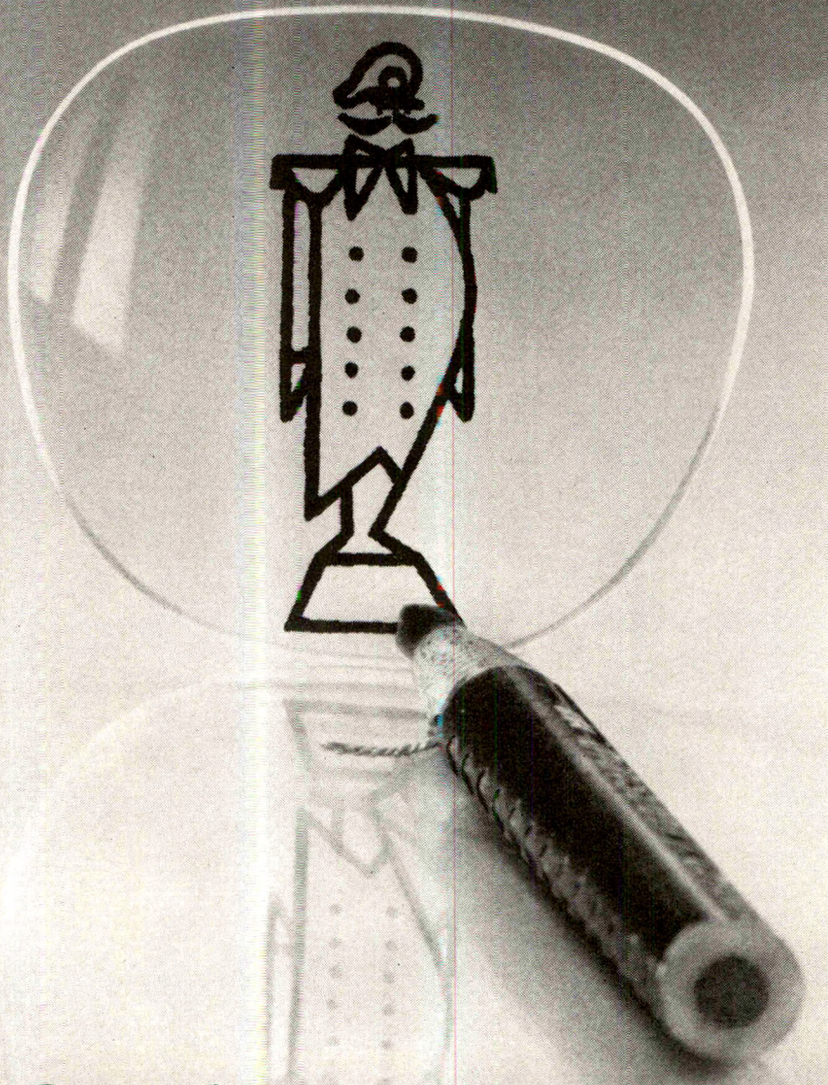
**Effectiveness:** The antibacterial spectrum of Vasocidin is particularly effective against the gram positive pyogenic cocci; E. coli, N. gonorrhoeae, Koch-Weeks bacillus and other bacteria susceptible to sulfacetamide. Because Vasocidin is a true solution, dosage is uniform and each drop is free of any irritating particles. The Vasocidin vehicle enhances the dispersion of active components. Sulfacetamide combats a wide range of pathogens; prednisolone reduces inflammatory reaction; phenylephrine relieves hyperemia. Local effects of active therapeutic agents appear to be prolonged by phenylephrine-induced vasoconstriction.

**Caution:** Federal law prohibits dispensing without prescription.



**Contraindications:** Steroids are contraindicated in dendritic ulcers (herpes simplex), vaccinia, varicella and most other viral diseases of the cornea and conjunctiva, as well as in fungal and tubercular ocular disease. Contraindicated in the treatment of purulent conjunctivitis or blepharitis. Should not be used by persons with narrow-angle glaucoma or those sensitive to sulfonamides. If irritation persists or increases, discontinue use and consult physician.

**Side Effects:** Extended use of topical steroid therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. In those diseases causing thinning of the cornea, perforation has been known to occur with the use of topical steroids.



Vasocidin is sterile when packaged. To prevent contaminating the dropper tip and solution, care should be taken not to touch the eyelids or surrounding area with the dropper tip of bottle. Keep container tightly closed.

**Supplied:** Plastic dropper-tipped vials, 5 cc.

**Smith, Miller & Patch, Inc.**
401 Joyce Kilmer Avenue
New Brunswick, N.J. 08902

It's a lousy feeling
to wake up in the morning
with your eyelids
stuck together.
No medication residue with Vasocidin.
Nothing to wash away in the morning.
It's an antibacterial, steroid, decon-
gestant combination in true solution.
Works fast because it disperses fast.
Helps relieve nonpurulent blepharitis
and conjunctivitis more effectively.
Starts the day right.
Vasocidin
a clear solution that isn't sticky

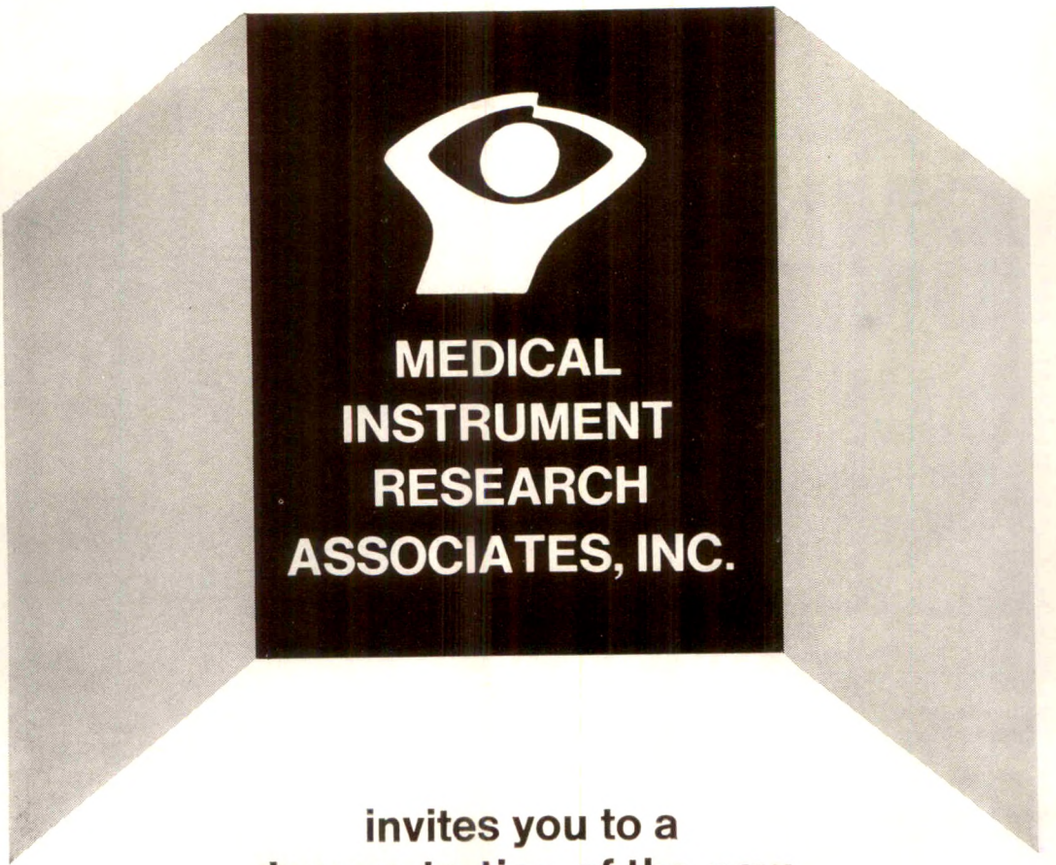
*RLI...has a contact lens protection program that has been thoroughly tested for 10 years...*

# NOW PROTECTS ALL "SOFT" CONTACT LENSES

RLI began preparations for the new soft contact lens years ago. Yes, that's right! RLI's regular contact lens protection program has been years ahead of its time. Our program has been thoroughly and successfully tested by the ophthalmic profession for ten years. This is your assurance of simplicity, reliability and integrity for you and your contact lens patients. Its many easy operating features, low premium cost, the highly effective recall system are immediately adaptable to the new soft contact lens situation.

We have made one significant change for soft contact lens wearers. RLI has strengthened the automatic recall system by adding a **six month recall** regardless of the term of the patient's policy. This means that your soft contact lens patients will receive a reminder to have their eyes examined and/or lens inspected **every six months.** This six month recall for soft contact lens wearers will be available through both our regular, and the Rx 6/12 laboratory programs.



For further information about RLI's regular and soft contact lens insurance program, contact RLI today!

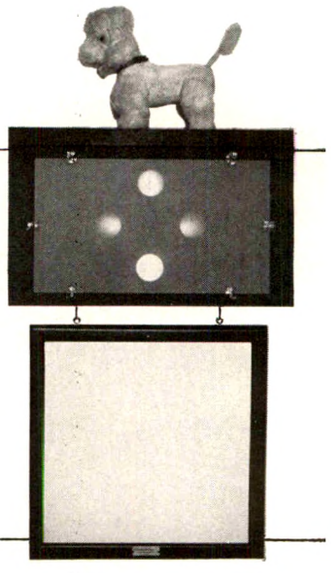
## A complete examination center in one compact modular unit.



# DA-LAUR OMNIBUS UNITS

with add-on extension desk and instrument case

*The most sophisticated ophthalmic control unit available today. Lets you conduct the entire examination from your chair by remote control.*

- **Unmatched accessibility —** base of unit contains 5 drawers, easily accessible even with writing slide open.
- **Optional desk extension —** for lensometer, telephone, etc. Standard is shown, other sizes and shapes available.
- **Optional instrument case —** holds and protects your diagnostic instruments.
- **Adaptable to any and all requirements —** trial lenses are illuminated and complete controls can be provided for instruments, room lights, chart lights and testing devices.
- **Available with automatic controls —** when you pick up your ophthalmoscope for example, it activates automatically, room lights go out and fixation light appears. *A DA-LAUR original.*

**ANIMATED PUPPY UNIT**
maintains fixation during examination. Illuminated puppy's motion and bark keep children attentively fixing. Unit has standard adult white fixation light, changing color fixation light, and Worth 4-dot test — each with its own control switch. Shown with optional projector screen.

**See us in Booths 16-17-18 at the Academy Meeting.**

MURO

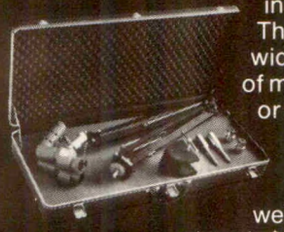
# GONIO-GEL

A STERILE GEL OF METHYLCELLULOSE 4000 cps 2.5%
Preservatives: Methylparaben and Propylparaben

## VALUABLE FOR BONDING OF GONIOSCOPIC PRISMS TO THE CORNEA

- Simplifies gonioscopy in upright and recumbent positions
- Reduces fluid spillage
- Helps maintain a tight lens fit
- Index of refraction 1.336

Apply small amount of Gel to inner surface of Gonio lens.
Available in ⅛ ounce ophthalmic tubes.



MURO PHARMACAL LABORATORIES, INC.
121 Liberty Street • Quincy, Mass. 02169
Area Code 617 • 479-2680

# Born free

Like trend-setting CM-II, the new Mentor* CM-III Portable Operating Microscope gives total freedom to the surgeon—freedom to swing the microscope in when he wants it, out when he doesn't, freedom to turn away momentarily, freedom to carry it anywhere and set it up quickly, freedom from wearing or holding any equipment.

What's new is CM-III's steadiness. We have entirely redesigned the arm, pivot, and clamp for firmer, smoother action. When you swing it back in you return to the same focus, same angle, and same field of view without readjustment. (It's parafocal.) The maneuvering handles are sterilizable.

And the coaxial light source. The neat pool of light makes finding the subject much easier, then illuminates it at an intensity of 600 foot-candles. The optics present a bright, wide, flat field at your choice of magnification—7X, 10.5X, or 14X.

The price of the CM-III, complete with attractive, lightweight carrying case, is only $1060. Let us send you complete information. Mentor Division, Codman & Shurtleff, Inc., Randolph, Mass. 02368.

Codman Mentor DIVISION

# Invisible bifocals are no longer a novelty, so when you prescribe them . . . specify YOUNGERS, and here's why!

Younger Seamless Lenses were introduced almost fifteen years ago and have been actively promoted ever since. When a sufficient market for this type of lens was created, other invisible bifocals were introduced. Most are based on the somewhat dubious assumption that the human eye can effortlessly seek a "graduated" power which would give adequate vision at a predetermined distance.

Fine in theory — but in actual practice, certain optical aberrations are thus introduced, such as undesirable lateral astigmatism in measurable amounts when any part of the lens other than optical center is used. This, in turn, can be aggravated by an Rx with the cylinder correction at odds with the lens fields.

Not so with Younger Seamless Lenses, because these fine lenses are ground on the sound ophthalmic principle that the patient *must* have non-aberrated distance and reading areas for efficient vision. To achieve this, Youngers are ground with only a narrow transition zone between two optically correct powers which can be instantly checked with conventional instruments merely by masking off the transition zone and taking a reading as on any ordinary bifocal!

And if you're concerned about the width of the transition zone, be assured that it is *narrow!* It's true the original Younger Lens had a wide transition zone, but credit fifteen years of constant research and modern technology for reducing this zone to manageable width.

If you haven't inspected a Younger Seamless Lens recently, do so now. You'll be pleasantly surprised and your patients will be exceptionally grateful. Remember: if your patient isn't satisfied, the lenses will be replaced with multifocal blanks of your choice.

**Younger Lenses are available through most independent labs and all American Optical branches . . . in glass or hard resin.**

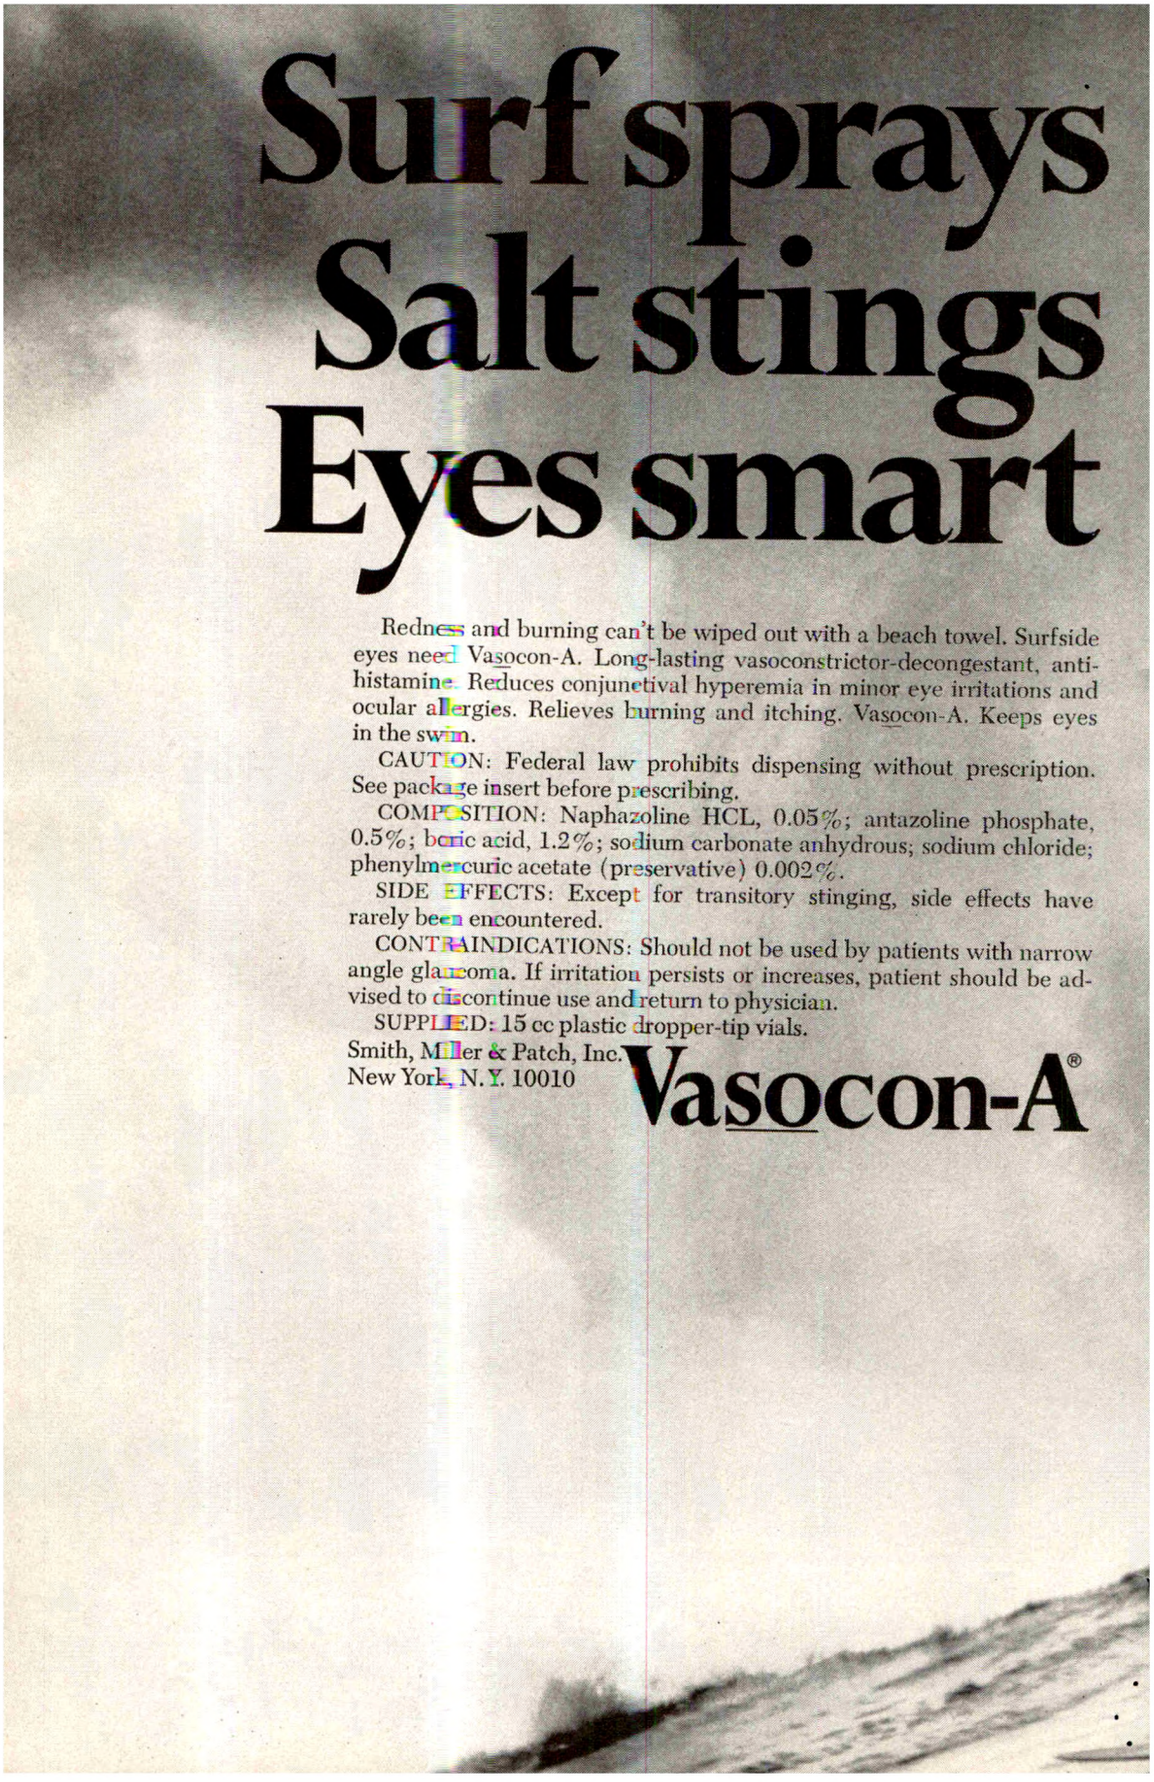
# Optemp®

## sterile, disposable cautery designed especially for the ophthalmic surgeon

**Optemp offers the ocular surgeon these important advantages...**



**optimal temperature**
Optemp is only 300°C at the tip...hot enough for instant occlusion of individual capillaries, "cool" enough to minimize damage to surrounding tissues

**excellent visibility**
Optemp, with an elongated operating tip, offers the surgeon an unrestricted field of vision...the instrument, being light weight and well balanced, is easily maneuverable with no cumbersome cords to get in the way.

**sterility, economy**
Optemp is sterile as received, eliminates the possibility of cross-infection... battery powered and inexpensive, it saves on resterilization and reprocessing.

Ask for Optemp at your local hospital and see why it's the dependable ophthalmic cautery that meets your needs in every way.

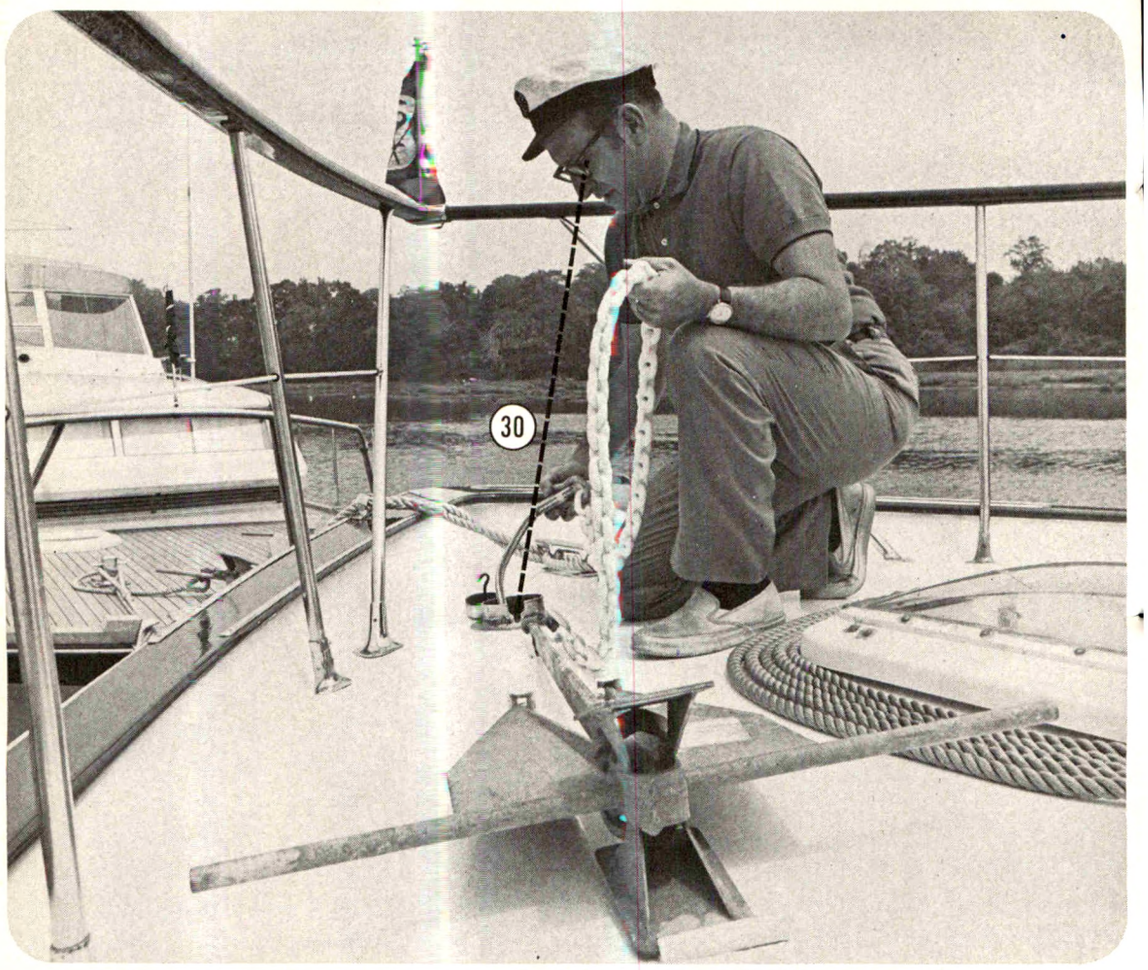
Surgical Products Division,
Alcon Laboratories, Inc.

Redness and burning can't be wiped out with a beach towel. Surfside eyes need Vasocon-A. Long-lasting vasoconstrictor-decongestant, antihistamine. Reduces conjunctival hyperemia in minor eye irritations and ocular allergies. Relieves burning and itching. Vasocon-A. Keeps eyes in the swim.

CAUTION: Federal law prohibits dispensing without prescription. See package insert before prescribing.

COMPOSITION: Naphazoline HCL, 0.05%; antazoline phosphate, 0.5%; boric acid, 1.2%; sodium carbonate anhydrous; sodium chloride; phenylmercuric acetate (preservative) 0.002%.

SIDE EFFECTS: Except for transitory stinging, side effects have rarely been encountered.



CONTRAINDICATIONS: Should not be used by patients with narrow angle glaucoma. If irritation persists or increases, patient should be advised to discontinue use and return to physician.

SUPPLIED: 15 cc plastic dropper-tip vials.

*Occupational Vision Studies*
*(From Study #25, Volume II, Guide to Occupational and Other Visual Needs)*

# Boating

(Power Boats)

When "boating" is mentioned as an occupation or an avocation, the first thought that comes to mind is "glare protection", which is a perfectly obvious visual need of the man who spends time on the water.

What is not generally recognized is that the boating enthusiast has an astonishing range of vision needs, from the ability to read the fine print of a chart through the arm's-length requirements of power boat operation to the good distance vision necessary to travel over large expanses of water.

And when you consider that the sailor also may maintain his own machinery, tie fishing flies and need to judge distances accurately, it is perfectly obvious that he has a much wider range of vision needs than appears on the surface.

That's where Vision-Ease comes in, because there is a Vision-Ease multifocal form for any of the boat operator's needs. Ask your lab.

Significant new findings
Drug penetration
into the human eye

# for the first time independent research relates ocular drug penetration in humans to your choice of ophthalmic vehicles

## Proof of penetration—new fluorophotometry concentration/duration study[1]

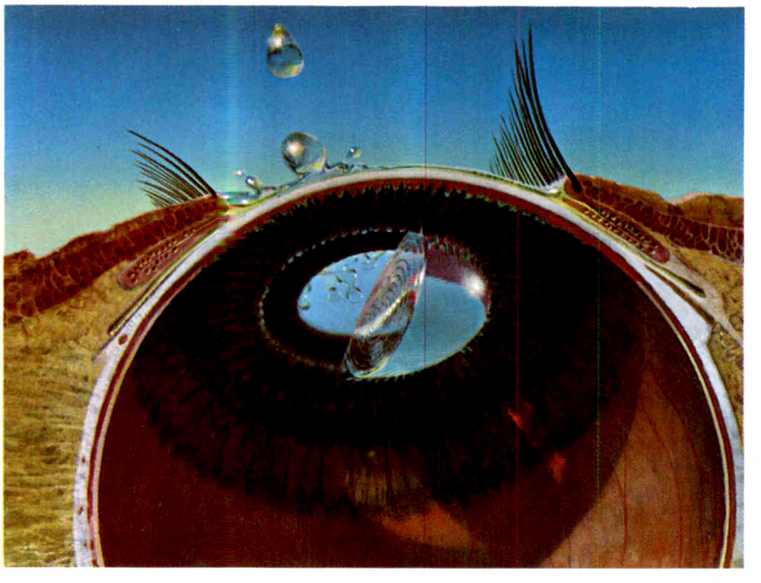
Using a slit lamp fluorophotometer, "the effects of ophthalmic vehicles on the intraocular penetration of topical fluorescein in man" were determined. "Quantitative data on ocular penetration of this drug, in man, in vivo, are presented."

### The study

Fluorescein combined with hydroxypropyl methylcellulose 0.5%, polyvinyl alcohol 1.4% and aqueous; each vehicle instilled in the eyes of 20 normal subjects; each subject served as his own control; hourly measurements of attained drug concentration were made quantitatively using a slit lamp fluorophotometer.

### The findings

CORNEA

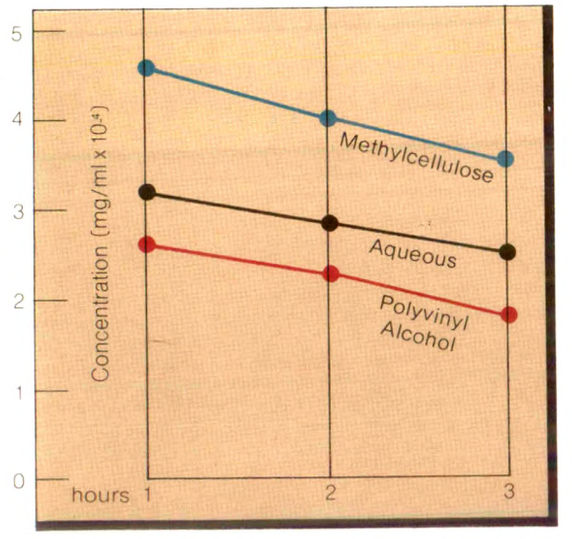


Over a three hour period, hydroxypropyl methylcellulose produced corneal drug levels 85% higher than polyvinyl alcohol and 43% higher than the aqueous vehicles.‡

AQUEOUS HUMOR

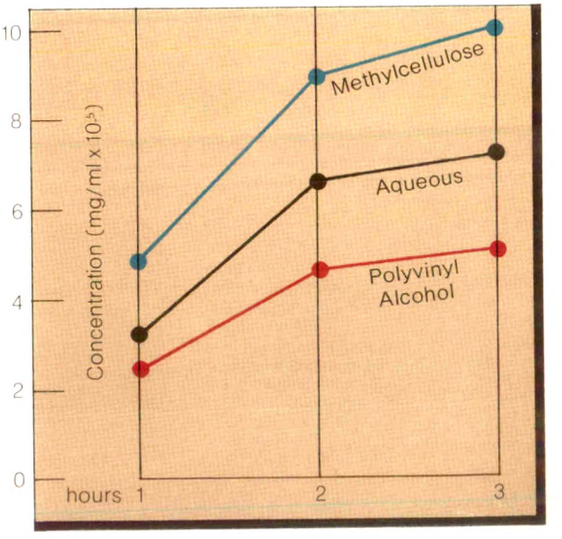
Over a three hour period, hydroxypropyl methylcellulose produced aqueous humor drug levels 93% higher than polyvinyl alcohol and 42% higher than the aqueous vehicle.‡‡

### The authentication



The authors state that their findings may, or may not, be true for drugs other than fluorescein. However, the findings reported above were achieved "consistently and reproducibly"; data were analyzed and tested for significance on a computer.

Isopto® vehicle (hydroxypropyl methylcellulose 0.5%)
produced significantly higher drug penetration and concentration
compared with 1.4% polyvinyl alcohol or aqueous vehicles.



‡Concentration in human cornea

Corneal fluorescein concentration after topical 2% fluorescein in various vehicles.

‡‡Concentration in human aqueous humor

Aqueous humor fluorescein concentration after topical 2% fluorescein in various vehicles.

Adapted from Waltman, S.R. and Patrowicz, T.C.: Effects of hydroxypropyl methylcellulose and polyvinyl alcohol on intraocular penetration of topical fluorescein in man, Invest. Ophthal. 9:966, 1970.

...therefore, when penetration makes the clinical difference

# when infectious inflammations demand a long-lasting sulfa/steroid

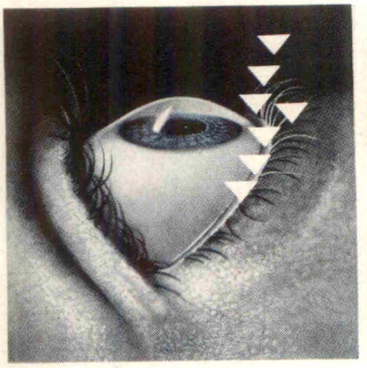
The Isopto® Cetapred vehicle makes for greater concentrations[1] of drug in ocular tissue. Combined with broad, anti-infective range, the high levels of anti-inflammatory action provide rapid and prolonged relief of symptoms—pain/hyperemia/exudation—greater therapeutic efficacy, and maximum patient comfort.

**Cetapred® Ophthalmic Preparations:**

**Description:** *Solution:* Sterile, containing: *Active:* Sodium Sulfacetamide 10%, Prednisolone Acetate 0.25%; *Vehicle:* Hydroxypropyl Methylcellulose 0.5%: *Preservatives:* Thimerosal 0.01%, Sodium Thiosulfate 0.1%; *Inactive:* Sodium Biphosphate, Dried Sodium Phosphate, Hydrochloric Acid (to adjust pH), Purified Water.

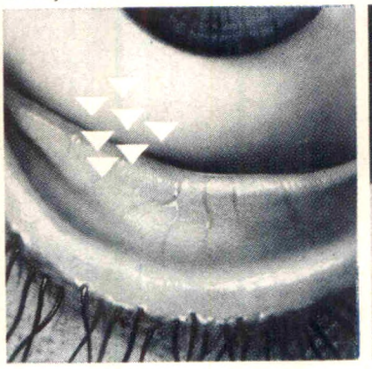
**Ointment:** Sterile, containing: *Active:* Sodium Sulfacetamide 10%, Prednisolone Acetate 0.25%; *Preservatives:* Methylparaben 0.05%, Propylparaben 0.01% *Inactive:* White Petrolatum, Anhydrous Liquid Lanolin, Mineral Oil.

**Precautions—Adverse Reactions:** Extended use may cause increased intraocular pressure, which should be checked frequently. Perforation may occur in diseases causing thinning of the cornea. Institute other therapy if favorable response is not obtained within reasonable period. Discontinue if sensitivity occurs.



**Contraindications:** tuberculosis, fungal, and most viral lesions of the eye; vaccinia; varicella; acute purulent conjunctivitis, acute purulant blepharitis.

**Supplied:** In 5 cc and 15 cc Drop-Tainer® dispensers; sterile ointment in 1/8 oz. tubes.



**References: 1.** Waltman, S.R. and Patrowicz, T.C.: Invest. Ophthal. 9:966, 1970.

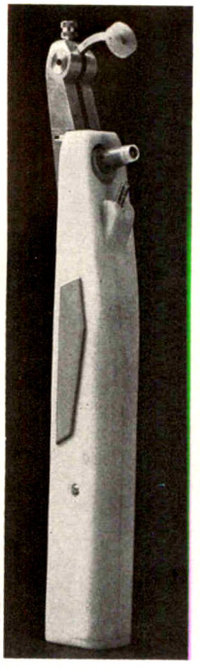
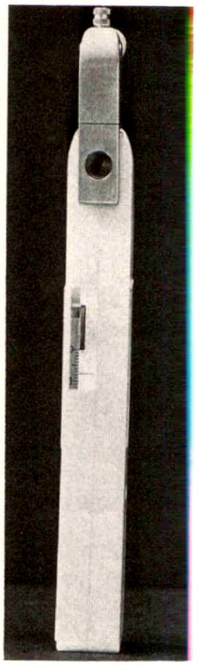
# NEW DEVELOPMENTS . . .





## ORA SERRATA ATTACHMENT TO THE GOLDMANN 3 MIRROR LENS

The periphery of the fundus near the ora serrata and the ciliary body cannot be examined under normal conditions with the 3-mirror lens alone. The ora serrata attachment along with the 3-mirror lens allows the observation of these most peripheral parts in its entire circumference.

The attachment is shaped like the 3-mirror lens. Half a steel-ball is fixed to the scleral part of the attachment which presses on the sclera above the ora serrata so that the fundus at its periphery near the ora serrata can be seen in the gonio mirror of the 3-mirror lens. The ora attachment can be used either with the 3-mirror lens in a locked or moveable position.

Stereo slit lamp photo showing zonular cataract. Courtesy of F. E. Cignetti, M.D., Eye & Ear Hospital, Univ. of Pittsburgh

# Look deep into the eye (stereoscopically) with this Photo Slit Lamp.

Besides its purely optical advantages such as high resolution and large magnification range, the Zeiss Photo Slit Lamp has two truly unique features.

First is the illumination system. It contains a specially designed, built-in flash unit of extremely high power (720 watt-seconds). Because of the brilliance of this flash illumination system you can narrow the slit beam down as far as 0.05mm. The built-in aperture diaphragm creates a practically parallel beam so that you can photograph in color with great, really great, depth of focus anything that can be seen with the slit lamp biomicroscope.

And, second, you can do it stereoscopically. Stereo slit lamp photos are as superior to conventional photos as 3-dimensional biomicroscopy is to examination with a monocular microscope. And since observation is uninterrupted during photography, you are assured of recording exactly what you see. A wide variety of attachments provides unmatched photographic versatility. You can, of course, use the Photo Slit Lamp, too, for regular biomicroscopy.

For the full story, write Carl Zeiss, Inc., 444 5th Avenue, New York, N.Y. 10018.

# CONTACT LENS PRACTITIONERS

The next few years promise tremendous changes in the contact lens field. New types of lenses, materials, equipment and fitting techniques will compete for the practitioner's time and attention.

We believe the fitter will look to his laboratory for advice and instruction, as well as for the latest and best lenses. Thus, the need for dependable laboratories with research facilities, knowledgeable personnel and adequate resources, will be evident as never before.

Recognizing this need, we have formed UNION OPTICS CORPORATION, comprising a select group of established laboratories under the leadership of respected contact lens authorities. This organization is now the second largest contact lens manufacturing entity in the U.S.A. We expect it to play a major part in research, development and improvement of contact lenses in the future.

If you are not yet acquainted with our laboratories, we invite you to get in touch with the one nearest you.

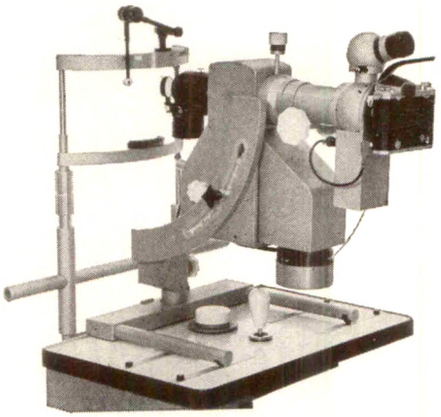
# Look what fluorescein fundus photography can tell you.



This fluorescein angiogram of a diabetic retinopathy, revealing a gross vasculopathy in micro and macro vessels, is only one example of the results that can be easily obtained with the new Zeiss Fundus Flash II. Of the many features of this unique instrument, four are particularly worth citing here:

(1) The light source, adjustable for low, medium or high intensity, with low heat, fast recycling, short warm-up (0.5 sec.) and long flash tube life.

(2) The built-in digital data timing system which indicates automatically the time lapse between photographs.

(3) The control system which allows preselection of frame sequences from 1 to 4 frames/sec., time exposures, and automatic shutoff of film transport after a selected number of frames.

(4) The exclusive Allen Stereo Separator for taking stereo photographs automatically with no equipment adjustment.

For complete details on the many other features of this easy-to-use instrument, write Carl Zeiss, Inc., 444 5th Avenue, New York, N.Y. 10018.

# acts against pathogens, but rarely sensitizes

For bacterial infections of the external eye, including conjunctivitis, due to susceptible organisms. Provides a broad spectrum of antibacterial activity. Rarely sensitizes. Particularly helpful for patients who have shown a previous sensitivity to other topical antibiotics.

Available in ⅛-oz. tube with ophthalmic tip.

*Contraindications:* This product is contraindicated in those individuals who have shown hypersensitivity to any of its components.

*Caution:* As with other antibiotic products, prolonged use may result in overgrowth of nonsusceptible organisms, including fungi. Appropriate measures should be taken if this occurs.

# LAST YEAR WE TOLD YOU ABOUT THE "PRESSURE-SPARING" EFFECT OF HMS...

(medrysone)

# ...APPARENTLY YOU WANT TO KNOW MORE.

# SO TAKE THIS NEW LOOK AT HMS.

Drawing on nearly seven years of extensive clinical research experience, let's consider those questions you have asked most frequently.

### "Is HMS too mild to benefit my patients with inflammatory conditions?"

In the past five years, numerous independent studies on HMS (medrysone) have been published including those by Becker, and Thygeson.[1-4] Virtually all have reached the same conclusions: HMS is an effective treatment for superficial ocular inflammations.

Additionally, in a recent survey, 76% of the ophthalmologists interviewed who had tried HMS, found it effective when used for the recommended conditions.[5]

### "What therapeutic possibilities are now open to me, with HMS, that were not available with other mild steroids?"

First, over 30% of the population is likely to respond to steroids with an intermediate to high increase in intraocular pressure; steroid use with these patients must therefore be selective and cautious.[6] With HMS, most of these patients now can safely receive long-term steroid treatment.

Secondly, there are those glaucoma patients who must be treated specifically with epinephrine but are nevertheless sensitive to this drug. With HMS as concomitant therapy, Becker and Kolker reported that there was "sufficient improvement in glaucoma control so as to avoid surgery" by allowing continuation of epinephrine therapy.[7]

### "I haven't seen a rise in IOP with mild steroids. Isn't the real concern with the more potent steroids?"

There is ample evidence that .1% dexamethasone produces significant increases in IOP[1,4,8], and even .12% prednisolone, the mildest of the commercially available ophthalmic steroids, has the potential to increase IOP. Conversely, Doctors Becker and Kolker found in their investigational study that "medrysone (HMS) can be administered to patients four times a day for periods of several months with essentially no elevation of intraocular pressure even in individuals highly susceptible to such elevation."[7]

### "Can I treat uveitis and iritis with HMS?"

It is *not* indicated for these conditions. Its merits should only be judged in those conditions where indicated: allergic and vernal conjunctivitis, episcleritis, and epinephrine sensitivity.

### "Is HMS uncomfortable for the patient to use?"

Results of a recent patient study showed that 96% of those tested found HMS completely comfortable in the eye.[9] Though early batches of the product did cause some minor irritation to the eyes of a few patients, this has not been a recurring problem.

HMS® (medrysone)
LIQUIFILM® OPHTHALMIC SUSPENSION

ALLERGAN

Please see next page for Prescribing Information.

Prescribing Information for

# HMS®(medrysone)

LIQUIFILM® OPHTHALMIC SUSPENSION

DESCRIPTION: Contains:
medrysone.....1.0%
Liquifilm® (polyvinyl alcohol).....1.4%
with: benzalkonium chloride, disodium edetate, sodium chloride, potassium chloride, sodium phosphate monobasic monohydrate, sodium phosphate dibasic anhydrous, methylcellulose, purified water, and sodium hydroxide or hydrochloric acid if needed to adjust pH. HMS (medrysone) is related structurally more to progesterone than to other available corticosteroids.

INDICATIONS: HMS (medrysone) is effective in the treatment of allergic conjunctivitis, vernal conjunctivitis, episcleritis and epinephrine sensitivity. HMS (medrysone) is not indicated in iritis or uveitis as its therapeutic effectiveness has not been demonstrated.

CONTRAINDICATIONS:
HMS (medrysone) is contraindicated in the following conditions:

1. Acute untreated purulent ocular infections.
2. Acute herpes simplex (dendritic) keratitis.
3. Viral diseases of the conjunctiva and cornea.
4. Ocular tuberculosis.
5. Fungal diseases of the eye.
6. Hypersensitivity to any of the components of the drug.

WARNINGS:

1. Infectious diseases of the eye may be masked, enhanced or activated by steroids.
2. Corneal or scleral perforation occasionally has been reported with prolonged use of topical steroids. In high dosage they have been associated with corneal thinning.
3. Prolonged use of topical steroids may increase intraocular pressure although data from 2 uncontrolled studies[4,7] indicate that in patients with increased intraocular pressure and in those susceptible to a rise in intraocular pressure upon application of topical steroids, there is less effect on pressure with HMS than with dexamethasone or betamethasone.
4. Prolonged use of topical corticosteroids may rarely be associated with development of posterior subcapsular cataracts.
5. Systemic absorption and systemic side effects may result with the use of topical steroids.

PRECAUTIONS:

1. HMS (medrysone) is not recommended for use in iritis and uveitis as its therapeutic effectiveness has not been demonstrated in these conditions.
2. With prolonged use of HMS (medrysone) the intraocular pressure and lens should be examined periodically.
3. In persistent corneal ulceration where a steroid has been used, or is in use, fungal infection should be suspected.
4. The use of topical steroids in pregnancy should be limited to conditions serious enough to warrant such treatment, so that possible risk to the fetus may be justified by the expected benefit to the mother.

ADVERSE REACTIONS: Occasional transient stinging and burning may occur on instillation.

DOSAGE AND ADMINISTRATION: One drop instilled in the conjunctival sac up to every four hours.

SUPPLY:
As a 5 cc. sterile suspension in plastic dropper bottles on prescription only.

NOTE: Bottles filled to one-half capacity for proper drop control. Do not freeze.

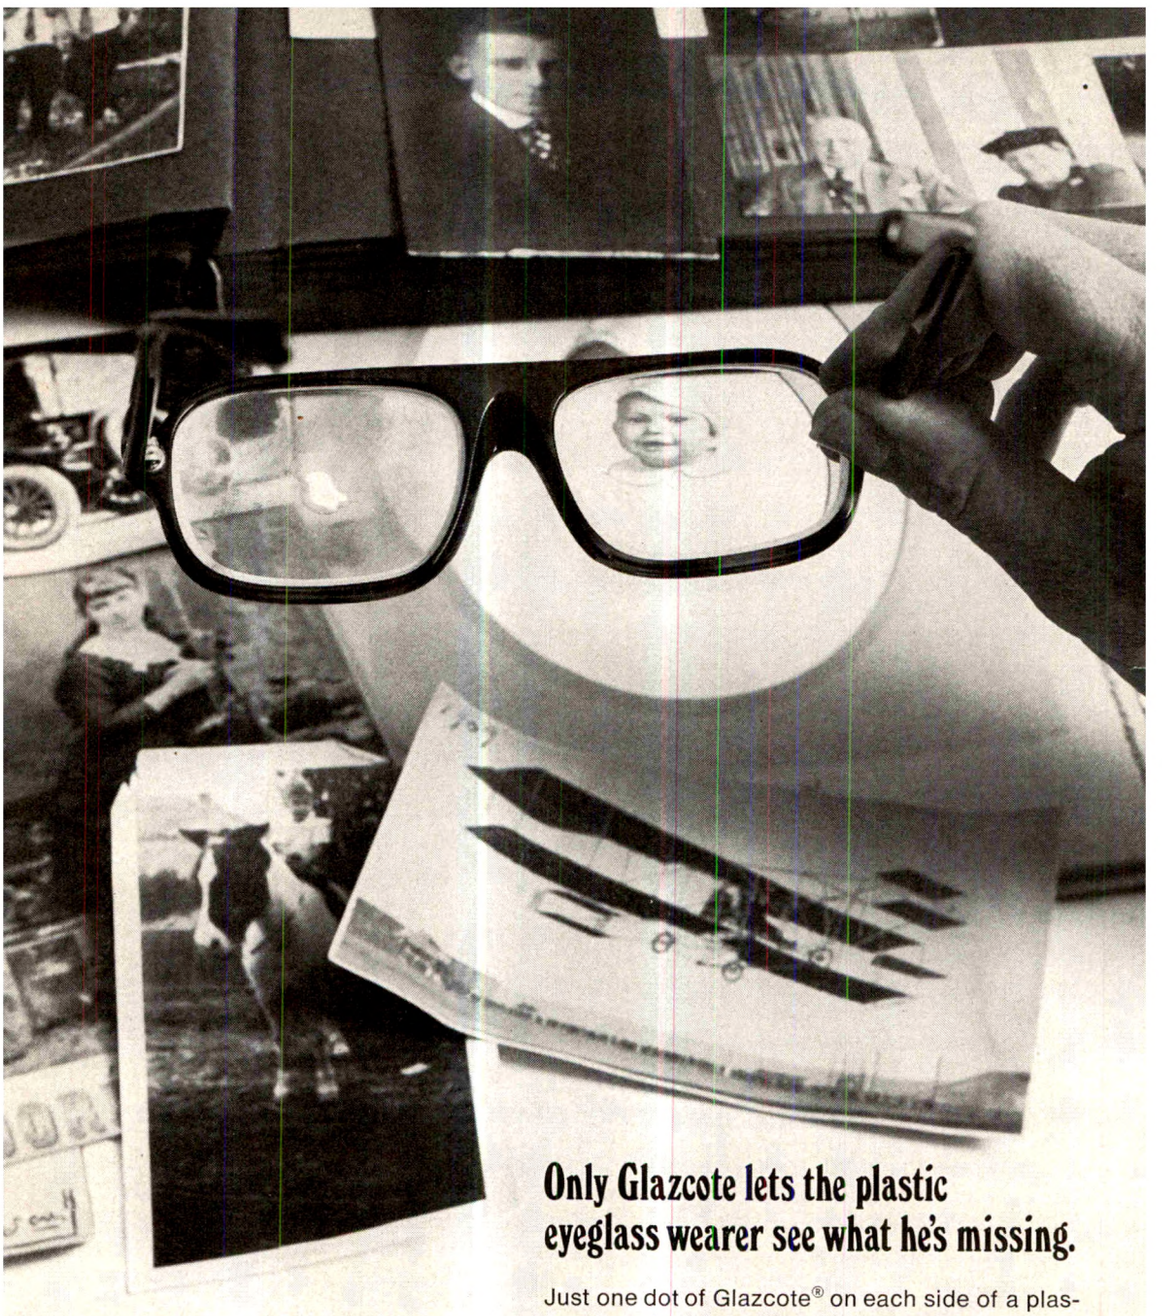
## A Closed Envelope of Compression Means Full Impact Resistance from Center to Bevel Crown

Legislation requiring impact-resistant lenses in all prescriptions is on the books in several states. A federal regulation requiring them is being considered. And with these acts comes the unsettling question of responsibility and liability for the protective lenses you dispense.

This unique and unretouched photograph shows in cross section three lenses heat-treated in a B&L Compact Heat-Treating Unit. Polarized light reveals the evenly balanced, compression-expansion stress structure that imparts so much extra strength. The continuous dark line marks the boundary between tension and compression layers. You can see that the compression layer is closed and uniformly thick; there are no openings for tension "leaks" or soft spots to give way under a tension shift.



B&L Compact Heat-Treating Unit gives you lenses with no tension "leaks."

This kind of structural uniformity is possible only with the even, low turbulence quenching of the exclusive B&L large-orifice, high air-volume process. A Compact Heat-Treating Unit produces lenses which have impact resistance far in excess of all legal or proposed standards.

Experience the confidence of dispensing the locked-in strength of lenses treated in a B&L Compact Unit. Ask your B&L Branch or B&L Distributor about this.

## Only Glazcote lets the plastic eyeglass wearer see what he's missing.

Just one dot of Glazcote® on each side of a plastic or hard resin lens fills hair line scratches and helps protect the lenses against future possible scratches. This unique product was developed for the Space Program, for use on spacecraft windows, and to clean, polish and protect astronauts' plastic face shields. And continuous use of optically clear Glazcote helps keep the lenses clean, static free, and polished as well as filling hair line scratches. ALLERGAN Irvine, Calif.; Montreal, Canada

# Jet or Drop

***DACRIOSE gives you complete control of ocular irrigation. You can provide a gentle but thoroughly cleansing "jet-like" action . . . or you can use it drop-by-drop.***

This modern irrigating solution, in the unique *Jet-Stream* dispenser, is ready-to-use and self-sterilizing.

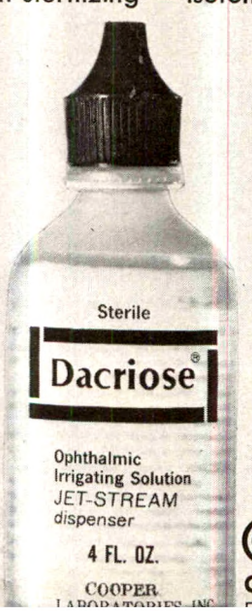
Use DACRIOSE

☐ *In the office:* after tonometry and gonioscopy — to wash away fluorescein — to wash out secretions and discharges.

☐ *In the emergency room:* for quick, safe removal of foreign bodies.

☐ *In the operating room:* for sterile and convenient irrigation of the eye pre- and post-operatively.

☐ *At the bedside:* to clean and irrigate eyes — to save staff time.



**Formula:** A sterile, stable, buffered isotonic solution of boric acid, sodium carbonate, potassium chloride. Preserved with benzalkonium chloride, 0.01%; with 0.01% disodium ethylenediamine tetraacetate.

**Warning:** Do not dilute or reuse the solution. Do not touch dropper tip to eye or any surface as this may contaminate solution.

**Supply:** 0.95 fl. oz. and 4 fl. oz. plastic Irrigator bottles.

**COOPER LABORATORIES, INC.**

Introducing A New Concept in

# Argon Laser Photocoagulation

**Preferred method for treatment of retinal vascular diseases**

**Portability within clinic area**

**Indirect monocular retinal viewing**

**Treatments easily given prone or seated**

**Reproducible doses insured by miniature computer**

**Single dial exposure control**

**Special air-cooled (burst mode) argon laser**

**System engineered for complete safety and reliability**

**Compatible with use of Goldman corneal contact lens**

**System adaptable to slit lamp viewing**

LYNEX, INC. now offers the "Second Generation" Argon Laser Photocoagulator. The new LYNEX Model 4000 Photocoagulator permits treatments to be given with shorter exposures and higher peak powers than is possible with a conventional argon laser system. Such a portable, compact system is possible because of a specially designed "Burst Mode" Argon Laser which requires only a standard 220 V. electrical outlet for operation. Water cooling is not required. A miniature (solid state) electronic computer insures that the pre-selected doses are delivered precisely, safely, and with unerring reproducibility. A single dial provides complete control of the laser power and exposure time. This unique exposure regulator insures that the same energy density is delivered to the retina independent of the changes in spot size which may be required during a treatment session.

ecialists in Optical/Laser Instrumentation

LYNEX INC.

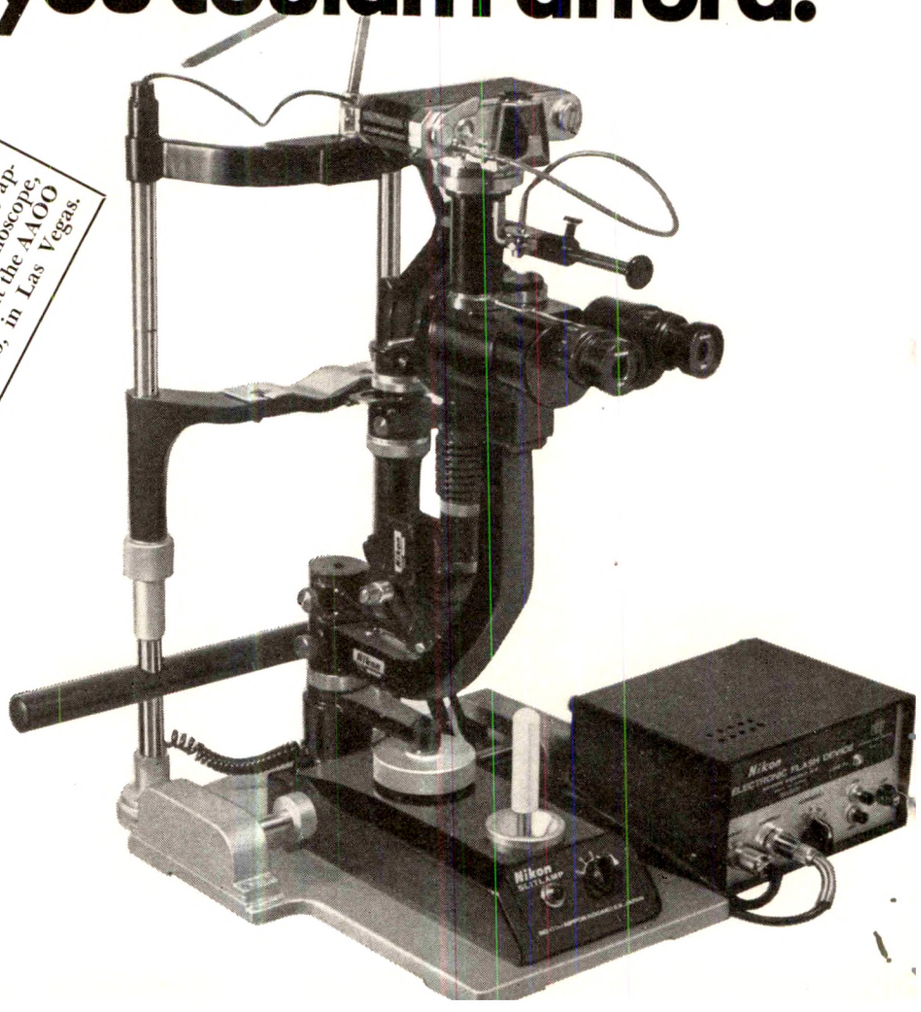
e our booth at the AAOO meeting in September."

**Zoom optics**—A true zoom unit, the Nikon Slit Lamp Microscope has continuous variable power from 7x to 35x. And yet, the image remains precisely centered and in critical focus throughout the entire range of magnification.

**Simultaneous Photography**—With the Nikon Slit Lamp Photo Attachment, you can view critically and photographically record exactly what you see—at the moment you see it. It is not necessary to remove your examining eye from the microscope to focus or use the camera. If needed you can freeze eye motion completely by use of strobe light.

**Unique Controls**—The slit mechanism is precisely controlled by coaxial vertical and horizontal controls. You can continuously vary the size of the slit with either your right or left hand from one set of controls. And the degree of control is exceptional too. *Both* the width and length of the slit can be p cisely adjusted to complete extinction.

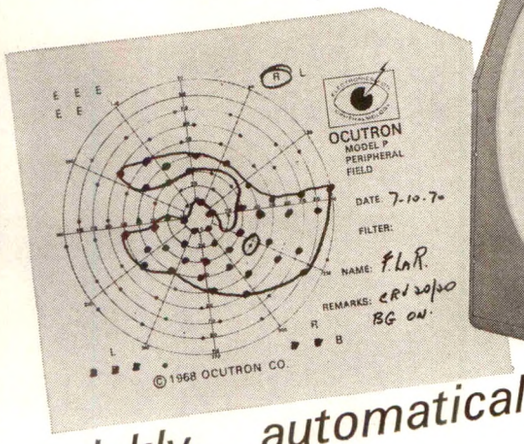


**Versatility**—Designed primarily for office practi the Nikon Slit Lamp is equally at home in the search laboratory. Equipped with the teaching he it is highly suitable for the classroom too. And l all Nikon Ophthalmic Instruments, it is guarante for 10 years.

We believe that once you examine a Nikon Zo Photo Slit Lamp Microscope, you'll be well on y way to having the instrument you've always wan at half the price you thought you couldn't afford.

Write for 8 page detailed brochure or call fo demonstration. Nikon, Inc. Instrument Divisi Subs. of Ehrenreich Photo-Optical Industries, In Garden City, N.Y. 11530. 516-248-5200. (In Canad Anglophoto Ltd., Ont.)

# Now, Nikon brings you the slit lamp microscope you thought you couldn't afford.



New wide angle (45°) fundus camera, applanation tonometer and ophthalmoscope, can be seen in Booth 105-106 at the AAOO meeting, September 19-23, in Las Vegas.

# *Now* OCUTRON®

## *offers you visual fields*

...whenever you want
...as often as you want
without your being there

*quickly... automatically!*

U.S. Patent Nos. 3,288,546
and 3,421,498

The Ocutron™ Visual Field Tester, developed by a leading ophthalmologist, is a highly precise electronic instrument that automatically examines the visual field and records it permanently on the standard chart that you are accustomed to using and interpreting.

Without the presence of doctor or nurse, the patient tests himself by push-button response to stimuli of standard light targets as they appear within the white hemisphere. This response is electrically registered on the chart.

Difficult and time-consuming fields like the above glaucoma field are as easily and quickly tested as a simple normal field.

Background may be lighted or not, as desired, for light or dark adapted fields. Built-in check on patient fixation and patient reliability.

Particularly suitable for high volume performance. Simple enough for screening. Accurate enough for definitive, repeatable field study.

For further information write for new literature
or contact your ophthalmic distributor.

available as sterile ophthalmic drops and sterile ointment...

Alcon *dedicated to advances in ophthalmic therapy*

DESCRIPTION: *DROPS*—Sterile suspension containing: *Active:* Dexamethasone 0.1%, Neomycin (present as sulfate) 3.5mg/cc, Polymyxin B Sulfate 6000 units/cc; Vehicle: Hydroxypropyl Methylcellulose 0.5%; *Inactive:* Sodium Chloride, Polysorbate 20, Hydrochloric Acid and/or Sodium Hydroxide (to adjust pH), Purified Water; Preservative: Benzalkonium Chloride 0.004%. *OINTMENT—Active:* Dexamethasone 0.1%, Neomycin Sulfate equivalent to 3.5mg/gm Neomycin; Polymyxin B Sulfate 6000 units/gm; *Inactive:* White Petrolatum, Anhydrous Liquid Lanolin; Preservatives: Methylparaben 0.05%, Propylparaben 0.01%. CONTRAINDICATIONS: This drug is contraindicated in tuberculous, fungal, and most viral lesions of the eye (herpes simplex/dendritic keratitis); vaccinia, varicella; acute purulent conjunctivitis and acute purulent blepharitis, and in those persons who have shown hypersensitivity to any of its components. PRECAUTIONS: Extended use may cause increased intraocular pressure which should be checked frequently and may result in overgrowth of nonsusceptible organisms. Perforation can occur in diseases causing thinning of the cornea. Discontinue use if sensitivity occurs. Not recommended for long-term use in pregnant patients.

# PHOTOCOAGULATION IN DIABETIC RETINOPATHY

A. E. KRILL, M.D., D. B. ARCHER, F.R.C.S., F. W. NEWELL, M.D. AND M. I. CHISHTI, M.D.

*Chicago, Illinois*

In 1966 we initiated a controlled study of the treatment of diabetic retinopathy by means of retinal photocoagulation in which we treated one eye and followed the natural course of the disease in the untreated eye. Fifty-six of these patients have been followed for one year or more after treatment and their cases are considered to be of value in assessing the effects of photocoagulation.

## MATERIALS AND METHODS

Pertinent parameters of these patients' diabetic histories, vision, and ocular findings are recorded in Table 1. These include age at which diabetes was diagnosed, age at which retinopathy was first observed, age at treatment, visual acuity before photocoagulation and at final follow-up visit, duration of follow-up, and classification data. Thirty-three patients were followed for 12 to 23 months, 14 for 24 to 35 months, and nine patients for 36 to 48 months.

Twelve patients had vision of 20/60 or better in each eye. Twenty-four patients had vision of 20/60 or better in one eye and 20/100 or worse in the other eye. Sixteen patients had vision of 20/100 or worse in both eyes. The four remaining patients did not fit readily into any of the groups (two had 20/80–20/200 vision; the other two had 20/80–20/30 vision). Visual acuities for all patients before and after treatment are shown in the table.

*Ocular evaluation*—In addition to routine examination, this included: perimetry with the Goldmann perimeter where possible; color photography with the Zeiss fundus camera; fluorescein angiography[1] when the media were sufficiently clear; drawings of fundi which could not be photographed or which had significant pathology in the peripheral fundus. Each patient's eyegrounds were assessed according to a classification developed at a symposium on the treatment of diabetic retinopathy held in Warrenton, Virginia, in 1968. This classification, which is described in detail elsewhere,[2] is now referred to as the Airlie classification (Fig. 1).

In the great majority of cases, photographs were used for evaluation. However, 23 eyes could not be classified because of dense vitreous hemorrhage, massive far-advanced proliferative retinopathy, or a combination of both.

Proliferative retinopathy was present in both eyes of 41 patients and in one eye of seven patients. Eight patients had nonproliferative retinopathy in both eyes. We considered the degree of elevation in the designation of proliferative retinopathy as early, moderate, or advanced. Proliferative retinopathy (PR) within one-fourth disk diameter of surface of attached retina was considered to be early; PR extending anterior to the retina's normal position by one-fourth to two disk diameters was considered to be

moderate; and PR extending anterior to the retina's normal position by more than two disk diameters was considered to be advanced.

*Indications for treatment*—In our series, the decision as to which eyes were to be treated was based on the following factors:

1. Bilateral early proliferative retinopathy with preretinal and vitreous hemorrhage in one or both eyes. Generally, the eye with the clearest media was treated.

2. Massive vitreous hemorrhage or widespread advanced proliferative retinopathy in one eye combined with either early or moderate proliferative retinopathy, or advanced localized proliferative retinopathy in the second eye. The better eye was treated.

3. Chronic macular edema with either documented progressive visual loss, or significant visual impairment (20/60 or worse) with no improvement on follow-up.

To minimize variability in technique, all photocoagulation was done by one person (A.E.K.). The Zeiss photocoagulator was used. The second or third intensity on the overload was used with as short an exposure time as possible. The aperture diameter was 4.5 or 6 mm when treating areas outside the macular branches of the superior and inferior temporal vessels, and 3 or 4.5 mm if inside these vessels. We tried to obtain a prominent grayish-white reaction outside the macular branches of the superior and inferior temporal vessels, and a fainter gray reaction within these vessels.

The photocoagulation marks were arranged in a U-shaped configuration with the open end at the optic disk. Two rows of photocoagulation marks were placed outside the macular branches of the superior and inferior temporal vessels. These areas were joined by a double row of photocoagulation marks crossing over the horizontal raphe about 3 or 4 disk diameters temporal to the fovea. In patients with significant macular edema a single row of photocoagulation burns was placed just inside the macular branches of the temporal vessels, in addition to the above-mentioned areas.

This method of photocoagulation included the common sites of neovascularization alongside the major retinal veins, and their primary branches, especially those subserving the macula. Areas of surface neovascularization outside our selected photocoagulation sites were directly photocoagulated. When new vessels extended into the vitreous, photocoagulation marks were placed around their base. New vessels on the surface of the optic disk were usually treated by placing photocoagulation marks close to the disk, avoiding the temporal margin. Small preretinal hemorrhages, when distant from a major retinal vessel, were directly photocoagulated.

Of the 56 patients photocoagulated, 21 required retreatment. At the first treatment, 50 or more photocoagulation marks were placed as described above; on retreatment, fewer photocoagulation marks were necessary.

Initially, all patients were hospitalized, but eventually most patients were treated on an outpatient basis.

Retrobulbar anesthesia was used routinely

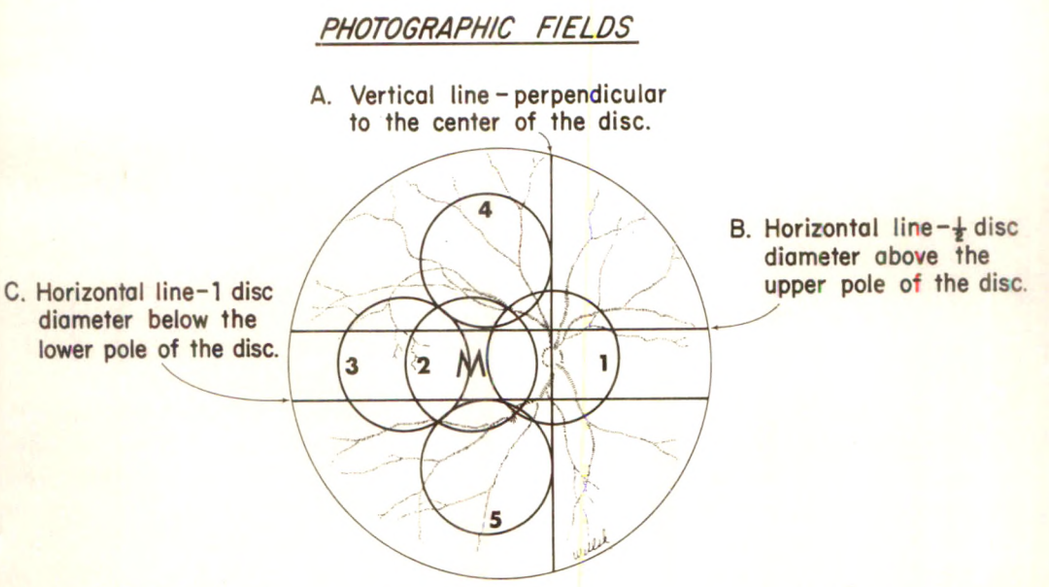

Fig. 2 (Krill, Archer, Newell, and Chishti). Here, the five photographic fields used in the Arlie classification are outlined. Area 1 is centered on the optic disk. Area 2 is centered on the macula. Area 3 has its nasal limit tangent to the macula and is the area covered temporal to the macula. Area 4 includes the region superior to the macula, and Area 5 includes the same region inferior to the macula. The nasal limit of these two areas is tangent to a perpendicular line through the center of the disk. The inferior limit of Area 4 is tangent to a horizontal line one-half disk diameter above the upper pole of the optic disk. The upper limit of Area 5 is tangent to a horizontal line one disk diameter below the lower pole of the optic disk (from Goldberg and Fine[2]).

with initial treatment. When only minimal retreatment was required, anesthesia was often not needed.

## Results

The primary parameters assessed before and after treatment were visual acuity and status of the eyegrounds. Changes in vision of at least two lines on the Snellen chart were considered to be significant, as one-line changes may sometimes reflect variations in testing circumstances.

In evaluating fundi by the Airlie classification (Figs. 1 and 2), we selected what we considered to be the most relevant parameters and weighted each according to our estimate of its importance.

The point total for each fundus area considered was determined by multiplying the Airlie figure (0, 1, 2) by a weighted number (detailed explanation will follow). The total for each category (i.e., nonproliferative, proliferative, preretinal, and vitreous hemorrhage) is the sum of the weighted numbers. These figures are shown for each patient in the table.

Under nonproliferative aspects in the Airlie classification we evaluated intraretinal hemorrhages, microaneurysms, and edema only in the macula, as these findings are of little visual or prognostic significance elsewhere. Each of these parameters was assigned a value of 1. Hard exudates were evaluated in the macula and temporal to this region (Area 3). The temporal location was also evaluated because hard exudates at this site are usually an indication of chronic edema in this area, which ultimately may spread to the fovea. Hard exudates in the macula were assigned a value of 1; temporal to this region, a value of one-half. Venous abnormalities above (Area 4) and below (Area 5) the macula, were given a value of

one-half. Such venous abnormalities may be associated with surface neovascularization, a possible source of preretinal and vitreous hemorrhages.

Neovascularization within one disk diameter of the optic disk, a common site for preretinal and vitreal hemorrhage, was given a value of two. Neovascularization above and below the macula was given one point value. (Neovascularization rarely was found to originate in the macula, and therefore this category was eliminated.) Preretinal hemorrhages in and below the macula were weighted with a value of two. Vitreous hemorrhage was considered to be important in any location; it was given two points at Area 2, one point at Area 1, and one-half point in the other three areas.

The four categories used in the Airlie classification, nonproliferative, proliferative, preretinal, and vitreous hemorrhage, are headings in the table. The total points before and after treatment for each eye are shown under these headings. A designation of "U" indicates that classification was impossible (usually because of vitreous hemorrhage).

Fluorescein data called for in the Airlie classification are discussed elsewhere in this paper under "Specific beneficial effects of photocoagulation," and also in another publication.[3]

In assessing the results of treatment, the patients were grouped in the following manner: 15 patients with early (surface) proliferative retinopathy, 31 patients with moderate to advanced proliferative retinopathy, and 10 patients with nonproliferative retinopathy and macular edema.

*Evaluation of proliferative retinopathy*—A patient was said to have a good result if the treated eye showed an overall improvement or remained static in the proliferative category, while the untreated eye showed deterioration or remained severely abnormal due to extensive vitreous hemorrhage or far-advanced proliferative retinopathy.

*Evaluation of macular edema*—A good result was one in which there was complete or almost complete disappearance of macular edema. This was usually associated with a concomitant resolution of intraretinal hemorrhage and hard exudates.

*Early proliferative retinopathy*—Of the 15 patients with early proliferative retinopathy, eight had good results. In five of these eight cases the retinopathy in the treated eye regressed, while that in the untreated eye progressed. In three of these eight patients, the retinopathy remained static in the treated eye, but deteriorated in the untreated eye. In six other patients with early proliferative retinopathy, photocoagulation did not obviously retard the progression of the retinopathy. The untreated eye in these cases also deteriorated or remained at a state of advanced retinopathy. The one remaining patient in this group showed a more marked improvement of the retinopathy in the untreated eye than in the treated eye.

*Moderate to advanced proliferative retinopathy*—Of the 31 patients with moderate to advanced proliferative retinopathy, 18 had good results following photocoagulation. This group was particularly significant as 11 of the untreated eyes had severely abnormal, mostly unclassifiable retinopathy on both initial and final evaluation. In the remaining 13 patients, three showed deterioration in both eyes, four showed marked deterioration in the treated eye with little change in the untreated eye, and in six cases both eyes remained unchanged.

*Macular edema*—In the 10 patients with macular edema and nonproliferative retinopathy, the principal changes were partial or complete disappearance of edema, exudates, and intraretinal hemorrhage. One patient developed advanced proliferative retinopathy in the treated eye.

### Combined vision and classification data

The visual and classification data of each patient were assessed together to more accurately appraise the effects of photocoagulation.

Results were described as "Good," "Fair,"

"Poor," and "Inconclusive or difficult to assess."

Criteria for a good result was as follows: (1) improvement in vision in the treated eye and deterioration of vision in the untreated eye; (2) improvement of vision in the treated eye with no change of vision in the untreated eye; (3) vision remaining the same in the treated eye with deterioration in the untreated eye; (4) regression of retinopathy in the treated eye and progression in the untreated eye; (5) regression of retinopathy in the treated eye and no change in the untreated eye; (6) no change in retinopathy in the treated eye with marked deterioration in the untreated eye.

A good result based on visual improvement must be accompanied by either improvement in retinopathy or no change in the status of the fundus. Similarly, a good result based on improvement of retinopathy must be accompanied by either improvement of vision or no visual deterioration.

A fair result indicates improvement in either vision or retinopathy. It is distinguished from a good result in that visual improvement may be accompanied by some deterioration of retinopathy, and, conversely, improvement in retinopathy may be associated with slight deterioration of vision.

A poor result is one in which there is a significant deterioration of either vision or retinopathy in the treated eye.

Inconclusive results included cases with improvement or deterioration in either vision or retinopathy in both eyes. In these cases it was difficult to determine the effects of photocoagulation.

The results of treatment were as follows: Twenty-two patients had good results, nine patients had fair results, 15 patients had poor results, and 10 patients had inconclusive results. Of the 10 patients in the last category, seven had improvement in both eyes, and three had deterioration in both eyes. Of the 15 patients with poor results, there were five in which the untreated eye was unclassifiable, both initially and at follow-up. Four patients in this group were legally blind (20/200 or worse) before treatment.

### Specific effects of photocoagulation

Effects on directly treated and adjacent areas are illustrated in Figures 3–12. These effects may be described as follows:

1. New retinal vessels, both surface and those extending slightly into the vitreous, disappeared six to eight weeks after treatment (compare Figs. 3, 4, 6-A and C).

2. Photocoagulation adjacent to the optic disk often caused atrophy of the new capillary vessels on the disk surface. Occasionally, vessels extending into elevated proliferative growths originating from the disk surface also atrophied, leaving only a fibroglial band (Figs. 5-A and B, 6-A through D, 7-B and D).

3. Photocoagulation placed around the base of proliferans extending far into the vitreous often caused atrophy of most or all of the vessels in the proliferative growth (Fig. 8).

4. Waxy exudates and macular edema decreased or occasionally completely disappeared about two to three months after treatment (Fig. 9). Abnormal retinal vessels in the macular area, although not directly treated, became less permeable after photocoagulation to adjacent areas. This is best shown in fluorescein angiography (compare Figs. 10-A and 11-A before photocoagulation with Figs. 10-B and 11-B after photocoagulation).

In patients with macular edema the maximum effect was produced when photocoagulation marks were placed inside and outside macular branches of the temporal vessels and temporal to the macula.

5. There was a general decrease in leakage from abnormal vasculature in both directly treated and untreated areas (see before-and-after photocoagulation photographs in Figs. 3, 4, 10, and 11).

6. Intraretinal hemorrhages often disap-

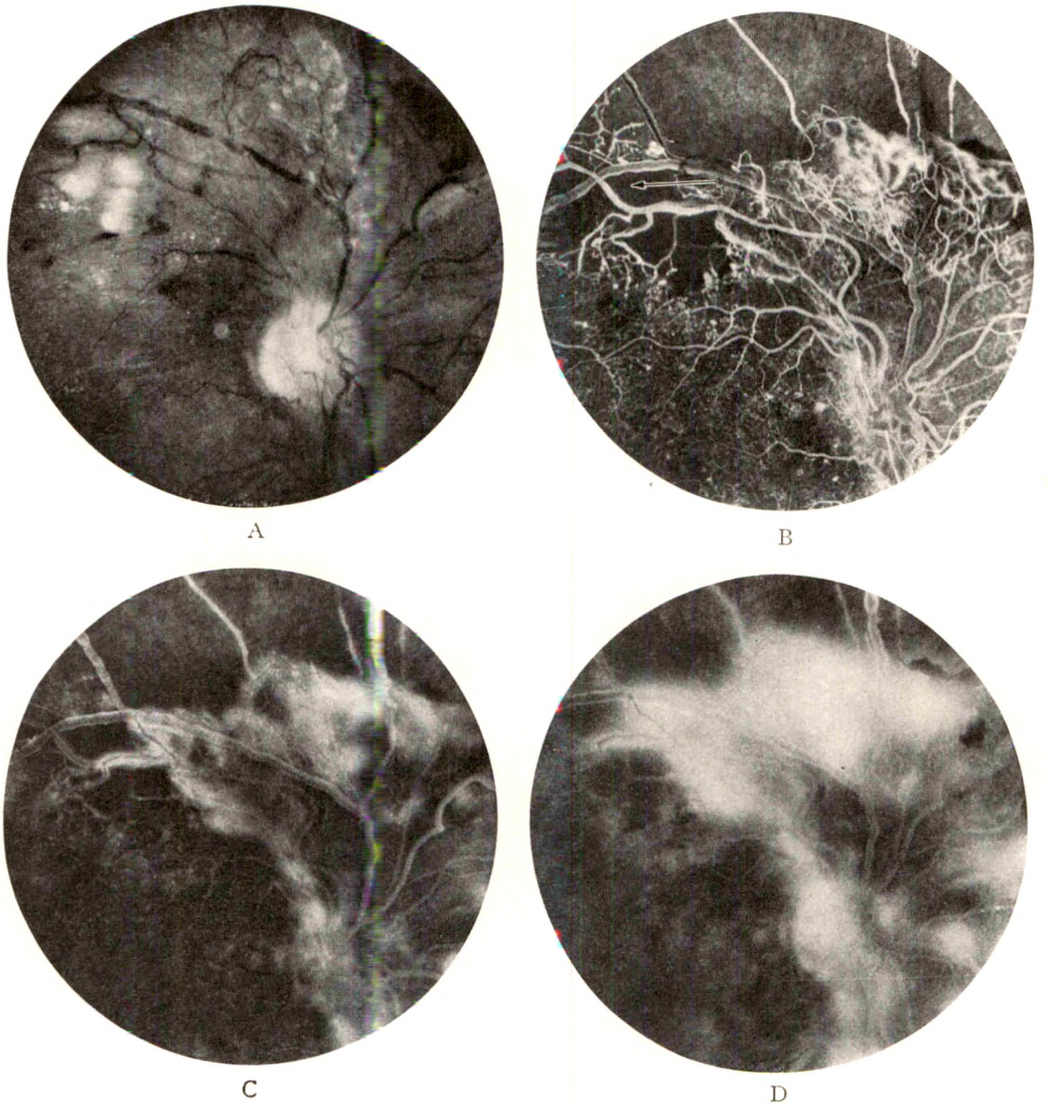

Fig. 3 (Krill, Archer, Newell, and Chishti). Right eye of 45-year-old man before photocoagulation showing (A) control photograph of posterior eyegrounds, and fluorescein angiograms during (B) early and (C) late venous stages, and (D) five minutes after injection. In control photograph (A), note extensive neovascularization superior to disk area and along disk surface. Also note superficial retinal hemorrhages, cotton-wool spots, and waxy exudates. Fluorescein angiograms show widespread areas of capillary nonperfusion, most easily seen during early stages (B and C) of angiography. One such area is indicated by an arrow along superior temporal vessel (B). Extensive capillary dilation, microaneurysms, and shunt vessels are noted in relation to the nonperfused areas. A conglomeration of new vessels, both surface and proliferating into the vitreous, can be seen (B and C) at the upper part of the optic disk extending along the superior temporal vessels. The late angiogram (D) shows profuse dye leakage into the macula and from areas of neovascularization at the optic disk and superior temporal vessels. The superior temporal retinal veins show marked dilation and beading. The vein walls are stained with fluorescein which leaks into the adjacent retina (B, C, and D).

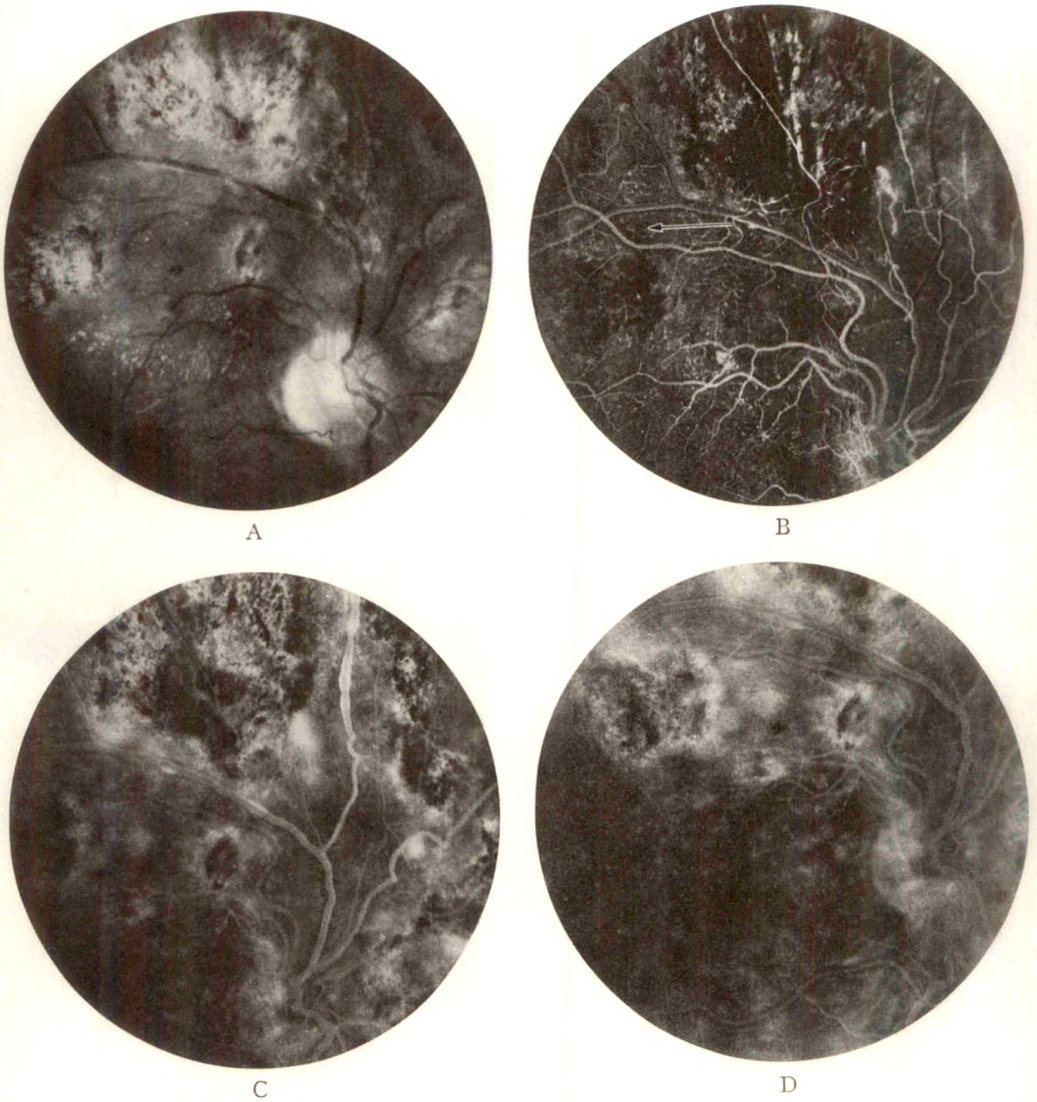

Fig. 4 (Krill, Archer, Newell, and Chishti). Same eye as in Figure 3 shown here five months after photocoagulation. Control photograph (A) may be compared with fluorescein angiograms during (B) early and (C) late venous stages, and (D) five minutes after injection. Note that most of the new surface retinal vessels have disappeared in the superior areas (A, B, and C), both in directly photocoagulated regions and adjacent retina. Most of the hemorrhages in directly treated and adjacent areas have completely disappeared, capillary dilation is now much less evident and the shunt vessels (A and B) are constricted. Many of the capillaries failing to perfuse with dye on previous angiography now appear to be adequately perfused (compare site of arrows in Fig. 3-B and 4-B). There is a dramatic reduction in the area of neovascularization, particularly in the region of the optic disk and along the superotemporal vessels (A, B, and C). Note the considerable reduction in dye leakage in the late angiograms (compare Figs. 3-D and 4-D). There is a marked decrease in caliber of the superotemporal arterioles and veins adjacent to photocoagulation marks (B, C, and D). The superior temporal retinal vein shows absence of beading following photocoagulation, although staining of the vessel wall with fluorescein still occurs (compare Figs. 3-B and 4-B).

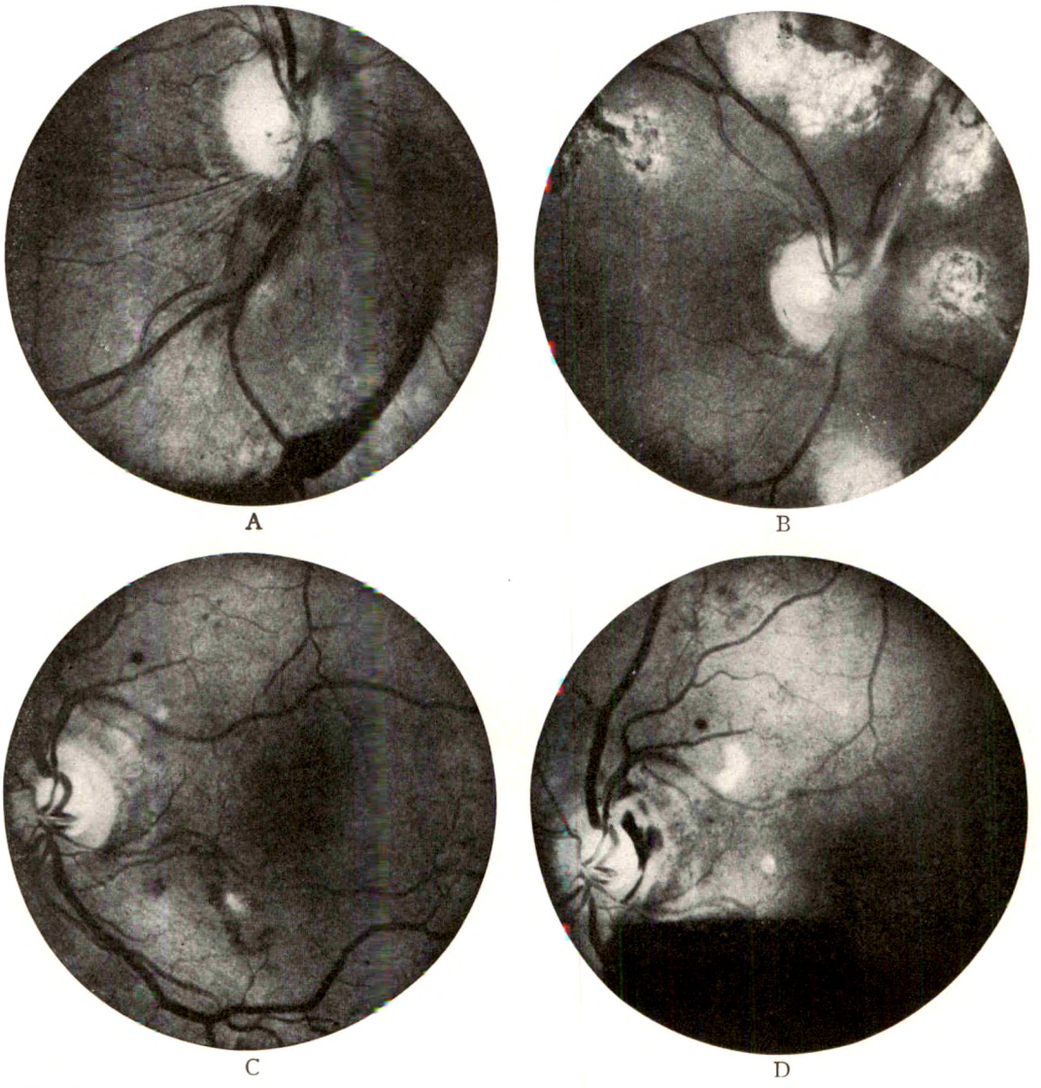

Fig. 5 (Krill, Archer, Newell, and Clashti). Right and left posterior fundi of 45-year-old man (Case 7). Top: Right eye (A) prior to photocoagulation, and (B) seven months after photocoagulation. Bottom: Left or control eye photographed at the same time as treated eye, both before (C) and (D) seven months after right eye had received photocoagulation. There is a considerable decrease in the caliber of the veins and arterioles of the treated eye, whereas in the untreated eye these vessels have remained the same in size. Note disappearance of vessels on surface of right optic disk. Retinal folds temporal to right disk before photocoagulation have disappeared following treatment. Follow-up revealed a preretinal hemorrhage inferior to the optic disk in untreated eye, whereas the treated eye is free from macular edema and hemorrhage.

peared after photocoagulation (Figs. 3, 4, and 6).

7. Microaneurysms, shunts, and areas of capillary dilatation decreased or occasionally disappeared (compare Fig. 10-A with 10-B, 7-A with 7-C, and 3-B with 4-B). Some dilated arterioles and venules also appeared to decrease in caliber.

8. In general, areas of capillary nonperfusion (as demonstrated by fluorescein angiography) failed to reopen following photocoagulation. However, in the macula, some non-

perfused areas did reopen after treatment (compare arrows in Figs. 3-B and 4-B).

9. Many directly treated preretinal hemorrhages partially or completely absorbed within 48 to 72 hours following photocoagulation (Fig. 12-A and B).

10. Photocoagulation marks frequently restricted the spread of preretinal and vitreal hemorrhages, except those originating at the optic disk.

11. Photocoagulation often reduced folds in the retina by causing atrophy of the proliferative fibrous bands producing traction on the retina (Figs. 5 and 8).

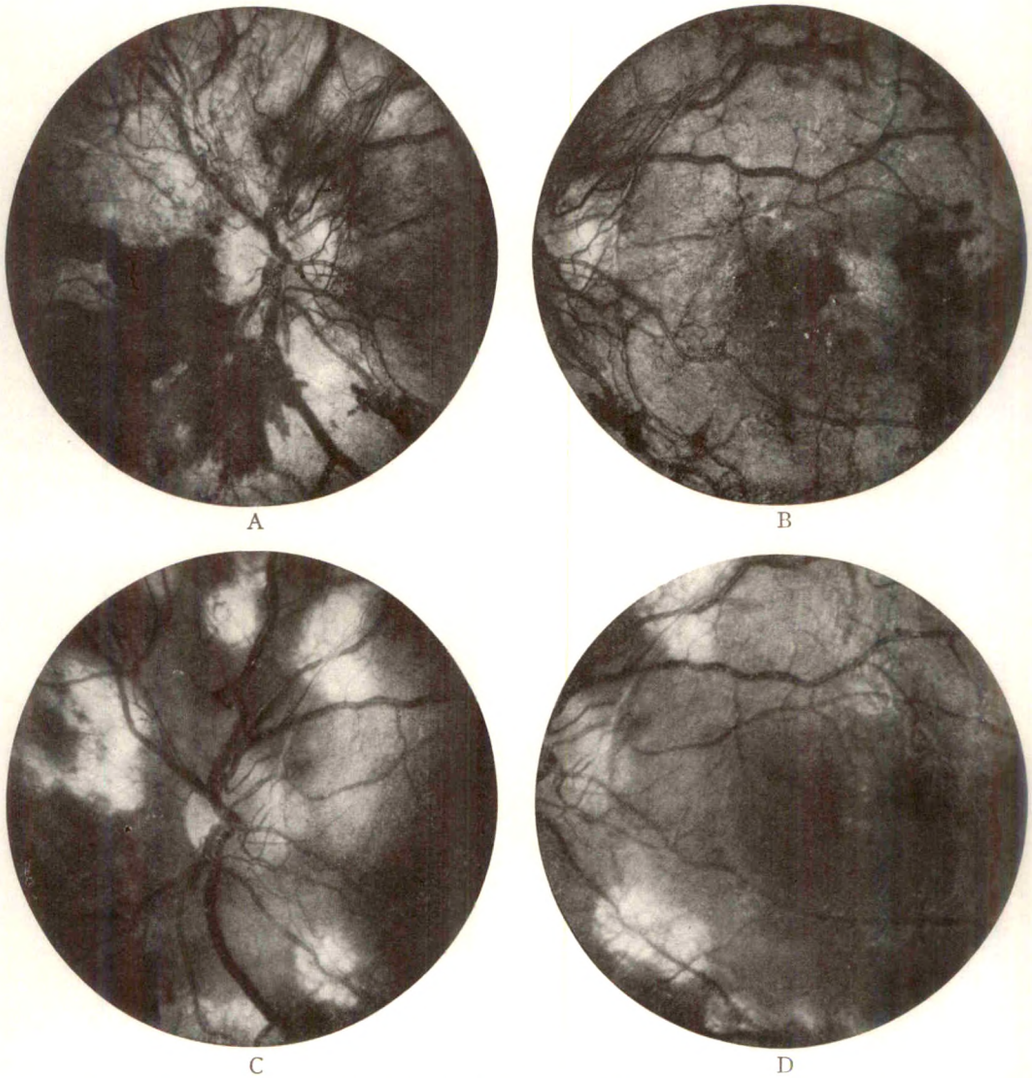

Fig. 6 (Krill, Archer, Newell, and Chishti). Photographs of left posterior eyegrounds and macular area from a 19-year-old diabetic woman before (A and B) and six months after (C and D) photocoagulation. Extensive retinitis proliferans is seen at the optic disk and along the superior and inferior temporal vessels prior to photocoagulation (A and B). These vessels have largely disappeared following treatment (C and D). The retinal vessels show an overall decrease in caliber and most of the hemorrhages have disappeared in areas at or adjacent to the sites of photocoagulation (D).

12. Photocoagulation often prevented the extension of localized detachments by sealing the edges of such areas.

### General effects of photocoagulation

Some of the general effects of treatment were as follows:

1. Reduction in caliber of retinal veins and arterioles was observed (compare inferotemporal vessels in Fig. 5-A and B). Dilated retinal veins occasionally returned to normal size (compare Fig. 3-B with 4-B, and 5-A with 5-B). Segmentation and beading often became less obvious. Retinal venous circulation times improved, but rarely returned to normal.

2. There was disappearance of widespread areas of neovascularization with a replacement by fibrous tissue (Figs. 5, 6, and 7).

3. There was production of a mild optic atrophy and reduction or disappearance of new vessels on the optic disk surface (compare Figs. 8-A and C), even when photocoagulation was not directly adjacent to the disk surface. Extensive disk neovascularization extending into the vitreous was not significantly affected by distant photocoagulation.

### Specific complications of photocoagulation

The specific complications seen in our series of patients are as follows:

1. Inadvertent macular photocoagulation caused visual loss in one patient. The spread of heat from the photocoagulation marks caused a foveal scar. (We have also seen loss of central vision following photocoagulation of the papillomacular bundle in a patient photocoagulated for another disease.[4])

2. Small, spotty visual field defects were frequently noted as a result of receptor damage at photocoagulated sites. Usually patients suppressed such scotomas. Arcuate scotomas reflecting nerve fiber damage were elicited in a few patients.

3. Inadvertent photocoagulation of large retinal veins in two patients resulted in retinal hemorrhage. In one patient treatment had to be completed at a later date.

4. Some patients with vitreous retraction and advanced proliferative retinopathy later developed more extensive vitreous retraction. Perhaps the disease process was accelerated by photocoagulation in such patients.

Two aphakic patients developed posterior vitreal traction at the macula with deterioration of central vision after photocoagulation. One of these patients received less than the usual amount of photocoagulation. Neither had obvious posterior vitreous disease before treatment.

5. Mild iridocyclitis was common, but only of consequence in one patient who developed posterior synechiae. It is important to obtain wide dilation of the pupil before photocoagulation.

6. An effusive retinal detachment of the macula and mid-temporal retina was seen a day after photocoagulation in one patient. Spontaneous absorption of fluid occurred within one week and the patient eventually obtained a good result.

7. New vessels and fibrous tissue occasionally formed adjacent to photocoagulation sites (see arrow in Fig. 10-C). Perhaps this was due to obstruction of small retinal vessels at this site, producing areas of retinal hypoxia.

9. Photocoagulation over an abnormal middle-sized or large retinal vein occasionally produced temporary obstruction (seen on fluorescein angiography). New surface retinal vessels sometimes formed at the margins of such sites, and retreatment was necessary.

Conceivably, photocoagulation of the optic nerve could cause an arcuate scotoma or central visual loss if the papillomacular fibers were damaged. We did not have this complication.

### Causes of poor results

Poor results were obtained in 15 patients in our series. Of these, nine patients had widespread advanced proliferative retinop-

athy and vitreal changes at the time of treatment, causing significant posterior retinal traction. It is doubtful whether most of these patients would be considered for treatment at present. Four patients were considered to have inadequate photocoagulation. One patient did well for two and one-half years and then bled severely from a new proliferative

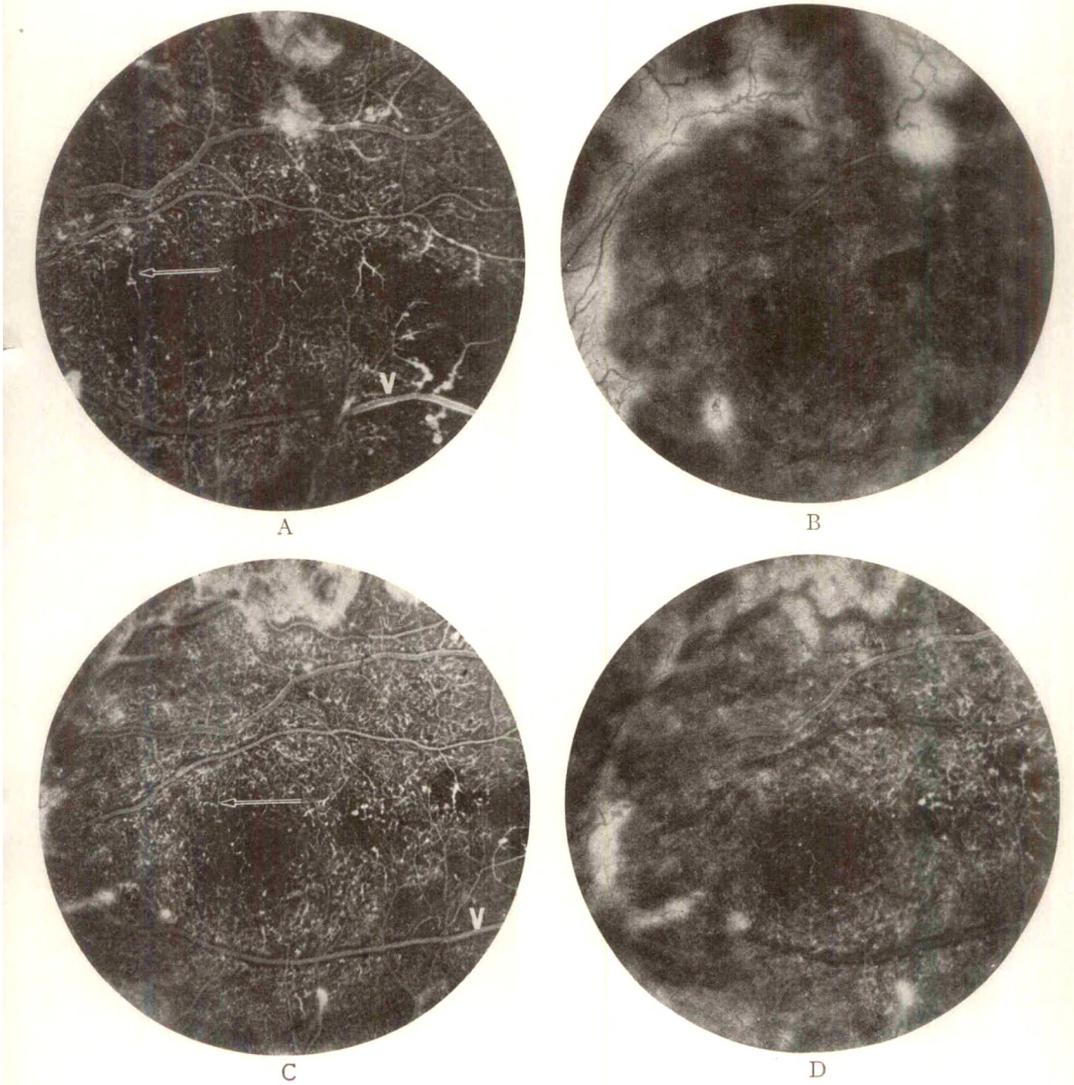

Fig. 7 (Krill, Archer, Newell, Chishti). Fluorescein angiograms of same eye as in Figure 6, shown here before photocoagulation (A and B), and six months afterwards (C and D). Photographs at the left (A and C) were taken during mid-retinal venous phase. Photographs at the right (B and D) were taken three minutes after dye injection. Retinitis proliferans is evident along the superotemporal vessels, which show considerable dye leakage in the late picture (B). Following photocoagulation, there is less retinitis proliferans and reduced dye leakage (D). The details of capillary architecture are more distinct following photocoagulation (compare Figs. A and C). Note many of the capillaries and hairpin-like dilations have disappeared or have become considerably reduced in caliber after photocoagulation (compare arrows in Figs. A and C). The retinal vein walls stain less following treatment, and there is also a reduction in caliber of the venous wall (compare area marked V in Figs. A and C).

site. It is likely that closer follow-up may have been beneficial in this patient. The cause of a poor result in one patient was unknown.

### Precautionary measures in photocoagulation

Based on our experience, certain precautions are advised. These are as follows:

1. High intensities should be avoided. Photocoagulation marks within the macula may cause unexpected foveal or papillo-macular bundle damage when high intensities are used.

2. Photocoagulation should be avoided in patients with advanced proliferative retinopathy and extensive posterior eye-ground traction. Treatment may cause further traction and even hole formation and subsequent retinal detachment.

3. It is questionable whether aphakic eyes should be treated, based on our experience with two patients. If used, photocoagulation should be limited or perhaps divided over several sessions.

4. Treatment should be avoided, if possible, in eyes with extensive vitreous hemorrhage, even though visibility may be adequate. Eyes with blood in the vitreous often require greater intensities to produce adequate photocoagulation. Such intense photocoagulation is more likely to damage the vitreous and lead to eventual retraction. It is best, if possible, to limit the amount of treatment in any eye when more than usual energy is required to produce an adequate burn. Additional photocoagulation can be given at another date.

5. Since vitreous detachment alters the effectiveness of photocoagulation, even in the absence of significant proliferative retinopathy, treatment should be staggered in such areas.

6. One should photocoagulate close to the disk (except, of course, at the temporal margin) in eyes with extensive optic disk proliferation, even if vessels extend far into the vitreous. Atrophy of the vitreal vessels may occur as a result of such treatment. Extensive proliferative retinopathy on the optic disk surface is often the source of additional vitreous hemorrhages after photocoagulation, and may be the most frequent cause of failure of treatment.

7. The amount of photocoagulation used is important. It was soon discovered that in order to significantly decrease macular edema it was necessary to photocoagulate inside, as well as outside, the macular branches of the temporal vessels. It was also noted that photocoagulation temporal to the macula was necessary to eliminate persistent edema and waxy exudates in this region. If not eliminated, edema in this area sometimes spread directly into the center of the macula.

In general, our best results occurred in patients who had extensive photocoagulation, we believe from the elimination of areas of hypoxic retina.

8. Direct photocoagulation of middle and large sized retinal veins should be avoided. As pointed out, hemorrhage may occur at the time of treatment or partial obstruction of these vessels may result, with the formation of new retinal vessels near such sites.

9. Careful follow-up is essential. Even with initially successful results, new retinal vessel growth may continue to form, particularly near the site of previous photocoagulation. Macular edema may also reappear. Additional photocoagulation may be beneficial in such patients. In regard to possible permanent remissions observed in patients followed over long periods, it is our impression that this is more likely to occur with proliferative retinopathy rather than with macular edema, where abnormal retinal vessels may again leak fluid.

## Discussion

In general, our data support the concept that photocoagulation is of greatest value in eyes with early or moderately advanced proliferative retinopathy.[5-14] However, in our experience, this treatment may be of value even in far-advanced proliferative retinopathy, providing it is localized and not associ-

ated with significant posterior retinal traction.

Photocoagulation has both specific and general effects which should prevent or greatly retard future hemorrhagic episodes. These episodes often result in vitreal and proliferative retinal changes with subsequent permanent loss of vision. Furthermore, it is obvious from our data that massive vitreal hemorrhages may take a long time to absorb,

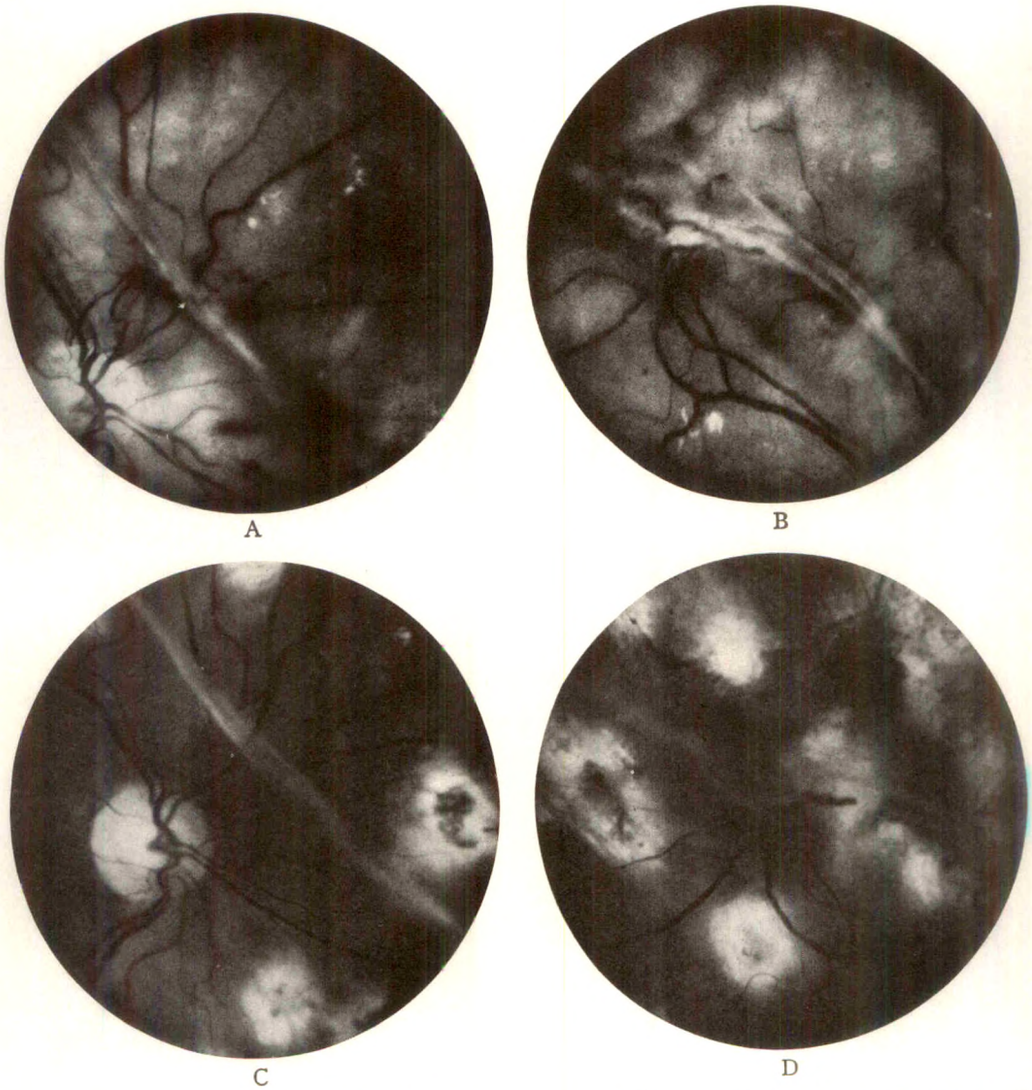

Fig. 8 (Krill, Archer, Newell, Chishti). Photographs of posterior eyegrounds and superotemporal areas of right eye of 47-year-old woman before photocoagulation (A and B) and almost three years afterward (C and D). Note large band-like area of proliferans extending into the vitreous with hemorrhage around and above the proliferative areas (A and B). After photocoagulation, the fibrotic mass is completely devoid of vessels, as the result of photocoagulation of many sites around the base of the proliferative area (C and D). Some of the retinal vessels are significantly reduced in caliber (compare superotemporal retinal veins and arterioles in Figs. A and C), and some of the tortuosity in the superonasal vessels has diminished (compare Figs. A and C). Most new vessels seen (A) on the surface of the optic disk disappeared following photocoagulation (C), although no photocoagulation burns were applied adjacent to the optic disk. Retinal folds present before photocoagulation largely disappeared afterwards.

or may never completely absorb. Only two of 20 untreated eyes, originally unclassifiable because of severe vitreal hemorrhage, cleared sufficiently for later classification. Davis[15] has also commented on the long persistence of large vitreal hemorrhages.

In our experience, proliferative diabetic retinopathy is usually an asymmetrical disease. Only a relatively small number of our patients were considered to have symmetrical proliferative retinopathy when comparing initial classification data. Therefore, patients are often seen with far-advanced disease in one eye and relatively early proliferative retinopathy in the second eye. The justification for treating the second eye is based

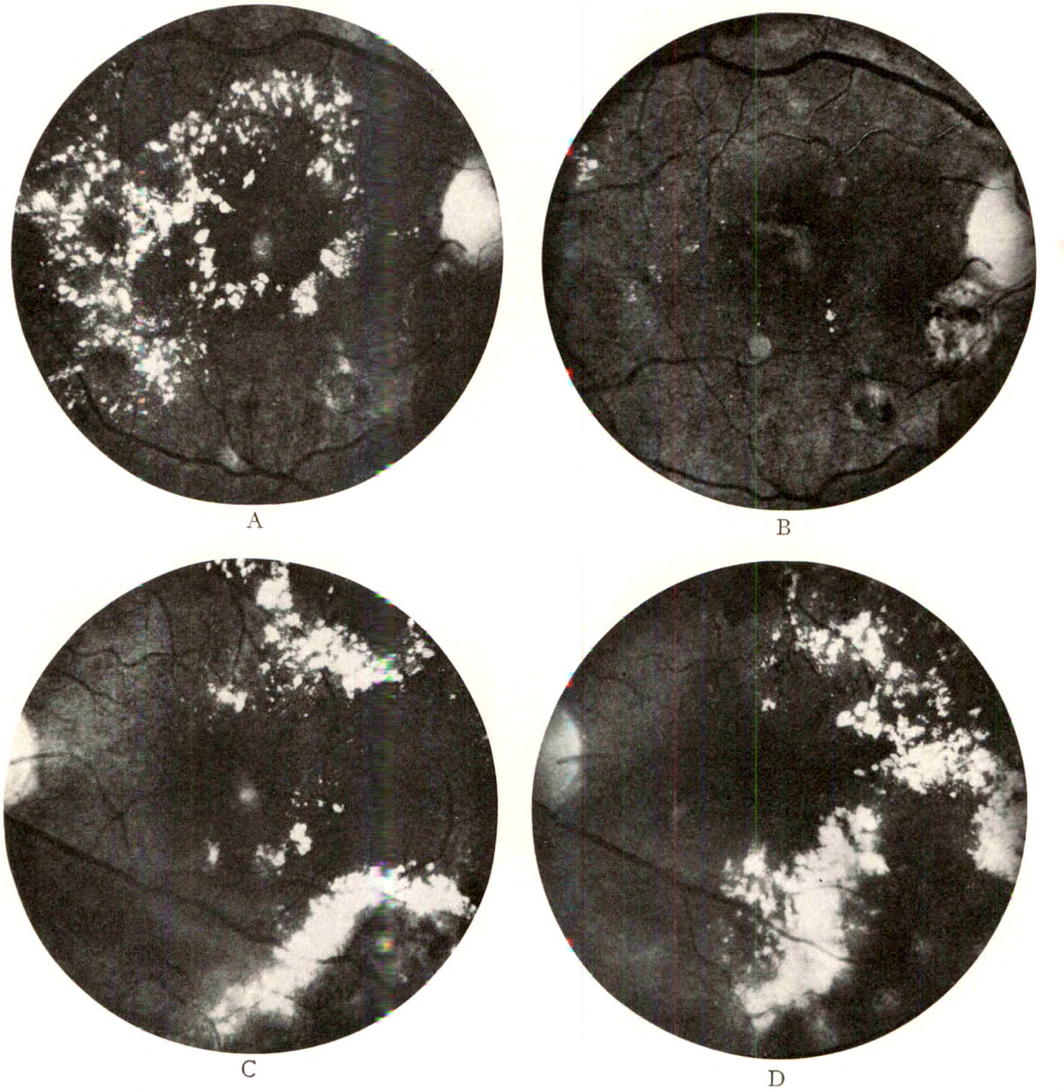

Fig. 9 (Krill, Archer, Newell, Chishti). Right and left posterior fundi of 66-year-old man (Case 12). Top: Treated right eye (A) two weeks after photocoagulation, and (B) 15 months after photocoagulation. Bottom: Corresponding photographs of the left, or control eye. After 15 months, most waxy exudates have disappeared in the treated eye (B), whereas after this lapse of time, there is an increase in the number of waxy exudates in the untreated eye (C and D). Macular edema almost disappeared in the treated eye.

on data indicating that once one eye has far-advanced disease, the other eye often follows the same course.[16]

Several other factors favor treatment of certain eyes with early proliferative retinopathy (PR):

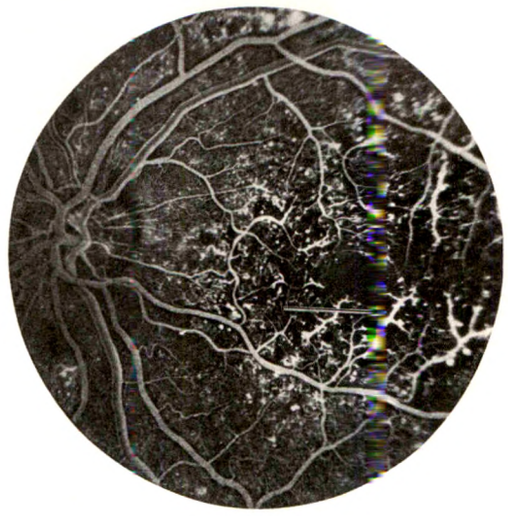
1. Several long-term studies indicate that eyes with PR do not do well.[15,17-20] Approximately 50 to 60% of the eyes with early PR are blind (20/200 vision or worse) within five years and few retain normal vision.

2. In general, eyes with PR near the disk do worse than those with PR elsewhere.[18] Fifty percent of eyes with PR near the disk are blind in two to three years, whereas 50% of the eyes with PR elsewhere are blind in five years. At sites distant from the disk, surface vessels occasionally show spontaneous regression.

3. The older the patient is, the worse his prognosis with either proliferative,[16,18-22] or nonproliferative retinopathy.[19,23,24]

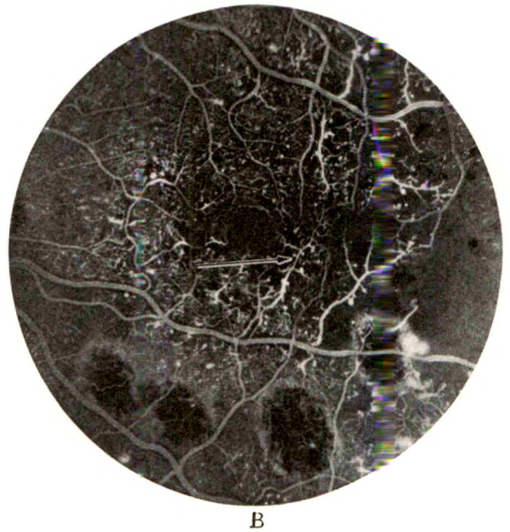
4. Visual prognosis after a vitreous hemorrhage is particularly dismal. Even after the first vitreous hemorrhage, one-third of such eyes are permanently blind within one year and another one-third have permanently impaired vision.[19]

It seems, then, that eyes with PR most likely to benefit from treatment are: (1) those from older patients (beyond the age of 40), (2) those with vessels near the optic disk, (3) those with a past or present vitreous hemorrhage, or (4) the fellow eye of patients with a severe vitreous hemorrhage or far-advanced PR in the other eye.



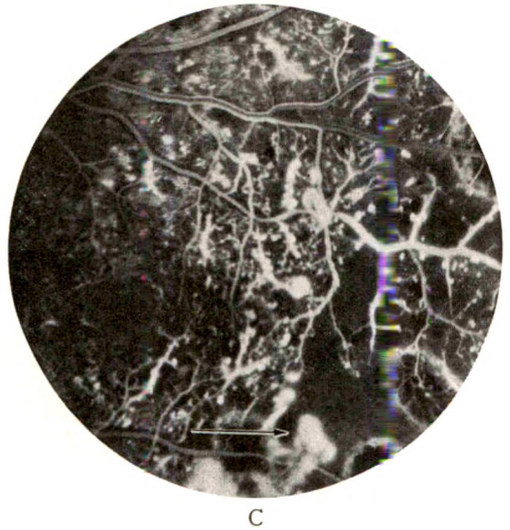
The average follow-up in our series of 56 patients is only two years; however, some published data on the natural course in eyes with PR which can be used for comparative purposes are:

1. In one study[16] it was shown that patients severely blind in one eye (20/200 or worse vision) frequently become blind in the remaining good eye (defined as 20/80 or better initial vision in this study) in a relatively short period of time. Among 17 of our patients whose treated eyes had good vision (20/80 or better), six (35%) with blind fellow eyes eventually had visual acuity of 20/200 or worse in their treated eye during follow-up periods which averaged 24 months. In the study cited,[16] where no treatment was given, 59% of the good eyes became blind within one year.



2. Deckert, Simonsen, and Poulsen[18] noted that 46% (12* out of 26 patients) of eyes with pre- and peripapillary proliferation went blind (20/200 vision or less) within two years of follow-up. Twenty-seven percent (7 out of 25 patients) of the eyes we treated in this category went blind upon follow-up (a period averaging close to two years).

3. Beetham[17] reported data from two-year and longer follow-up periods in eyes with initial vision of 20/40 or better in patients over 20 years of age. The exact number of eyes could not be calculated from the data given in the paper. After two years, 20% of the eyes had less than 20/200 vision, and in another 20% vision was between 20/50 and 20/200. Of our 20 eyes in this category, five (25%) had worse than 20/200 vision and four (20%) had vision between 20/50 to 20/200. However, the average age of our group (46 of our 56 patients were 45 years or older) may have been considerably higher. (We could not determine how many of Beetham's patients were in this age range.) It has been shown that in eyes with PR the long-term visual prognosis is considerably worse in those who are 40 years of age or older than it is for a younger age group.[17-19,21] Furthermore, valid comparisons between eyes should probably include classification as well as visual acuity data. It is of interest that in several other series of photocoagulated eyes where vision initially was 20/40 or better, one-year follow-up studies revealed 53 to 76% of the treated eyes



* Figure 3 of the original publication indicates that three eyes were blind when originally seen and therefore these were eliminated from this calculation.

A

B

C

kept this vision.[25] In our series 53% maintained 20/40 vision or better.

The claim that only five-year data are valid in evaluating treatment[25] is questionable when referring to eyes with PR. This is true particularly where the second eye is already severely blind,[16] of eyes with vitreous hemorrhage,[19] and of eyes with proliferative retinopathy near the disk,[18] as it has been pointed out that blindness occurs in many of these eyes within one or two years after initial evaluation.

Most important in this type of study was the comparison of both visual acuity and classification data from treated and untreated eyes on follow-up. Such evaluation indicated that 31 eyes definitely benefited from photocoagulation. In seven patients, both the treated and untreated eyes did well; therefore, it is uncertain that treatment was of any value in these patients. It is difficult to compare our data with that of other workers, since there are few series in which one eye alone was treated. Okun[26] published data

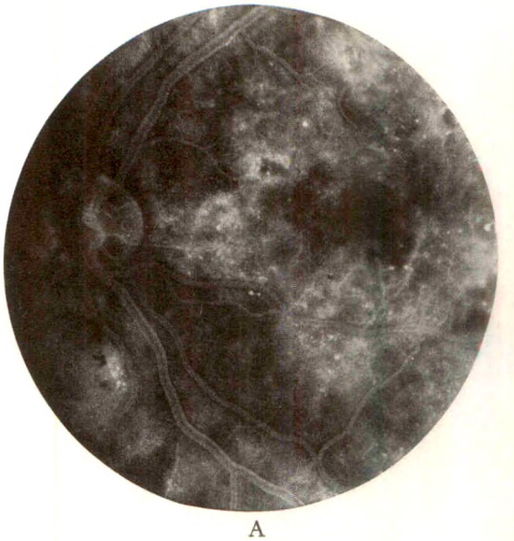


Fig. 10 (Krill, Archer, Newell, Chishti). Fluorescein angiograms of the left posterior eyegrounds of a 28-year-old diabetic woman. The angiograms were taken during the midretinal venous phase in all photographs: (A) before photocoagulation, (B) three months afterwards, and (C) six months afterwards. Note the dilated and irregular capillaries in the macula and surrounding areas before photocoagulation. Typical dilated hairpin-like shunt vessels (arrow points to one) are frequently associated with areas of nonperfused retina. The major retinal veins and arteries are dilated and many microaneurysms are evident. Three months after photocoagulation (B), the retinal capillary architecture is more regular. The capillaries, shunt vessels, and microaneurysms are all reduced in size, although there is no obvious change in the number of microaneurysms present. The hairpin-like capillary dilations are less obvious (compare arrows in Figs. A and B). Six months after photocoagulation (C), the capillary architecture is again indistinct and microaneurysms are again prominent. Dye leakage is again seen (even more than before photocoagulation) from several dilated capillaries and microaneurysms, particularly near sites of photocoagulation (see arrow at bottom of Fig. C).

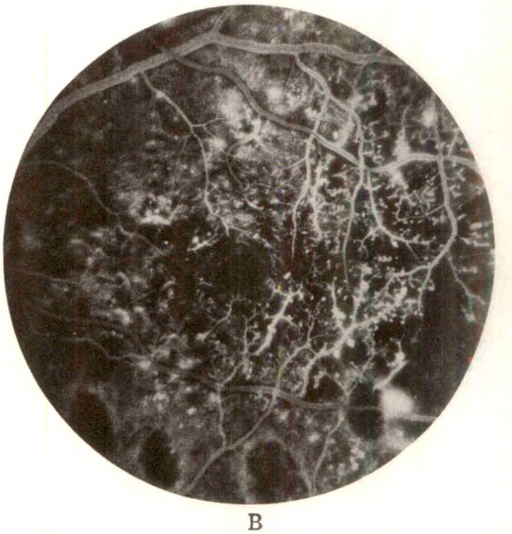
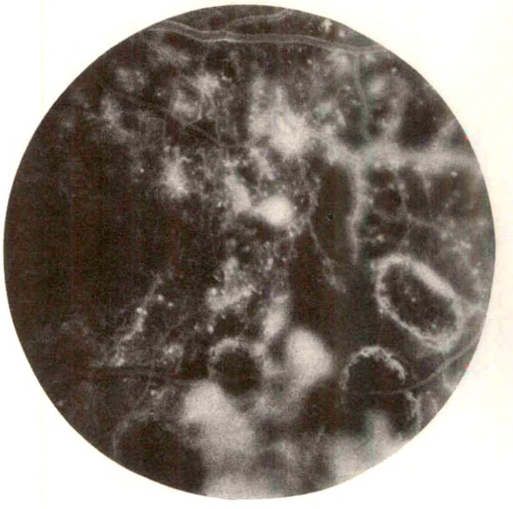
from 50 patients where one eye only was treated. In 25 patients, there was no change of status in either eye. In the other 25 patients, progression occurred in 23 untreated and two treated eyes.



In contrast to our experience with PR, patients with no or minimal PR and bilateral macular edema often had symmetrical involvement. At first, visual results were poor in many patients with bilateral macular edema. However, the visual results improved when we photocoagulated inside the macular branches of the temporal vessels and temporal to the macula, in addition to the routine sites. All patients treated in this latter manner have shown at least partial absorption of macular edema, although vision has not improved in some because of permanent damage to the fovea, particularly as a consequence of cystoid degeneration.

We particularly favor treatment of older diabetic patients with chronic bilateral macular edema, since spontaneous resolution is unlikely after the age of 40.[19,23,27] In general, we follow patients with macular edema until progressive visual loss can be adequately documented, or where, in eyes with vision of 20/60 or worse, we establish that there are no signs of improvement within two to four months. It should be emphasized that the longer macular edema persists, the greater the likelihood of permanent macular damage.



We have only treated diabetics with nonproliferative (simple or background) reti-

A

B

C

Fig. 11 (Krill, Archer, Newell, Chishti). Same eye as shown in Figure 10. All photographs were taken three minutes after dye injection: (A) before photocoagulation, (B) three months afterward, and (C) six months afterward. There was considerable decrease in dye leakage throughout the macular area three months after photocoagulation (B), with better visualization of small vessel architecture. Six months after treatment (C), vessel details are again blurred with considerable dye leakage evident, particularly adjacent to sites of photocoagulation.

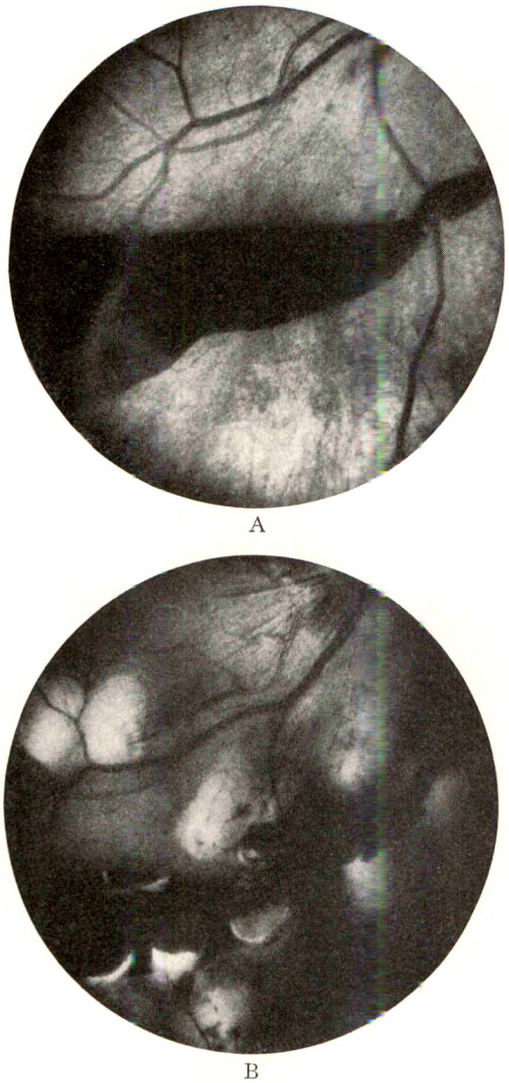


Fig. 12 (Krill, Archer, Newell, Chisati). Photograph at site of pre-retinal hemorrhage in 48-year-old man (A) before photocoagulation and (B) 24 hours later. A considerable portion of the hemorrhage has disappeared after direct photocoagulation.

nopathy for chronic macular edema. Because of the favorable natural course in many of these patients,[19,23,27-30] it is questionable whether such eyes should be photocoagulated. In fact, in one study 61% of eyes with nonproliferative retinopathy were unchanged visually after 10 years.[28] Visual prognosis is worse in eyes with hemorrhages and exudates than in eyes with only microaneurysms.[28] Also, as indicated previously, the prognosis is worse with age.

On the other hand, some eyes with simple diabetic retinopathy progress to proliferative diabetic retinopathy.[15,30] At present, it is uncertain which eyes are likely to show such progression. Furthermore, some workers[31-33] feel that there is a predisposition toward either proliferative or nonproliferative retinopathy and that these are separate entities. Data which may support this latter notion are the findings that glaucoma and a positive response to topical corticosteroids are more common in patients with nonproliferative retinopathy than in the normal population, but in patients with PR there is the same incidence as in the normal population.[34]

Probably the two most important beneficial effects of photocoagulation are the elimination of neovascularization on the retinal surface and a decrease in permeability of small intraretinal vessels.

Neovascularization on the retinal surface or extending only slightly into the vitreous is usually eliminated by direct photocoagulation of such areas, or at times, of adjacent retina. New vessels extending more into the vitreous cannot be directly treated with the xenon instrument, but these vessels may decrease in number or even disappear when photocoagulation is placed around the base of such areas. New vessels on the optic disk surface or elsewhere may atrophy even when treatment is quite distant. However, this does not occur with extensive proliferation extending significantly into the vitreous. Photocoagulation in such instances may be placed around the base of such areas, as pointed out, or adjacent to the optic disk if this site is involved.

A pronounced decrease in permeability of smaller intraretinal vessels, best demonstrated by fluorescein angiography, occurs after photocoagulation. Leakage of fluorescein from abnormally dilated capillaries and shunt vessels in both directly treated and adjacent retinal areas was sometimes considerably reduced by photocoagulation. This is true even if these vessels persist after treat-

ment. Persistent vessels are usually reduced in caliber.

Decrease in leakage from intraretinal vessels in the macula and reduction in their caliber is most likely secondary to the diminished blood supply requirement of and reduced venous return from destroyed retina. A decrease in the pressure head of venous return ultimately should cause a reduction in the size, and probably the permeability, of small vessel radicles. Possibly, the destruction of hypoxic areas may also have reduced the production of or eliminated tissue metabolites with local toxic effects (such as increased permeability and dilation) upon the retinal vasculature.

Wide ranging changes after extensive photocoagulation were demonstrated. These general effects included disappearance of surface retinal vessels at sites distant from photocoagulation, such as on the optic disk surface, reduction in caliber of large retinal veins and arterioles, and frequently mild optic atrophy concomitant with arteriolar attenuation. The changes in the large retinal vessels, like those in the small retinal vessels, may also be secondary to some extent to diminished blood supply required and reduced venous return from destroyed retina. However, this reasoning does not explain attenuation of larger retinal vessels, which may occur in untreated as well as treated retinal quadrants. It is obvious that it is not necessary to photocoagulate along retinal arterioles, as previously claimed, to produce arteriolar attenuation and optic atrophy in patients with diabetic retinopathy.

The atrophy of surface retinal vessels at sites a considerable distance from photocoagulation, such as on the surface of the optic disk, may be due to the elimination of an abnormal chemical factor speculated to originate in hypoxic tissue, which is converted to anoxic tissue. The possibility of a vasoformative factor originating in hypoxic tissues has been previously suggested.[35-37] The disappearance of new vessels after treatment suggests that such a factor may aid in maintaining new vessels as well as stimulating their original formation. Strong support for the existence of a chemical factor in hypoxic tissues comes from the notation of the disappearance of new vessels on the surface of the iris after photocoagulation in one patient with diabetic retinopathy and in another with a branch vein occlusion.[4]

The beneficial effect of reducing the amount of retinal tissue to supply with a presumably limited circulation is also suggested by observations that diabetic retinopathy is less frequent or less severe in patients with a reduction in actively metabolizing retinal parenchyma. For example, it is known that severe PR is rare in eyes with myopia over five diopters, in eyes with advanced glaucoma, in eyes with severe chorioretinitic atrophy, or in eyes with a retinal degeneration.[28,34,38,39]

Photocoagulation is probably contraindicated in patients with advanced PR where there is significant vitreoretinal traction, since the procedure may hasten progression of the disease. Furthermore, on the basis of our limited experience, less photocoagulation should be used in the treatment of aphakic patients with diabetic retinopathy, since it appears that vitreous retraction in the macular area is more likely to occur in such patients.

In general, our best results were obtained with extensive photocoagulation. Direct treatment of only proliferative areas was not enough. In such cases, new surface retinal vessels continued to form and generalized effects were lesser in degree, or not noted. It is recommended that photocoagulation should destroy not only obvious proliferative sites, but in addition, destroy retina considered unimportant for visual purposes. The beneficial effects of such treatment were demonstrated in this report. The results of inadequate treatment in patients with chronic macular edema was also discussed.

Careful follow-up of treated patients with diabetic retinopathy is important for several reasons. First of all, the full effect of extensive photocoagulation may not be noted for up to four months after treatment. Secondly,

certain changes may necessitate retreatment. Fresh areas of retinitis proliferans and surface neovascularization may occur adjacent to areas of photocoagulation, probably as the result of venous obstruction, stasis, and hypoxia with renewed stimulus to new vessel growth. This finding was most frequent where a photocoagulation scar occurred directly over or adjacent to a large retinal vein, compromising blood flow in the vessel. Finally, some patients with previously resolved macular edema may again start to leak from dilated capillaries and shunts in the macula within six to 12 months after initial treatment. Retreatment may be beneficial in such patients. Also, on occasion, dilated capillaries and shunts which had atrophied reappeared in such patients.

It appears on the basis of our experience to date, that "permanent" remissions occur more commonly in patients in whom PR is the sole reason for treatment. Such patients may be hastened into the final atrophic stage by photocoagulation, supposedly the end stage of many untreated eyes with PR.[40] On the other hand, the problem of permanently diseased, leaky, small intraretinal vessels in the macular area of treated patients with macular edema remains, and possibly such patients will never have a permanent "cure" after photocoagulation.

The most frequent cause of a poor result in patients with early PR was the eventual development of an extensive proliferative growth on the optic disk surface. Perhaps extensive photocoagulation, including treatment adjacent to the nasal half of the disk, prevents this occurrence. Only a few patients treated in this manner have developed significant proliferation on the disk surface. Therefore, we now routinely photocoagulate patients with PR nasal to the optic disk.

Hopefully, the argon laser, which photocoagulates vessels that are not in contact with the retinal surface, can be used to treat many of the eyes with extensive vasculature a sufficient distance above the retina that have not responded to photocoagulation. Preliminary data in this area are encouraging.[41]

## Summary

Data are presented from 56 patients with diabetic retinopathy who were followed for one year or more after photocoagulation of one eye only. On the basis of visual acuity and changes in classification in the treated eye, 31 of these patients had some benefit from photocoagulation. Fifteen patients did poorly. Ten of these had advanced proliferative retinopathy. Four were thought to have had inadequate photocoagulation. (The necessity for extensive photocoagulation in most patients is stressed.) One patient had insufficient follow-up, and the importance of adequate follow-up is emphasized, particularly in patients with macular edema.

Ten patients had inconclusive results. In seven of these, both treated and untreated eyes did well, and three had deterioration in both eyes. No conclusions regarding the effects of photocoagulation were possible in these patients.

Photocoagulation has both local and widespread effects. Probably the two most important effects are the elimination of areas of surface proliferation and a general decrease in the permeability of small retinal vessels.

The possibility of a chemical factor existing in hypoxic tissues causing the formation and maintenance of new vessels, even at distant sites, is suggested. It is speculated that photocoagulation converts hypoxic to anoxic tissue, presumably eliminating such a factor.

Photocoagulation, if used properly, is of definite value in certain patients with early and moderately advanced proliferative diabetic retinopathy, and in certain patients with chronic macular edema.

## Acknowledgment

We acknowledge the valuable assistance of Mrs. Miriam Creeden in the handling of the large body of data accumulated in this study.

# OPHTHALMOSCOPIC MONITORING OF OXYGEN THERAPY IN PREMATURE INFANTS

## Fluorescein Angiography in Acute Retrolental Fibroplasia

S. J. Cantolino, M.D., Guy E. O'Grady, M.D., Jose A. Herrera, M.D., Charles Israel, M.D., Johnny Justice, Jr., and John T. Flynn, M.D.

*Miami, Florida*

Retrolental fibroplasia (RLF) was first described by Terry[1] in 1942. In the early 1950s, studies by Patz[2] in the United States, Ashton and associates[3] in England, and Gyllensten and Hellstrom[4] in Sweden demonstrated a toxic effect of oxygen therapy in premature infants. With this discovery there followed a period of curtailment of oxygen administration in the premature nursery and the almost complete elimination of RLF. During this period of restricted oxygen therapy, infant mortality associated with respiratory distress,[5,6] as well as the incidence of cerebral palsy,[7] was increased. It has since been shown[8–10] that infants with respiratory distress syndrome frequently require a high concentration of oxygen for survival. In the past several years, pediatricians have tended toward a more liberal use of oxygen in managing this problem. As a result, there may be an increase in the incidence of RLF.[11]

About 10% of infants born before 37 weeks' gestation develop the respiratory distress syndrome in the neonatal period; this is the most common cause of death in newborn infants. Standard practice has been to administer oxygen to these infants only when clinically indicated by cyanosis, retraction, or other signs of respiratory distress. Fetal hemoglobin can carry more oxygen than adult hemoglobin; thus, clinical recognition of hypoxia is more difficult in the newborn. Cyanosis might not be noticed in an infant until oxygen saturations of 75-85%,[12] which corresponds to an arterial oxygen tension of 32-42 mm Hg on the fetal hemoglobin dissociation curve. On the other hand, an infant can appear pink and have an arterial oxygen tension lying between 80 and 400 mm Hg due to flattening of the fetal dissociation curve at its upper end. Ideally, oxygen administration is also monitored by serial measurements of arterial oxygen tensions. Such methods require special personnel and laboratory facilities, repeated arterial punctures or indwelling arterial catheters, and involve risks.[13,14] Compounding the problem is the fact that the upper limit of a safe range of arterial oxygen tension before irreversible retinotoxicity is not presently known.

Because of these difficulties, it was suggested that the ophthalmologist might provide an additional guideline in oxygen therapy by serial ophthalmoscopic monitoring of retinal vessel caliber.[15] Experimental[3,16,17] and clinical[18–21] observations suggested that retinal vasoconstriction appeared to be the earliest sign of hyperoxygenation. In an effort to test the feasibility of this suggestion, the present study was undertaken.

### Materials and Methods

Daily, over a 10-month period beginning in August of 1969, all infants receiving oxygen in the premature nursery of Jackson Memorial Hospital were ophthalmoscopically examined. The indirect ophthalmoscope was used, permitting examination without opening the incubator. The examiner could simply

introduce his arms through the portals of the incubator, holding the lens with one hand and immobilizing the infant's head and hands with the other (Fig. 1). A self-retaining infant eyelid speculum was used, when necessary, to hold the eyelids apart. Care was taken to prevent undue pressure on the globe (Fig. 2). Dilitation of the pupil was effected with 1 or 2 drops of 1% cyclopentolate HCl (Cyclogyl) and 2.5% phenylephrine HCl (Neosynephrine) applied at one hour and then one-half hour before examination. In a few infants, an increased number of apneic episodes were associated with ophthalmic examination, despite the utmost care on the part of the examiner.

Whenever possible, the ophthalmoscopic examinations were performed at the same time that arterial oxygen tension determination was being made. Retinal vessel caliber was graded as normal, dilated, or slightly, moderately, or markedly constricted. In selected cases, arterial specimens were drawn for oxygen tension determinations after the ophthalmoscopic examinations to determine if they correlated with the clinical impressions. When an infant's oxygen therapy was discontinued, ophthalmoscopic examination was performed once a week. Following discharge, the infant was re-examined in two to three months, and thereafter, as indicated.

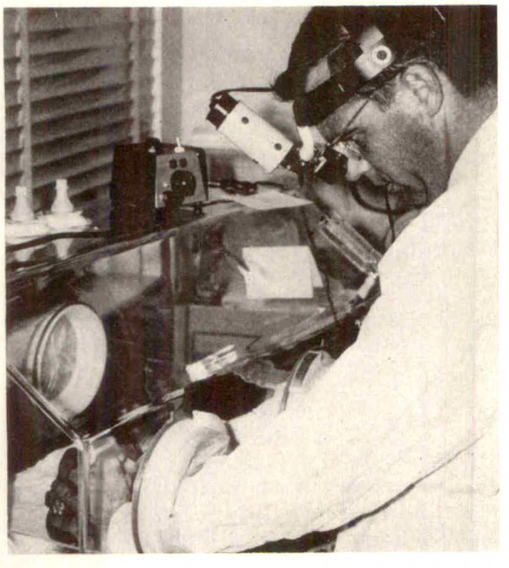

Fig. 1 (Cantolino and associates). Technique of indirect ophthalmoscopy.

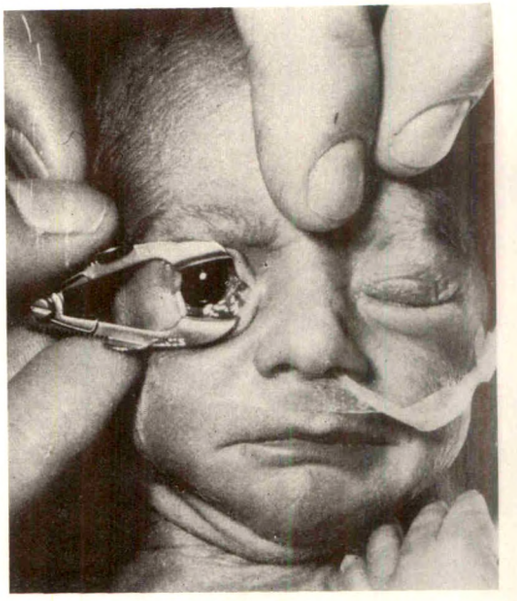

Fig. 2 (Cantolino and associates). Insertion of the infant eyelid speculum.

Whenever the clinical condition of the infant permitted, fundus photographs were taken to document the ophthalmic examination, using the Kowa fundus camera. Fluorescein fundus angiography was also performed on several premature infants, utilizing the Zeiss fundus camera (Fig. 3). For each of these studies, 0.3 ml of 5% fluorescein was injected intravenously.

Overall, a total of 102 infants were observed. Color fundus photographs taken on 68 occasions on a total of 29 infants and fluorescein angiography performed on 17 occasions on nine infants (Table 1).

## Results

Quite early in the study it became apparent that persistence haze made it impossible to visualize the fundus even with the indirect ophthalmoscope in many of the smaller prematures. This haze persisted for as long as four weeks after birth, followed by a period

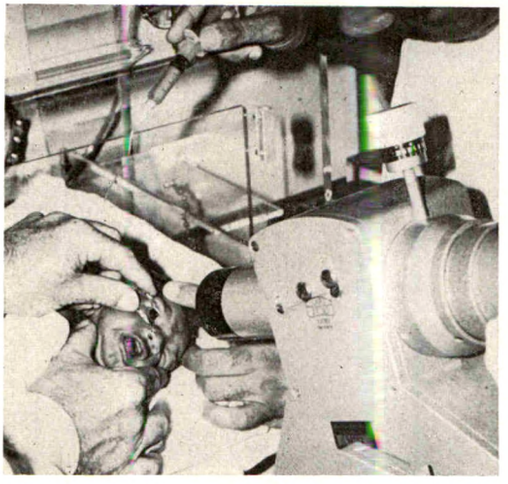

Fig. 3 (Cantolino and associates). Technique for performing fluorescein fundus angiography.

of gradual clearing. In general, it appeared the smaller the premature, the greater the incidence of haze and the longer it persisted (Table 2). Portable slit-lamp examination revealed the cornea and lens to be quite clear, excluding these two tissues as a cause of the haze. A persistent anterior tunica vasculosa lentis could often be visualized as multiple arcades of looped vessels in the pupillary space (Fig. 4). In several postmortem specimens obtained from very small infants, the hyaloid system extending into the tunica vasculosa lentis could be demonstrated (Fig. 5). We suggest that the persistence of this hyaloid system in very immature newborns may account in part for the presence of this haze.

In the course of this study we had occasion to follow three infants with respiratory distress syndrome who manifested a dense impenetrable haze during much of the time they received oxygen, thus precluding any possibility of effective funduscopic monitoring. Each of these infants went on to develop acute and then cicatricial RLF. The clinical course of these infants is as follows:

TABLE 1

CLINICAL MATERIAL

| Birth Weights | No. Infants |
|---|---|
| Under two pounds four ounces (1000 g) | 19 |
| Two pounds four ounces to three pounds five ounces (1000–1500 g) | 29 |
| Three pounds six ounces to four pounds seven ounces (1500 to 2000 g) | 42 |
| Over four pounds seven ounces (2000 g) | 12 |
| Total | 102 |
| Fundus photographs | 29 (68*) |
| Fluorescein angiography | 9 (17*) |

## CASE REPORTS

*Case* 1—Baby boy B had a birth weight of two pounds two ounces. Shortly after birth he was started on oxygen therapy was administered by mask, with the ambient concentration in the isolette varying between 28 and 54% during this period of time. For the first 10 days, the media were too hazy to visualize any fundus details, including the disk. By 11 days of age, the haze had begun to clear sufficiently so that the disk could just barely be seen. Oxygen therapy was discontinued when the child was two weeks of age, and at three weeks of age, a reasonable view of the retinal vessels was obtained for the first time. A significant degree of tortuosity of the arterioles and some dilitation of the veins was observed. Subsequent observations of this child revealed the progressive changes of acute RLF with large, tortuous, arterial trunks going out to the temporal periphery and ending in multiple, proliferative, branching arcades extending up to, but not beyond, a sharply delineated gray border of unvascularized retina. Fluorescein angiography was performed in the nursery when this infant was two

and one-half months of age, and it revealed vascular proliferation temporally and extensive leakage of dye in the area of the arcades. This infant has gone on to develop cicatricial changes with temporal detachment of the retina (Fig. 6).

*Case* 2—Baby boy R had a birth weight of two pounds four ounces. Because of respiratory distress, this infant was given oxygen by mask in his isolette over the first 18 days of life. The ambient oxygen concentration in the isolette was recorded as varying between 25 and 44% during this period, with the highest concentrations recorded over the first week of life when the infant's clinical status was most unstable. For the first eight days of life, this infant's media were too hazy to visualize the retinal vessels adequately. Over the next seven days, with gradual clearing in the media, progressive changes of acute RLF could be observed. Fluorescein angiography performed at one month of age revealed arcades of vascular proliferation extending temporally and ending abruptly at the gray zone of unvascularized retina (Figs. 7 and 8). These showed lighting up and leakage of dye in a pattern reminiscent of the sea fans described by Welsh and Goldberg.[22] This infant, also, has gone on to develop cicatricial changes of RLF.

*Case* 3—Baby boy, one of twins, had a birth weight of two pounds 14 ounces. Shortly after birth, because of respiratory distress, oxygen was administered by mask in concentrations of 34 to 50% over the first two days of life. Because of progressive deterioration in his clinical status, the infant was placed in a Bird respirator at the end of his second day of life. While on the respirator, periodic arterial oxygen tension determinations were made. These varied between 40 and 370 mm Hg. By five days of age, the infant's condition had stabilized and he was taken off the respirator and given oxygen by mask in concentrations of 30 to 36% until eight days of age, when all oxygen therapy was discontinued. Subsequently, the baby's course was unremarkable. Because of extremely hazy media, the fundus could not be visualized until seven days of age. At that time, vessel caliber was evaluated as normal to slightly dilated. Unfortunately, early serial fundus photographs could not be taken in this case, but from two months of age onward his retinal changes were documented photographically. This infant, also, went on to develop severe cicatricial changes of RLF, but in his right eye only (Fig. 9). The asymmetry of involvement is interesting in this case; the left fundus appeared essentially normal at the time severe cicatricial changes were present in the right eye.

## Comment

When hazy media was not a problem in these premature infants, it soon became apparent that clinical evaluation of retinal vessel caliber presented another area of difficulty in ophthalmoscopic monitoring. Independent attempts by three observers to estimate the presence of hyperoxia on the basis of constricted retinal vessels proved to be remarkably inaccurate (Table 3). In the course of this study there were 50 instances where a concomitant arterial oxygen tension value was available for comparison with the ophthalmoscopic evaluation of retinal vessel caliber. In 23 instances where the retinal vessels were judged to be of normal caliber, there were five occasions when the arterial oxygen tension

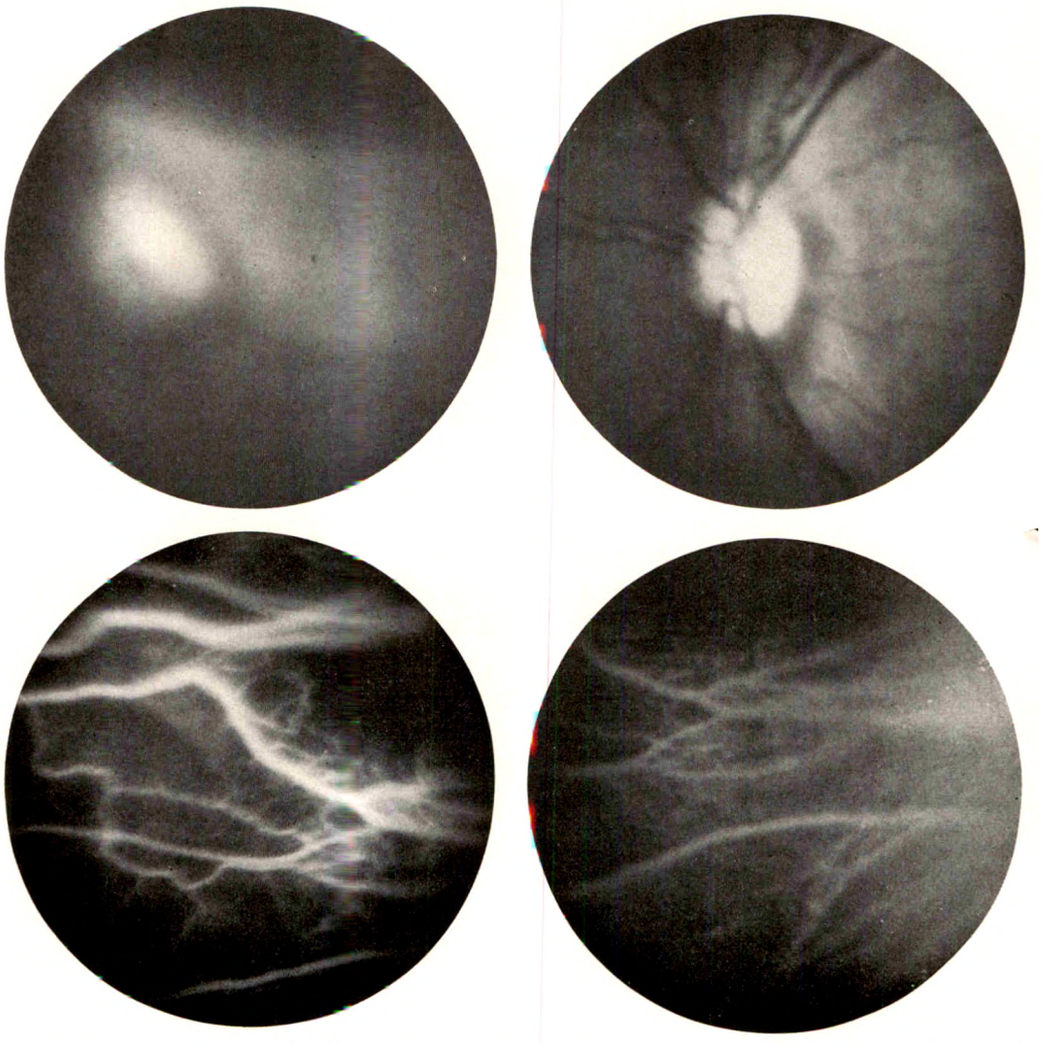

Fig. 6 (Cantolino and associates). Case 1. Top left: Age 15 days. Top right: Age 44 days. Bottom left and right: Fluorescein angiography, temporal periphery, age two and one-half months.

was 150 mm Hg or higher, with one as high as 400. Three of these arterial oxygen tension determinations were made on temporal artery specimens and the remainder were umbilical artery specimens. In 27 instances where retinal vessels were described as constricted, only three had arterial oxygen tension values greater than 150 mm Hg, with a fourth of 122 mm Hg, while the remainder were all under 70. Nine of these determinations were made on temporal artery samples, one on a radial artery sample, and the remainder were obtained from the umbilical artery. Right-to-left shunting of blood through the ductus arteriosus may make umbilical artery specimens less well oxygenated than radial or temporal artery specimens, which probably more accurately reflect the degree of oxygenation in the retina. In several of these infants with apparent constriction of vessels and extremely low umbilical artery oxygen tension values, the clinical signs of severe

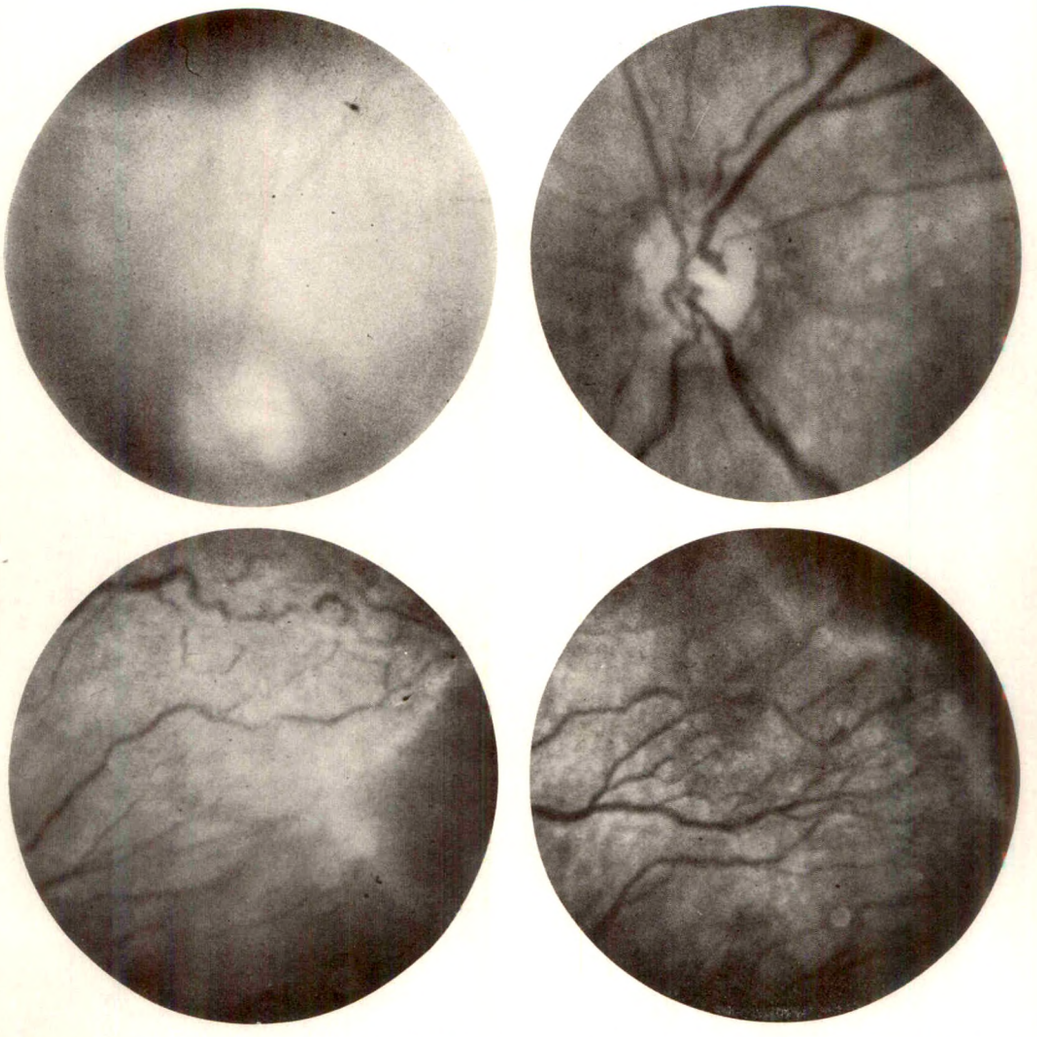

Fig. 7 (Cantolino and associates). Case 2. Top left: Age 10 days. Top right: Age two months. Bottom left and right: Temporal periphery at age two months.

respiratory distress, including cyanosis, appeared consistent with the arterial oxygen tension values. Photographic documentation of this poor correlation of arterial oxygen tension and retinal vessel caliber was obtained (Fig. 10). Retinal vessels frequently appeared quite narrow in infants of about 2¾ pounds (about 1300 g) or less during the first week of life, particularly when such infants were ill or in severe respiratory distress, regardless of the arterial oxygen tension.

## Discussion

The results of this study would seem to indicate that the proposed method of monitoring oxygen therapy by ophthalmoscopy has some serious problems: (1) the existence of hazy media in a significant number of infants at the time they need oxygen, and (2) poor correlation of ophthalmoscopically evaluated retinal vessel caliber and arterial oxygen tension values in many smaller, distressed premature infants.

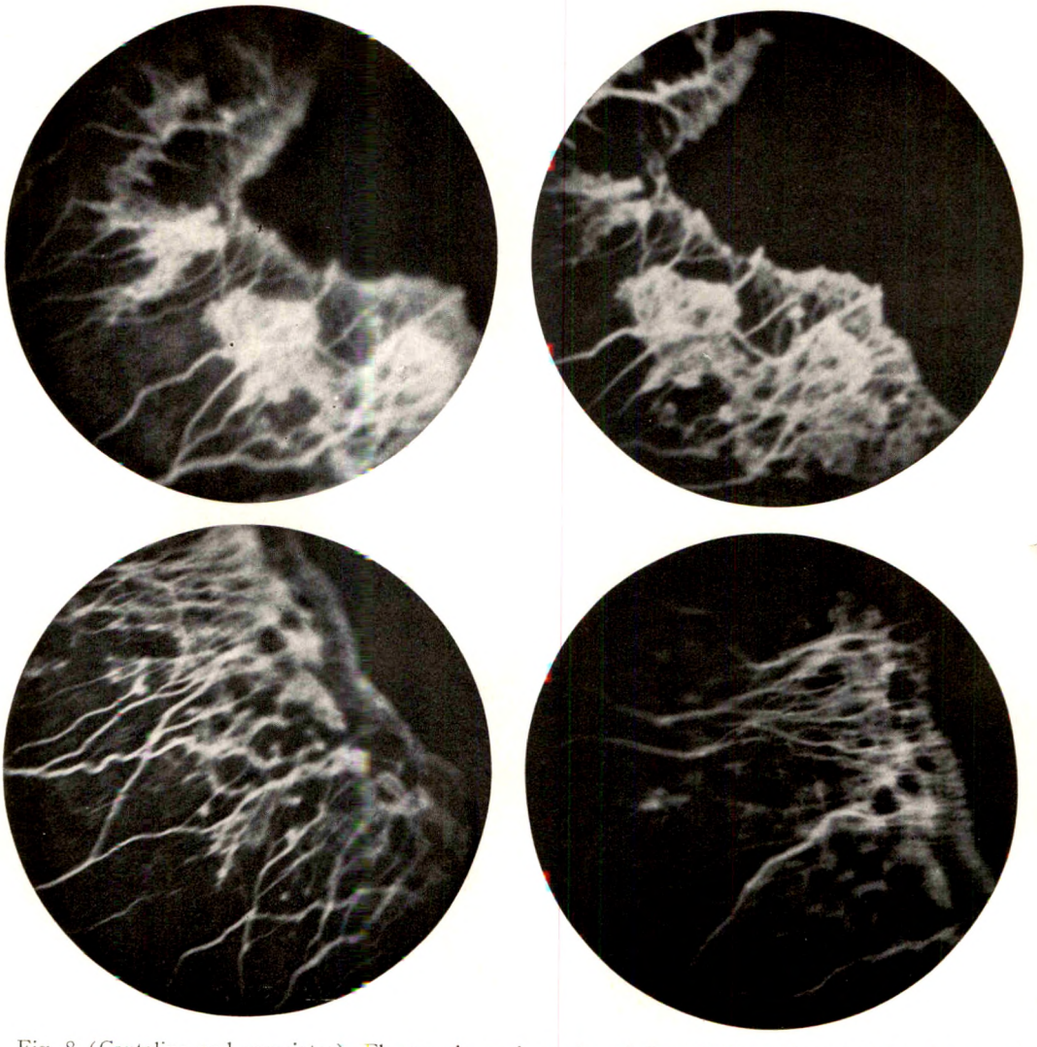

Fig. 8 (Cantolino and associates). Fluorescein angiography of Case 2. Top left and right: Temporal periphery at age two months. Bottom left and right: Temporal periphery at age two and one-half months.

The presence of hazy media in premature infants has been noted by other observers, but it has not been reported as significant an obstacle to ophthalmoscopy as we found it to be. It has been stated that in most instances where this haze is impenetrable to direct ophthalmoscopy, it could usually be penetrated with the brighter illumination of the indirect ophthalmoscope. We did not find this to be the case in a significant number of premature infants with low birth weights. While the mortality rate is highest among these low-birth-weight infants, it is the survivors of this group who require the most oxygen for the longest periods of time and who are therefore at greatest risk of developing RLF. This is supported by numerous studies, including the cooperative study of 1956[23] which showed an inverse relationship between birth weight and incidence of RLF. A survey conducted in 1967 by Silverman[24] concluded that 82% of all cases of RLF occurred in infants under three and one-half pounds (1500 g), and most of these were under two pounds six

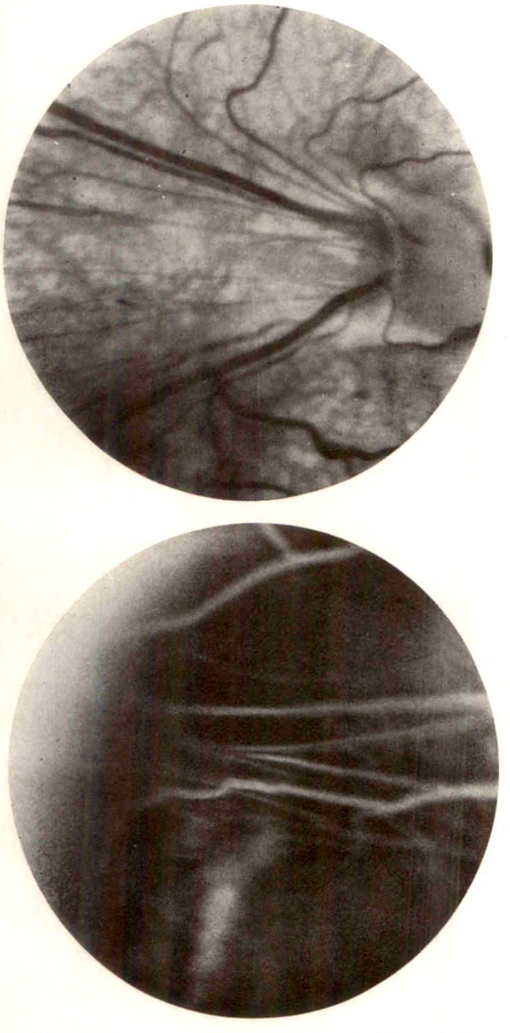

Fig. 9 (Cantolino and associates). Case 3. Top: Age two months. Bottom: Fluorescein angiography, temporal periphery (age two months).

ounces (1100 g). A recent retrospective study by Kalina[25] showed an incidence of RLF of 7% in premature infants weighing under two pounds 14 ounces (1300 g) at birth and an incidence of only 0.1% in those weighing more than this. Thus, while 80 to 90% or more of cicatricial RLF is occurring in premature infants under three pounds, we found that about 60% of this weight group have impenetrably hazy media for intervals of one day up to a month after birth.

Retinal vasoconstriction is well documented as a consequence of hyperoxygenation in extensive experimental work.[3,16,17,26] Clinical studies demonstrating this same vasoconstriction with hyperoxygenation in premature infants include reports by Huggert,[19,20] Patz,[18] and Lamotte.[21] In these clinical reports, however, there are no arterial oxygen tension values given to support the implication that all of these instances of constricted vessels represented concomitant hyperoxia. While it is established that hyperoxygenation is one of the causes of retinal vessel vasoconstriction, we contend that in small, sick, premature infants, evaluation of retinal vessel caliber is as a sign of hyperoxygenation is fraught with difficulty and is often misleading. We have documented this in showing apparent vessel narrowing with hypoxia in some of these infants. This narrowing of vessels in hypoxic infants may in fact represent reflex vasoconstriction, observed in other animal species, which tends to centralize the circulation of blood in the brain and heart when the newborn is subjected to stresses such as acidemia, hypothermia, hypovolemia, or even hypoxemia. We did note that several infants manifested a degree of vessel narrowing which occurred with hyperoxygenation. It was, however, too subtle to be clinically useful. This is demonstrated by a five-pound two-ounce infant whose narrowing of retinal vessels could not be appreciated on clinical observation, but when fundus photographs of this child at the normal and high levels of arterial oxygen tension were compared side by side, it could be

seen that there was narrowing with hyperoxygenation (Fig. 11).

On the basis of this work, we contend that our pediatric colleagues should not be lulled into a false sense of security because an ophthalmologist is in attendance in the premature nursery; we were of no assistance in preventing RLF, and they will have to continue their efforts at maximum clinical surveillance of these infants, utilizing frequent, periodic arterial oxygen tension values as a guide, until a practical means for constant monitoring of arterial oxygen tension becomes available. While we believe that it is not feasible to monitor oxygen therapy ophthalmoscopically, the suggestion to try was an excellent one. We are presently extending our fluorescein fundus angiographic studies of these infants in hopes of adding another dimension to the study of the natural history of this disease process. When more is known about the course of this retinopathy, it might

become possible to use cryotherapy or photocoagulation to interrupt or to modify its development before severe cicatricial changes ensue.

## Summary

Daily ophthalmoscopic monitoring was performed on 102 premature infants to test the feasibility of such monitoring as a guide to oxygen therapy. This monitoring was unsuccessful because of hazy media and the extremely small caliber of the retinal vessels. Fundus photography and fluorescein angiography were performed on selected infants to demonstrate the acute lesion of retrolental fibroplasia.

# INVERSE RETINITIS PIGMENTOSA, DEAFNESS, AND HYPOGENITALISM

NED M. REINSTEIN, M.D., AND ALAN I. CHALFIN, M.D.
*Brooklyn, New York*

The hereditary retinal abiotrophies are a group of disorders in which the common pathologic feature is a primary degeneration of the outer layers of the retina. In many cases hereditary abnormalities of other organs are found, and numerous syndromes have been described.[1]

This paper presents studies of a family in which three siblings demonstrate inverse retinitis pigmentosa, neurosensory hearing loss, and a dysfunction of the pituitary-gonadal system of a type previously not described in association with ocular pathology.

## FAMILY HISTORY

One brother and two sisters were studied; there were no other siblings. The family was Jewish; the parents were first cousins, as were the maternal grandparents. All members of the three preceding generations (Fig. 1) originated in the same area in Eastern Russia. The only married sibling (Case 3) has no children.

Although no other family members were available for study, many had had ophthalmologic and general examinations. The maternal grandmother (II-1), age 90, is reported to have glaucoma, but no other ocular abnormalities are known, nor any symptomatic eye disease. A first cousin (IV-2) is reportedly deaf, and has a son (V-1) with a hearing defect; neither has any visual difficulty. Another first cousin (IV-1) was mentally retarded and died in an institution. There is no known family history of any gonadal or other endocrine disturbance.

## CASE REPORTS

*Case* 1—This 62-year-old man (D.K.) noted the onset of a slowly progressive hearing loss at the age of 11 years. He first experienced blurring of central vision at age 20. There had been no previous ocular disease. Attempts were made initially to improve vision with glasses and vitamins, but they were not successful, and the visual impairment progressed slowly to reach a stable end point eight to 10 years later. There has been no further subjective loss of vision in the past 30 years, and he denies any impairment in night vision or color vision. The development of secondary sex characteristics (i.e., facial and pubic hair) began at age 14 and progressed normally. He denies impotence. There are no known systemic illnesses.

General physical examination was within normal limits, but the testes were small and soft. Laboratory examination of the blood and urine was normal, and the VDRL was nonreactive. X-ray films of the chest and skull were normal.

Otologic examination showed a moderately severe neurosensory hearing loss, with no demonstrable abnormalities of the canals or tympanic membranes.

Ocular examination revealed a central visual acuity of hand movements at three feet, both eyes. Midperipheral vision was finger counting at three to five feet, and eccentric viewing was prominent. Retinoscopy showed an error of −1.00 sph. ⊂ +0.50 cyl. ax. 90, both eyes. Ocular motility was full and normal. Slit lamp examinations of the adnexa and the anterior segments were normal, and the pupils were equal and reacted well to light. Applanation tensions were 18 mm Hg, both eyes. There was moderate nuclear sclerosis of both lenses and both showed small posterior subcapsular opacities centrally. In the right eye, the vitreous was clear, but in the left, there was a marked asteroid hyalitis. Examination of the fundus revealed multiple amorphous and "bone-corpuscle" pigment deposits confined to the posterior pole of both eyes. No abnormal pigment was seen anterior to the equator. There were well-circumscribed, mottled, yellowish lesions in both macular areas, approximately 1.5 to 2 disk diameters in size. No foveal light reflex could be seen, and there were a few small pigment deposits within the macular lesions. The vessels were narrowed with vascular sheathing more prominent around the arterioles. The disks were somewhat pale with distinct margins and small, shallow central cups. (Fig. 2A and B)

*Case* 2—E.K. is a 56-year-old woman who began losing central vision at the age of 21 years. The onset of symptoms was gradual and progressed over a period of 10 years, during which time repeated changes of glasses brought only transient and minimal improvement. She denies night blind-

ness, and has had no difficulty with color perception. For the past 15-20 years there has been a moderate, nonprogressive hearing defect. She states that she did not have spontaneous menarche; at the age of 16 years her first menstrual period was "brought on by an injection" (presumably a crude estrogenic compound). These injections were given monthly for a period of about five years, each time resulting in apparently normal menses, but on the few occasions that she did not get these injections, she did not experience bleeding. The development of secondary sex characteristics (i.e., breasts and female hair distribution) did not begin until about 12-18 months after she began receiving the injections, but thereafter development progressed normally. There was no masculinization or defeminization after the injections were stopped. She has not had a single menstrual period since the last injection some 36 years ago.

General physical examination revealed an apparently normal, healthy female. Laboratory studies of the blood and urine were within normal limits. X-ray films of the chest and skull were negative, and the VDRL was nonreactive.

Otologic examination demonstrated a marked neurosensory hearing loss for frequencies over 2000 cps. There were no defects noted in the external auditory apparatus including tympanic membranes.

The central visual acuity was hand movements, both eyes, but she was able to count fingers well at five feet with eccentric viewing. The refractive error was RE: —0.75 sph., LE: —0.50 sph. ⌒ —0.50 cyl. ax. 90. External examination of the adnexa and anterior segments revealed no abnormalities. Ocular motility was normal as was the pupillary response. Applanation tensions were RE: 18 mm Hg, LE: 20 mm Hg. The lens and vitreous were clear in both eyes. There were yellowish, mottled lesions in the macula of both eyes, covering an area of about 2 disk diameters, and no foveal light reflex was seen. The posterior pole had many "bone-corpuscle" pigment deposits with a few rounded pigment spots in the macula areas, but no abnormal pigment was seen anterior to the equator. The vessels were slightly attenuated with sheathing of the arterioles. The disks appeared pale and waxy. (Fig. 2-C and D)

*Case* 3—R.M. is a 48-year-old woman. At the

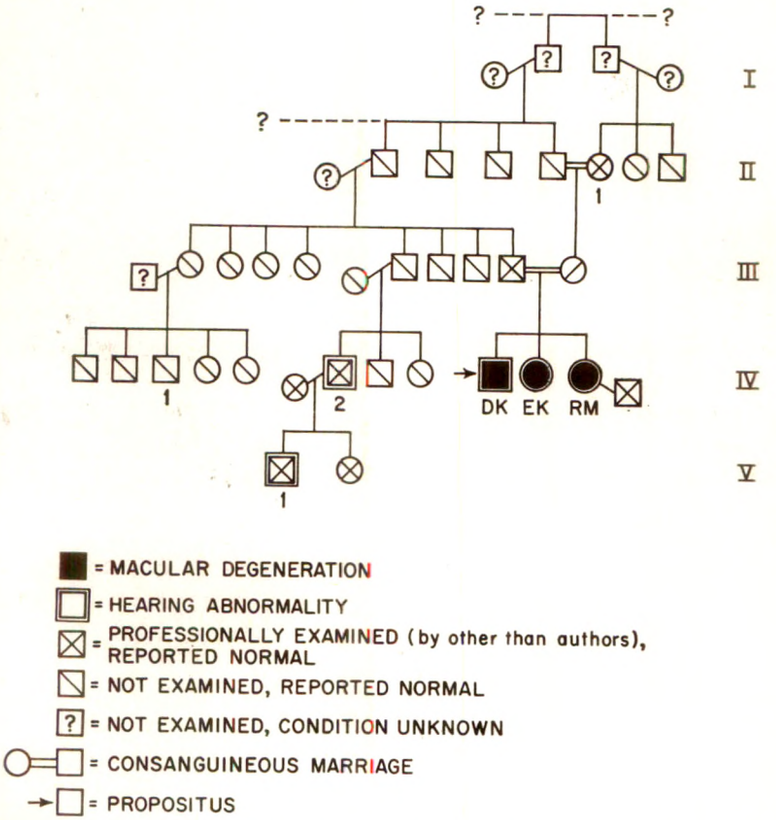

Fig. 1 (Reinstein and Chalfin). Family pedigree. Note the consanguinity of the parents and maternal grandparents of the siblings studied. The endocrine pathology (hypogenitalism) referred to in the text is not indicated in the above figure.

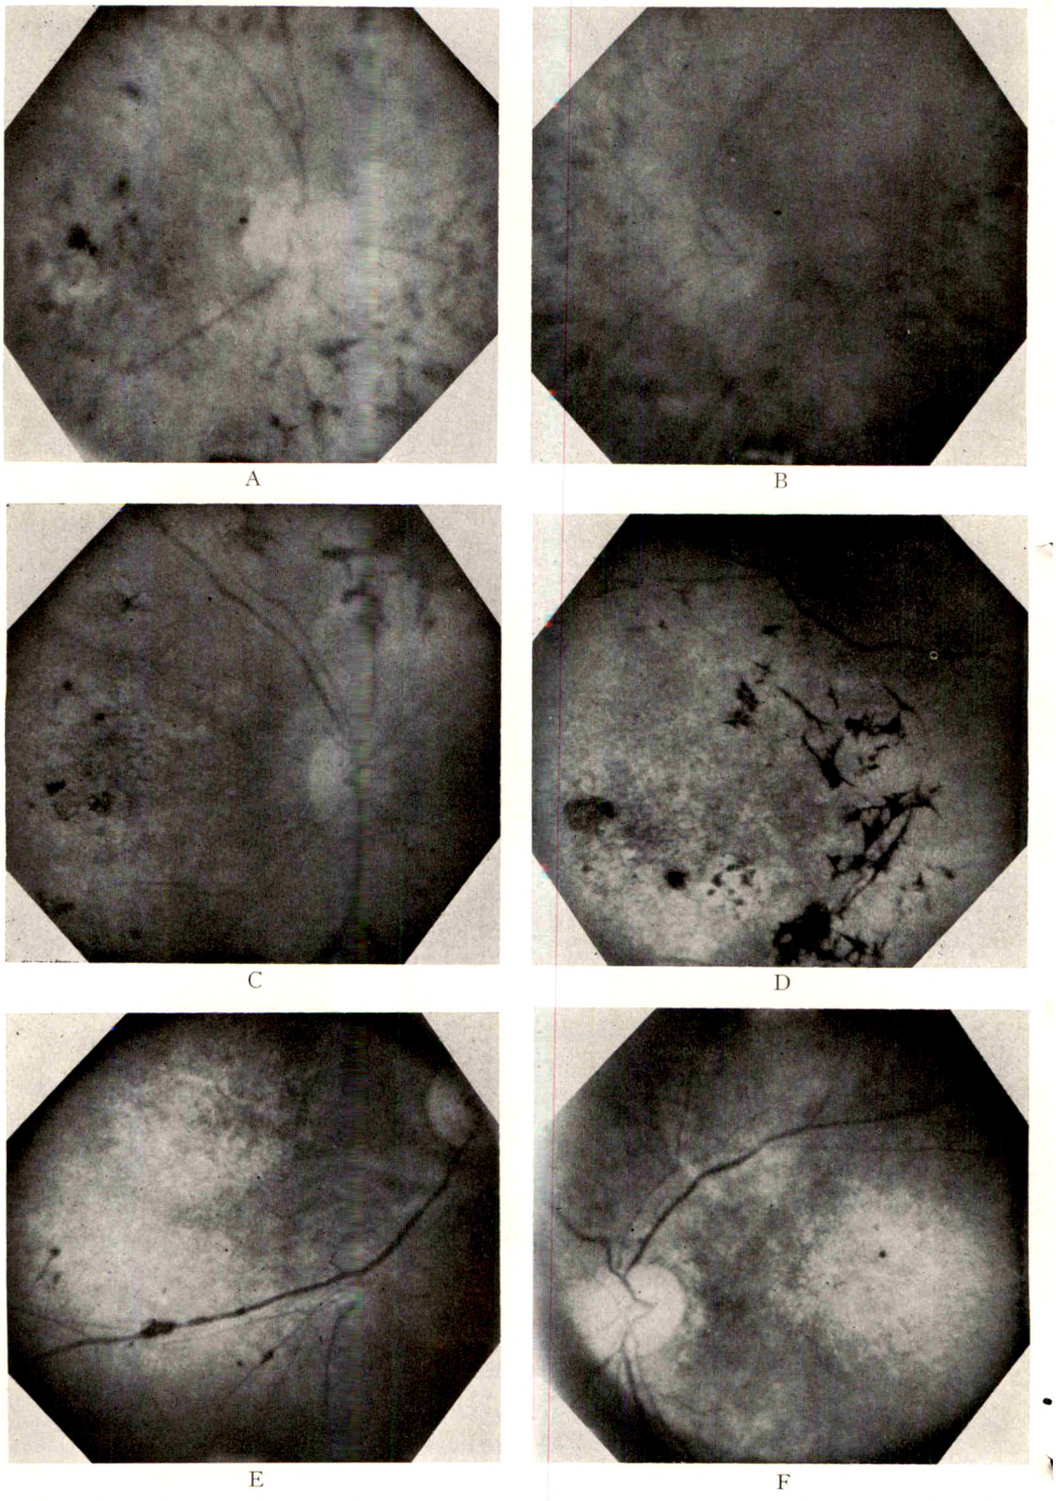

Fig. 2 (Reinstein and Chalfin). Fundus photographs. (A and B) Case 1 (DK). (C and D) Case 2 (EK). (E and F) Case 3 (RM).

age of 15 years, with the onset of the visual disturbance in the second of her two older siblings, she was given a thorough eye examination and states that she was told that her vision was "20/20 in both eyes and there were no abnormalities." (At the same time, both her parents also had their eyes examined, and no abnormalities were reported.) She experienced the onset of central visual loss at about age 32, and noted a rapid deterioration during the next three to five years. Hearing loss was first noted about five years ago. She, too, never had spontaneous menarche and had menses induced at age 16 by an injection. Breast development and growth of pubic hair began one year later and progressed normally thereafter. After five to six years of monthly injections, she elected to stop the treatments, and has not menstruated since. There have been no changes in the secondary sex characteristics since that time.

Physical examination was within normal limits. All laboratory studies, including x-ray examination of the chest and skull, were normal, and the VDRL was nonreactive.

Otologic examination showed moderate neurosensory hearing loss, but the external auditory apparatus was normal.

Central vision was light perception, both eyes, and she was able to count fingers at three feet with eccentric viewing. Retinoscopy showed an error of —0.50 sph. ⊃ —0.75 cyl. ax. 90, both eyes. The adnexa and anterior segments were normal as was the ocular motility. The pupils were equal and reactive. Applanation tensions were 19 and 20 mm Hg, respectively. There was early nuclear sclerosis and trace posterior subcapsular opacities in both lenses, but the vitreous was clear in both eyes. The macular lesions were identical to those seen in her two siblings, and covered an area of 2 disk diameters in each eye. No foveal light reflex was seen. There was practically no abnormal pigment seen, however, and the few deposits noted were confined to fine "lacy" lesions which appeared to encircle the blood vessel walls in the posterior pole. There were two small round pigment spots in the macular area of the right eye. The retina appeared normal anterior to the equator. The vessels were only slightly narrowed, and the sheathing was much less prominent than in her older siblings. Both disks appeared normal (Fig. 2-E and F).

## Special studies

In addition to the findings reported above, each of the three patients underwent the following examinations:

*Color vision*—Due to the marked impairment of vision, the patients were unable to perceive the details of the standard AO-HRR Pseudoisochromatic plates. Color sense was tested instead with 20-mm round test objects from the Berens' Test Object Set. Red, blue green, and white objects were used. The patients were able to identify readily the color of each, but they had to view them eccentrically to do so.

*Visual fields*—Peripheral fields were plotted with the Goldmann perimeter using a 16 $mm^2$ white test object at maximum illumination (Fig. 3). Despite the large, dense central scotoma in all six eyes, fixation was quite steady and the results were reproducible. In five of the six eyes there was a generalized depression of the peripheral field. The right eye of Case 3, however, showed only slight depression for the isopter plotted.

*Dark adaptation*—Simultaneous binocular evaluation of the dark adaptation thresholds were with the Goldmann-Weekers Dark Adaptometer. The patients were unable to maintain steady fixation for the full time of the test. Five minutes of total dark adaptation was followed by light adaptation at 3200 asb for seven minutes, and the thresholds of perception of a striped test field of 100% contrast was measured for 30 minutes. The initial (maximum) luminosity of the ground of the test field was 475 asb. The resulting curves (Fig. 4) show subnormal thresholds and decreased amplitudes.

*Electroretinography*—Photopic and scotopic ERG responses were measured on two of the three subjects (Cases 1 and 2). The photopic responses were made without specific control of the light-adapted state. Immediately after recording the photopic curves, the patients were adapted to total darkness for 10 minutes. For scotopic testing, a red filter was placed in front of the flashing light. In both instances the flicker frequency was 2/second and a total of 75 flashes were given. The photopic electroretinograms show marked depression with the individual wave components just recognizable, while the scotopic tracings are totally extinguished (Fig. 5).

*Audiometry*—Bone and air conduction thresholds were measured with the Beltone Clinical audiometer (Model 15 CX). Stimulus frequencies ranged from 250 to 8000 cps

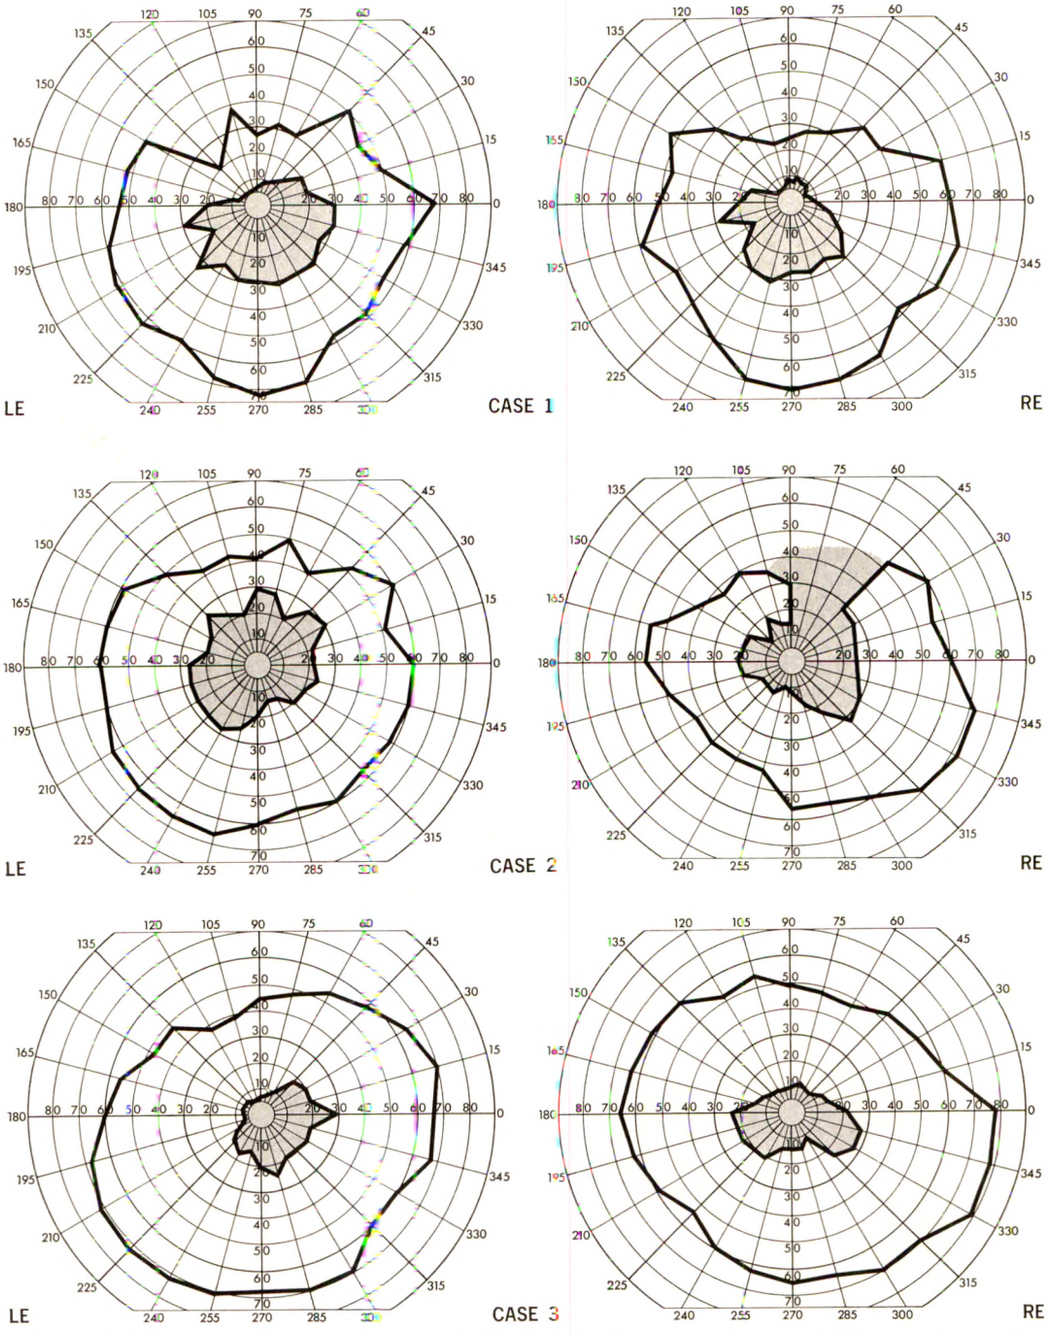

Fig. 3 (Reinstein and Chalfin). Visual fields. The isopter plotted was the same in all six eyes, but the extent of the peripheral depression is greatest in Case 1 and least in Case 3.

(Fig. 6). The findings indicate a neurosensory hearing defect most pronounced in the higher frequency ranges.

*Sense of smell*—Gross testing revealed no signs of anosmia in any of the three patients.

*Chromosomal studies*—Karyotyping was done on samples of heparinized peripheral blood of two of the three patients (Cases 2 and 3) after the method described by Valenti and Vethamany.[2] The karyotypes of the two patients tested in this study were normal with respect to chromosome number (46) and configuration.

## Discussion

Many forms of hereditary retinal dystrophies are described as distinct entities, and numerous classifications have been proposed.[3-7] Though the clinical manifestations vary considerably, several authors postulate a common genetic defect throughout this group.[5,6,8-13] There is lack of agreement, however, on a single uniform classification, or even the basis on which such a classification might rest. Several factors would seem to contribute to this problem: (1) the observed variations in a given form of dystrophy from one pedigree to the next as to pattern of inheritance, age of onset of symptoms, and area and extent of retina involved; (2) the varying association of many of these dystrophies with other ocular and extraocular genetic defects; (3) the occurrence of atypical forms; (4) in long-standing disease, senile vascular changes in the choroid often result in additional secondary changes in the overlying retina, producing a mottled appearance, and this may lead to difficulty in distinguishing one form of dystrophy from another on the basis of the appearance of the fundus. Despite all this, it is common for affected members of a family to parallel one another closely in the clinical manifestations of the disease.

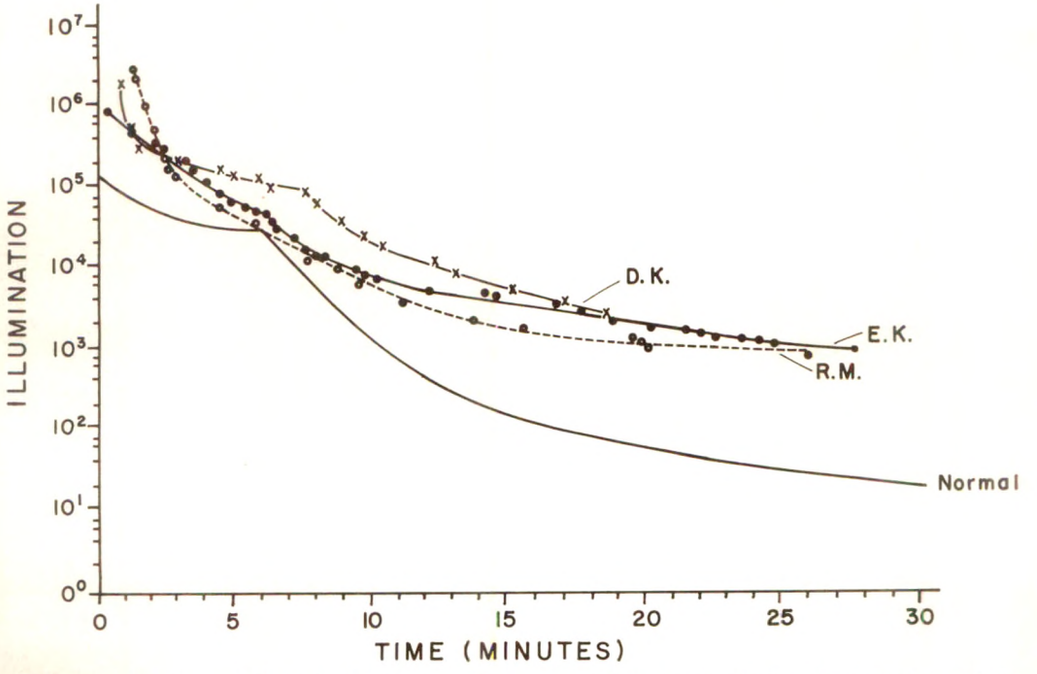

Fig. 4 (Reinstein and Chalfin). Dark adaptation curves. Both the amplitudes of adaptation and the absolute thresholds are subnormal. The configuration of the curves is not characteristic of either pure rod or pure cone dysfunction.

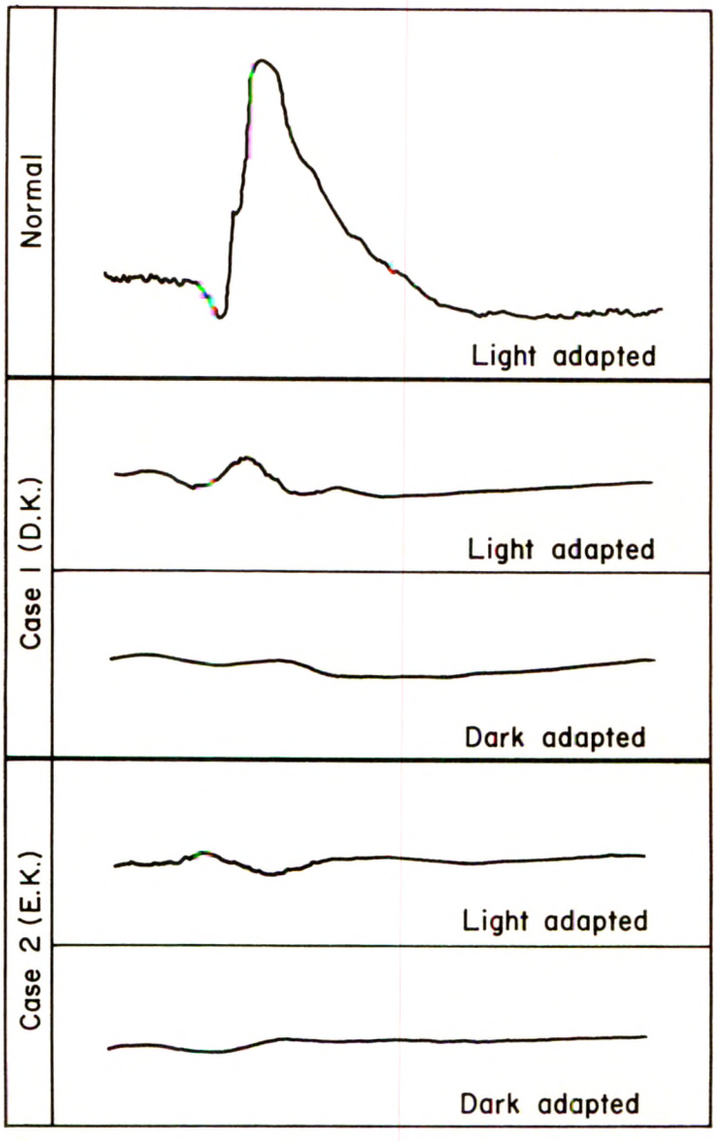

Fig. 5 (Reinstein and Chalfin). Electroretinograms. The photopic curves are markedly depressed while the scotopic curves are completely extinguished.

Numerous pedigrees have been described in which two or more abnormalities occur simultaneously in several individuals, while appearing as isolated disorders in other family members.[8-13] It has been proposed that the phenotypic variations arise from a single pleiotropic gene rather than from two or more separate genes.[8-13] If this were the case, the observed variations might be explained by the varying expressivity of the involved gene, by the presence of "modifying genes" in some individuals, or by modifying environmental factors such as nutrition. This last might play a significant role in the age of onset of symptoms. However, a demonstrable chromosomal defect has not as yet been identified in the hereditary retinal dystrophies, and experimental procedures

such as gene mapping are not readily applied in human genetics. Insofar as consanguinity leads to a greater congregation of recessive genes, the intermarriage of first cousins in two successive generations in our study is a significant factor. Consanguinity is far from uncommon in such pedigrees, but what is unusual in this case is the 100% phenotypic expression of three autosomal recessive traits in all three siblings.

The coincidence of hereditary retinal dystrophies with other disorders in various combinations is well known. The most commonly observed combination is that of retinal disease and deafness, first described by von Graefe in 1858. The reported coincidence of complete or partial hearing loss with abiotrophies of the retina has varied greatly with different observers, but it is not an uncommon finding. This might be explained by the close embrylogic relationship between the retinal neuroepithelium and the epithelium of the organ of Corti.[11]

Hypogenitalism in association with hereditary retinal disorders has been reported in the Laurence-Moon-Biedl syndrome, and, in a single case by Franceschetti and Klein.[12] The male proband in this study has small, soft testes. This might be a sign of hypogenitalism, but there is no proved history of decreased gonadal function, and no signs of feminization. Furthermore, the testicular changes could be due to simple senile atrophy. His two sisters, though phenotypically normal females, give a history of primary amenorrhea and lack of spontaneous development of secondary sex characteristics. These symptoms could be related to a structural or functional derangement of either the pituitary-hypophyseal system or the ovaries. Although primary amenorrhea and genital hypoplasia due to idiopathic hypogonado-

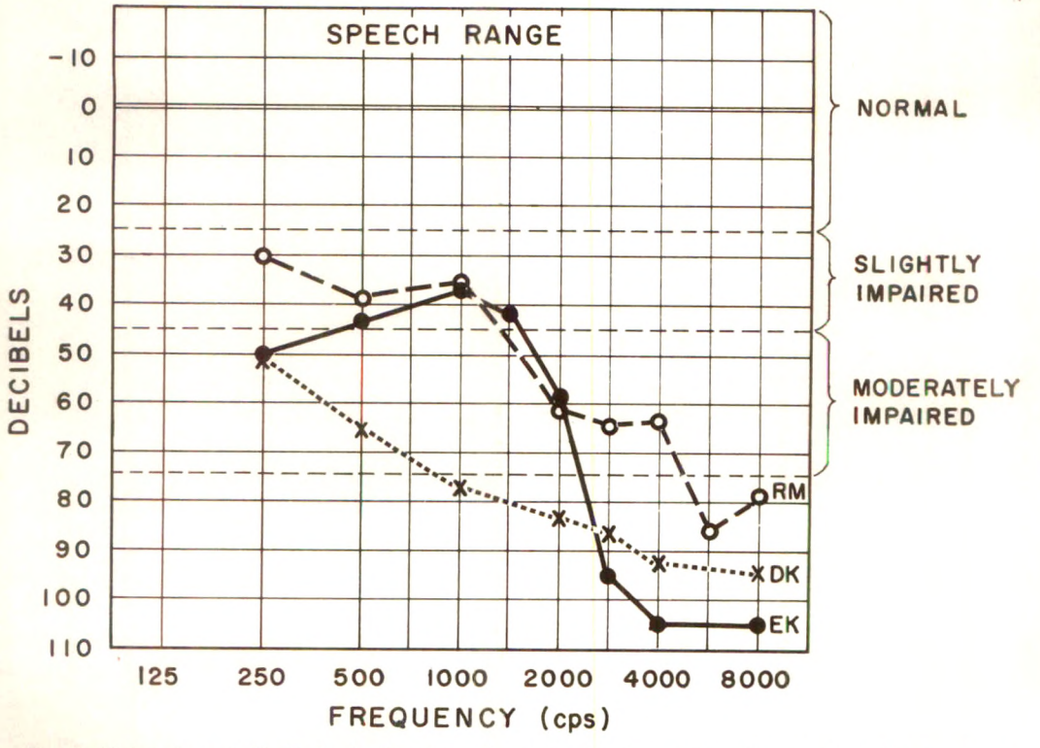

Fig. 6 (Reinstein and Chalfin). Audiometry—air conduction thresholds. The results indicate a neurosensory hearing defect.

trophic hypogonadism is known,[14] it is quite rare, and has not been reported in association with hereditary retinal disorders. The clinical evaluation of ovarian function in these patients was not possible, as they would not consent to laparoscopy with or without ovarian biopsy, and assays of endogenous hormone function would be of questionable validity at their present ages. Therefore, at this time, we cannot isolate with certainty the specific endocrine abnormality; we can only describe the clinical picture and relate it to the possible sites of dysfunction.

The patients in this study manifest an ocular disorder which, on the basis of the appearance of the fundus and the alterations in dark adaptation and electrophysiologic response of the retina, appears to be inverse retinitis pigmentosa. This entity is characterized by a concentration of abnormal pigmentation surrounding the macula and disk, sometimes in the form of a discrete ring, and often with attenuation of the retinal vessels and pallor of the disk. Frequently, a subjacent choroidal sclerosis or atrophy, which may be focal or diffuse also is found.[15] The discrete and prominent macular lesion seen in all six eyes in this study is not a typical finding in central retinitis pigmentosa, but is probably secondary to a choroidal change such as this. This finding led to much confusion in establishing the diagnosis, and serves to illustrate the difficulties in classification alluded to in the opening paragraph of this discussion. In contrast to the "typical" peripheral form of retinitis pigmentosa in which night blindness is the most prominent early symptom, patients with the inverse form lose central vision early, and often prefer dim to bright illumination. Although the dark adaptation curves shown in Figure 4 indicate abnormal function, their configuration is not characteristic for either pure rod or pure cone dysfunction. The three patients denied any subjective night blindness. The finding of unimpaired color vision in all three patients is inconclusive, owing to the gross nature of the testing procedure. However, the marked decrease in central vision precluded the use of more sophisticated studies. The progressive nature of this disorder is illustrated by the increasing depression of the peripheral visual fields (Fig. 3) which corresponds with the duration of symptomatic disease (Case 1, 42 years; Case 2, 35 years; Case 3, 16 years), and which is paralleled by an increasing amount of abnormal pigmentation in the posterior pole (Fig. 2-A through F). It is interesting that while the functional impairment and physiologic alterations seen in Case 3 are almost identical to those seen in her two older siblings, the abnormality in the pigment epithelium supposedly responsible for these changes has produced almost no observable changes in the fundus 16 years after the onset of symptoms.

## Summary

The coincidence of inverse retinitis pigmentosa, deafness, and hypogenitalism was found in three siblings. The patients, a man, age 62 years, and two women, ages 56 and 48 years, all had the onset of progressive visual loss in adult life (ages 20, 21, and 35 years, respectively). They all show typical "bone corpuscle" pigment deposits confined to the posterior pole with discreet mottled macular lesions. Dark adaptation thresholds were elevated, electroretinograms markedly depressed, and the visual fields showed dense central scotomas with peripheral depression. Color vision, however, appeared grossly intact. Audiometry revealed neurosensory hearing defects in all three patients. The two women never had spontaneous menarche and secondary sex characteristics developed only after treatment with exogenous hormones. The man has small, soft, possibly atrophic testes. Study of the family pedigree indicates an autosomal recessive inheritance pattern, but karyotypes revealed no gross chromosomal abnormalities. A review of the literature failed to reveal any previous description of this combination of genetic disorders.

ACKNOWLEDGMENTS

We thank Dr. Carlo Valenti, State University Hospital, Brooklyn, and his laboratory technician, Mrs. Jackie Lieberman, for performing the chromosomal studies; Dr. James Jones, State University Hospital, Brooklyn, for his aid in evaluating the endocrine disorder; Mrs. Aurora C. Clahane for editorial services; and Dr. Paul B. Bedrossian for his aid in translating the French literature and for reviewing the manuscript.

# AN OCULAR PATHOLOGIC STUDY OF REFSUM'S SYNDROME

DANIEL TOUSSAINT, M.D., AND PIERRE DANIS, M.D.
*Brussels, Belgium*

Refsum's syndrome, or "heredoataxia hemeralopica polyneuritiformis,"[7] is thought to be an inborn error of lipid metabolism, with abnormal storage of phytanic acid. The characteristic symptoms are mainly neurologic and the inheritance is autosomal.[1,2] This syndrome was described for the first time by Refsum in 1945 and again in 1949.[3,4] On account of a previous incomplete description of the disease by Thiébaut and associates in 1939,[5] the syndrome is sometimes referred to as Refsum-Thiébaut disease.[6] Since the first reports, 50 observations have been published and about 13 cases have been submitted to postmortem investigation. The eyes were examined in five instances,[7-11] but none of these description of the retinal lesions has included lipid studies.

The purpose of this paper is to present the ocular pathology of a case of Refsum's syndrome and a tentative theory as to the etiology of the associated retinitis pigmentosa characterized in this case by a lipid infiltration of the pigment epithelium.

The characteristic clinical abnormalities of Refsum's syndrome are: atypical retinitis pigmentosa with night blindness and constricted visual fields; pupillary abnormalities, miosis, poor reaction to light and accommodation-convergence; slow and incomplete dilatation following administration of mydriatics and cycloplegics; glaucomatous attacks following administration of a mydriatic; posterior subcapsular cataracts; anosmia; thickened peripheral nerves, chronic polyneuritis; weakness, paresis and amyotrophy of both lower extremities; sensory disturbances and hyporeflexia; ataxia with other cerebellar signs; increased protein in the cerebrospinal fluid without pleocytosis; icthyosis; anomalous development of hands and feet; epiphyseal dysplasia; changes in length of small bones; and cardiopathy.

From the Department of Ophthalmology (Dr. P. Danis) and the Department of Pathology (Dr. P. Dustin), University of Brussels, Belgium. This study was supported in part by Public Health Service Grant AM054990-05 PTHA from the Institute of Arthritis and Metabolic Disease and a grant from the Fonds de la Recherche Medical Scientifique (992).

## CASE REPORT

The clinical history of this patient was published in 1959.[12] A more detailed report of her general medical history from 1959 until her death, and the autopsy findings will be published elsewhere. The most important clinical and biological findings after her last admission in the Saint-Pierre University Hospital, Brussels, are as follows:

At the age of 44 years, this woman exhibited profound weakness. Her gait was ataxic, and unassisted walking was impossible. There was wasting of the hands, forearms, and legs; absence of abdominal reflexes; and absence of all deep tendon reflexes. She showed generalized icthyosis, loss of cutaneous sensibility, vibratory sense, and stereognosis for the lower limbs. Intention tremor was evident in both upper extremities. There was shortening of the fourth and fifth left metacarpals, and of the fifth right metacarpal, and bilateral shortening of the third and fourth metatarsals. She was both blind and deaf. The right eye showed retinitis pigmentosa with pale yellow disk, surgical aphakia, and total iridectomy. The left eye showed strong miosis, refractory to mydriatics, posterior cataract, and very poor visibility of the fundus. Laboratory test were as follows: total serum lipids, 695 mg/100 ml (phytanic acid, 39%); cerebrospinal fluid protein, 950 mg/100 ml.

*Ocular pathology report*—Both eyes were fixed in 10% Formalin 10 hours after death. The eyes were cut in three fragments from two horizontal sections 5 mm distant from one another. The median fragment of the right eye was embedded in paraffin, that of the left eye in gelatin. The retinal tissues of the four calottes were used for flat preparations after embedding in gelatin and for trypsin digestion. The sections were stained by standard techniques including Nile blue, Sudan III and Sudan black for gelatin-embedded preparations.

Fig. 1 (Toussaint and Danis). Cross-section from the posterior portion of the eye (Sudan III, ×100).

## Discussion

The pathologic abnormalities were identical in the two eyes. The rods and cones were almost entirely missing and the outer nuclear and outer plexiform layers were completely atrophic. The inner nuclear layer was thinned and the ganglion cells were reduced in number. The nerve fiber layer was thickened by glial proliferation. All the retinal vessels were narrowed and some were occluded. The vessels walls were thickened and diffusely loaded with lipid material which appeared red after Sudan III and black after Sudan black staining; in some places they were surrounded with pigmented cells similarly infiltrated with lipid material. On trypsin digestion preparations the atrophic vascular pattern was totally irregular and the walls of numerous main arterial and venous branches showed fibrotic nodular thickenings. In many areas of the posterior pole, the pigment epithelium was absent. Where it was present it was not particularly depigmented and in some areas it appeared deeply pigmented and several layers thick. The pigment epithelium was present from the equator to the ciliary processes. The pigment epithelium of the posterior (Figs. 1 and 2), equatorial (Fig. 3), and peripheral fundus, as well as that of the ciliary processes (Fig.

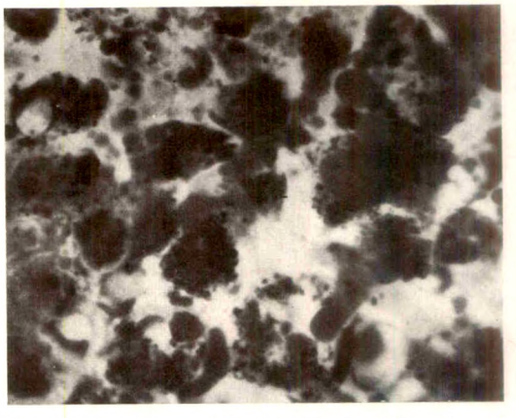

Fig. 2 (Toussaint and Danis). Horizontal section of the pigment epithelium (Sudan III, ×500).

Fig. 3 (Toussaint and Danis). Cross-section from the equatorial region (Sudan III, ×30).

4), was uniformly loaded with lipid material. Lipids were also grossly present in the scleral tissues and in the trabecular tissues surrounding Schlemm's canal (Fig. 5). Sudan III and Sudan black produced similar staining in the cornea and in the pigment epithelium. By contrast, Nile blue stained the pigment epithelium lipids partly blue and partly red (Fig. 6), whereas the lipids stored around Schlemm's canal stained uniformly red. The pigment epithelium of the iris was normal, but the sphincter and dilator muscles were infiltrated with lipids. Bruch's membrane, lamina vitrea, and choriocapillaris were entirely normal. Choroidal vessels did not show sclerosis. Optic nerves showed mild demyelination, but not gliosis. The nerve fibers were normal and the septa showed only mild sclerosis and thickening.

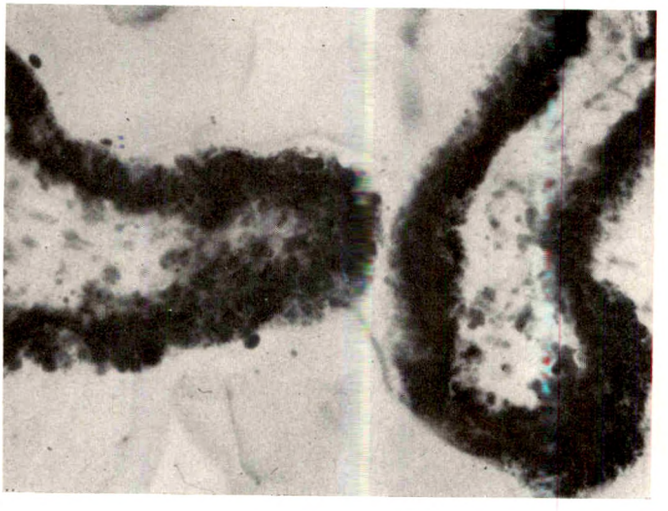

Fig. 4 (Toussaint and Danis). Ciliary processes (Sudan III, ×100).

## Comment

Refsum' syndrome results fron an inborn error of metabolism that induces lipidosis,[13-15] with general metabolic significance. The storage product is phytanic acid (3,7,15-tetramethyl hexadecanoic acid), an abnormal branched-chain fatty acid[2,13-19] found in the serum and in many different cell types. Little is known about the catabolism of phytanic acid in normal persons or in Refsum's disease. The relationship between accumulated phytanic acid and the clinical manifestations of Refsum's syndrome is still not clear. Histologic studies suggest that the peripheral neuropathy may be due to mechanical effects of the accumulated lipids, but this purely mechanical explanation does not satisfactorily explain the other symptoms (e.g., cataracts, retinitis pigmentosa, skin changes, heart disease). Animals fed with phytol or phytanic acid show an accumulation of phytanic acid without any pathologic changes in the retina or in the peripheral and central nervous system such as those observed in Refsum's syndrome.[20,21] Moreover, the demonstration of phytanic acid in two healthy mothers of patients with Refsum's disease also does not support a relationship between phytanic acid and clinical symptoms.[14]

The esterification of vitamin A has been found normal in liver tissue of patients with Refsum's disease[22] and must therefore be presumed to be normal in the pigment epithelium of the eye. One is left with the hypothesis that the massive accumulation of

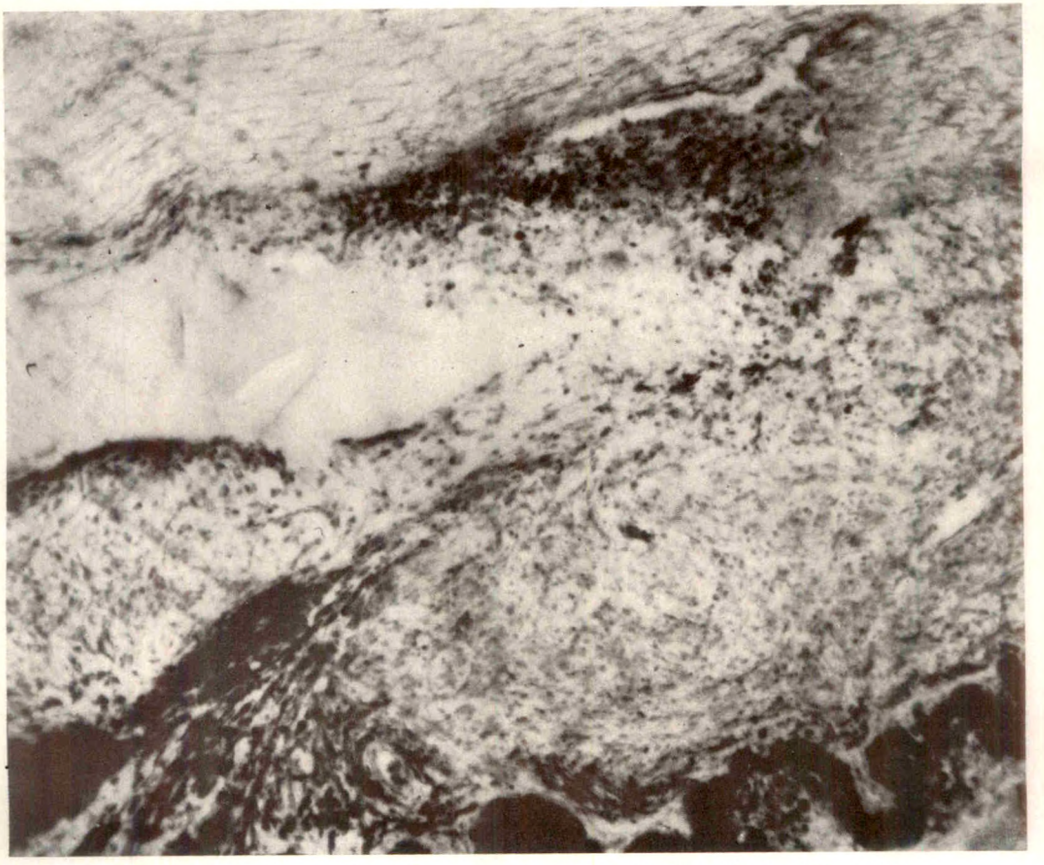

Fig. 5 (Toussaint and Danis). Angle of anterior chamber (Sudan III, ×100).

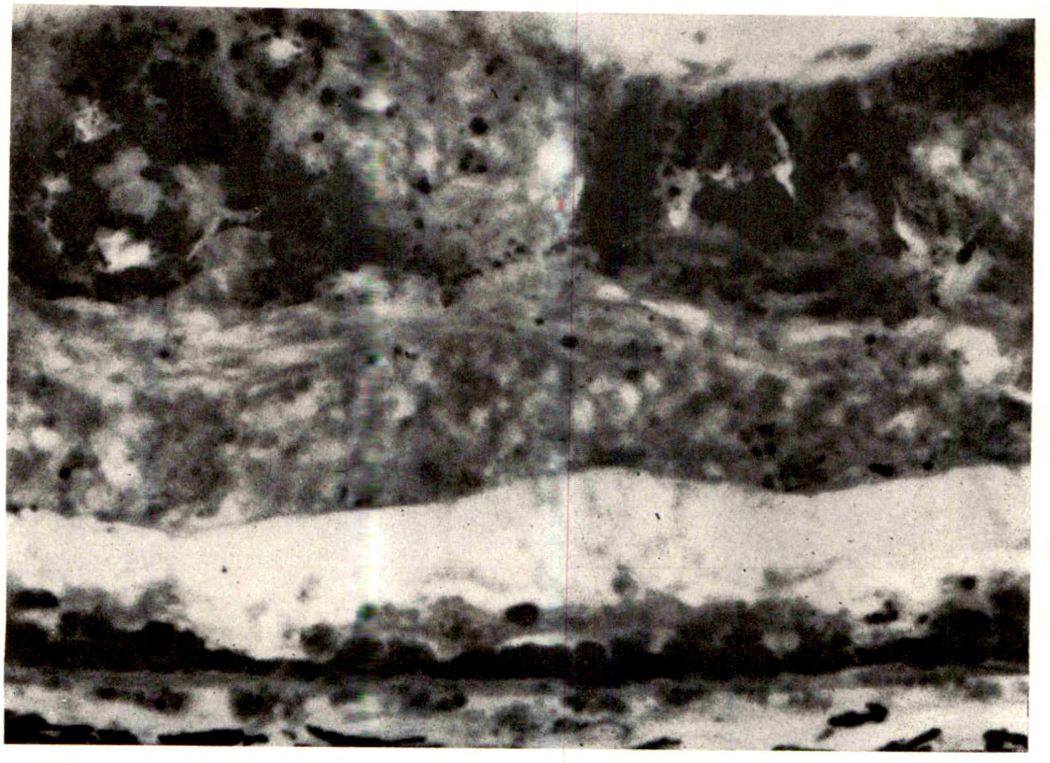

Fig. 6 (Toussaint and Danis). Cross-section from posterior portion of eye (Nile blue, ×100).

lipid in the epithelium, as shown in the present sections, interferes in some way with the transfer of retinal to the photoreceptors. No such accumulation of lipid has been found in a case of idopathic retinitis pigmentosa unassociated with Refsum's disease.[22]

The lipid material observed about Schlemm's canal suggests that the glaucoma in Refsum's syndrome following attempts to dilate the pupils results from the release of lipid from the ciliary processes and accumulation in the corneoscleral trabeculae. The reported "aqueous flare" with Refsum's syndrome[23] may have a similar origin.

## Summary

The ocular histopathologic abnormalities are reviewed in a 44-year-old woman with Refsum's syndrome who was blind and deaf and had polyneuritis, cataracts, and retinitis pigmentosa. The most noteworthy abnormality in the ocular tissues was the presence of sudanophilic material in the sclera, trabecular meshwork, iris muscles, and most especially, a coating of the retinal pigment epithelium with fat. It is suggested that this accumulation of lipid interfered with the normal generation of retinal, resulting in degeneration of the photoreceptors.

# THE ASSOCIATION OF PALE-CENTERED RETINAL HEMORRHAGES WITH INTRACRANIAL BLEEDING IN INFANCY

## A Report of Two Cases

Charles D. Phelps, M.D.

*Iowa City, Iowa*

Hemorrhages into the eye are a common sign of intracranial bleeding. Such hemorrhages may be in the retina, in front of the retina (preretinal or subhyaloid), or in the vitreous. Unusual hemorrhages—hemorrhages with pale centers—were found in the fundi of two children recently treated for intracranial bleeding.

Pale-centered retinal hemorrhages usually indicate either a severe hematologic disorder or septicemia. The association of pale-centered retinal hemorrhages and intracranial bleeding has not been previously described.

### Case reports

*Case* 1—This infant was admitted to University Hospitals on August 1, 1968, at the age of 31 days. Her mother had had a normal pregnancy, although the delivery had been by cesarean section because of a previous cesarean section for cephalopelvic disproportion. The baby's birth weight was 2640 g. She had progressed as a normal infant until two days before admission, when she became irritable without obvious cause; she had not been injured or exposed to infections. The day after onset of irritability, she did not eat and seemed feverish. Intermittent spells, during which she drew up her knees, shook her arms, and grew rigid, became increasingly frequent.

Examination on admission revealed the infant to be a normally developed white girl, weighing 3070 g. Her heart rate was 170/minute, and her temperature was 35.6° C. Seizures occurred every 10 to 15 minutes and lasted about one minute. During these, she would stiffen, develop rhythmic eye movements, and utter short cries. Between seizures she was unresponsive. Her anterior fontanel was tense. There were no skin lesions or enlarged lymph nodes. The spleen was not enlarged, but the liver extended 4 cm below the right costal margin. No bruises or other marks of trauma were seen. In the left fundus there were numerous retinal, preretinal, and vitreous hemorrhages. The right fundus was normal. Grossly bloody cerebrospinal fluid was obtained from a lumbar puncture. The baby was treated with ampicillin and paraldehyde.

The following day she had numerous pale-centered hemorrhages in the previously normal right retina (Fig. 1). In the left eye, the entire retina was hemorrhagic; where separate hemorrhages could be distinguished, they, too, had pale centers. A tap of the left cerebral ventricle produced clotting blood. Treatment was changed to kanamycin and diphenylhydantoin.

Laboratory studies showed a hemoglobin of 7.8 g%, packed cell volume of 25%, white blood count of 19,300/mm$^3$, and a platelet count of 790,000. Her differential white blood count showed 7% metamyelocytes, 9% band forms, 48% segmented polymorphonucleocytes, 33% lymphocytes, and 3% monocytes. Urine, BUN, creatinine, sugar, carbon dioxide combining power, chloride, sodium, potassium, and calcium levels were normal. Cultures of blood and spinal fluid were negative. Skull and chest x-ray films were normal.

Seizures became more frequent and could not be controlled by sedatives. On the third hospital day the child died. The final diagnosis was intraventricular cerebral hemorrhage. Her parents did not allow an autopsy.

*Case* 2—This seven-month-old black girl was healthy until December 14, 1968, when she fell from a bed, striking her head so severely that she was

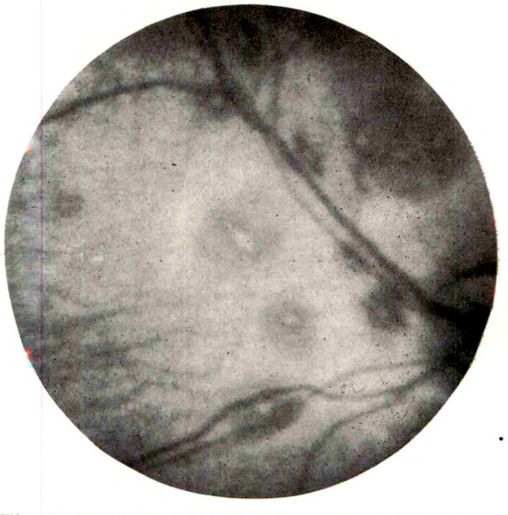

Fig. 1 (Phelps). Right fundus, Case 1. Numerous intraretinal hemorrhages with pale centers.

unconscious for a brief time. She was hospitalized in her home town; there she began to vomit and became lethargic. When aroused she was irritable. Two days following her injury, she developed seizures and was transferred to University Hospitals. Examination showed a lethargic infant with a heart rate of 84/minute, a temperature of 37.2°C, and a respiratory rate of 30/minute. She was having periodic left-sided seizures with a left hemiparesis between seizures. There were numerous white-centered intraretinal hemorrhages and large preretinal hemorrhages in both fundi (Fig. 2).

Subdural taps yielded 6 ml of blood-tinged xanthochromic fluid from the right side and 4 ml of similar fluid from the left. She was treated with phenobarbital.

Laboratory tests included: hemoglobin of 10.9 g%, packed cell volume of 32%, white blood count of 9,400/mm$^3$, and a differential count of 62% segmented polymorphonucleocytes, 1% eosinophils, 28% lymphocytes, and 9% monocytes, with normal cellular morphology. BUN, creatinine, carbon dioxide combining power, chloride, sodium, potassium, calcium, phosphorus, and sugar were all present in normal amounts in the child's blood. Cultures of blood and spinal fluid were negative. X-ray films of her chest and skull were normal. An electroencephalogram taken on the third hospital day was normal.

Subdural taps repeated on the third and fifth hospital days produced little fluid. By the sixth day she seemed completely recovered, and two days later she was discharged. On the day of discharge, there were only scattered remnants of the once numerous retinal hemorrhages.

The final diagnosis was bilateral subdural hematomas.

## Discussion

Retinal hemorrhages occur in about 20% of adults who have subarachnoid bleeding,[1] but are rare in adults who have subdural hematomas. In contrast, infants frequently have retinal hemorrhages in association with either type of intracranial bleeding.[2]

The generally accepted theory for the production of retinal hemorrhages by intracranial bleeding is that of Ballentyne.[3] Blood leaking from an intracranial vessel enters a non-distensible space. This causes the intracranial pressure to rise abruptly to a level approaching that of the arterial blood pressure. The cavernous sinus, into which most of the orbital venous blood drains via the ophthalmic veins, shares in the high intracranial pressure. Flow through the ophthalmic veins ceases until there is a buildup of pressure transmitted from the ophthalmic artery.

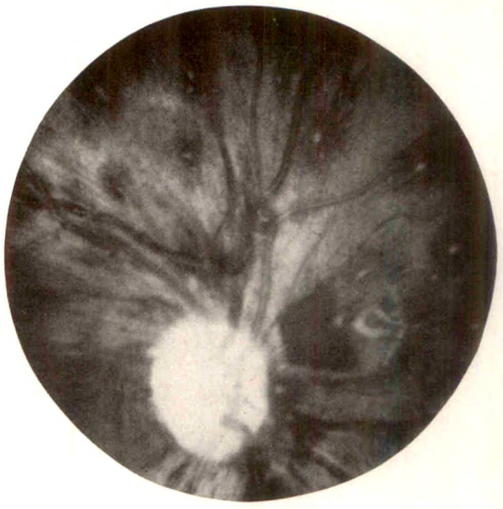

Fig. 2 (Phelps). Right fundus, Case 2. Peripapillary edema, one preretinal hemorrhage, and many intraretinal hemorrhages with pale centers.

An intolerable transmural orbital venous pressure is the result, and the vessel walls rupture at their weakest points. The frequent occurrence of small hemorrhages elsewhere in the orbit is evidence for this theory.

The unusual feature in these two infants is the pale centers of the retinal hemorrhages. Pale-centered retinal hemorrhages should alert a physician to search for chronic sepsis or for hematologic disorders such as leukemia, aplastic anemia, iron deficiency anemia, or pernicious anemia.[4,5] They are also rarely encountered in scurvy, diabetes, and collagen vascular disorders.[6,7]

It is appropriate, because of the widespread misuse of the term, to note that Roth's spots are not white-centered hemorrhages. Roth, a pathologist, described the gross and microscopic appearance of retinal hemorrhages and white, non-hemorrhagic retinal lesions in the eyes of patients who had died from acute septicemia.[8,9] The hemorrhages did not have white centers. The white lesions were composed of swollen nerve fibers, often containing a sharply circumscribed shiny swelling resembling a nucleus. In today's terminology, it seems likely that Roth was describing cotton-wool

patches which histologically were a collection of cytoid bodies.

Litten[10] first described the ophthalmoscopic picture of white-centered hemorrhages in the retinas of septic and anemic patients. He also described white spots without hemorrhages, which he properly called "Roth'sche Flecken." Unfortunately, subsequent writers misapplied the eponym "Roth" to the pale-centered hemorrhages which Litten first described. (It is an interesting coincidence that Litten is also credited with the first ophthalmoscopic description of a patient with retinal hemorrhages occurring in association with intracranial bleeding.[11])

In the two infants described in this report, the pale-centered retinal hemorrhages led to a fruitless search for septicemia and blood cell disorders. In each case the clinical findings and negative blood cultures made septicemia unlikely. The first infant had moderate anemia, a mild leukocytosis with some immature forms in the granulocytes, and a moderate thrombocytosis. It might be argued that she had leukemia; however, it was our interpretation that the high white cell and platelet counts were a secondary response to her severe intracranial bleeding. The second infant had normal blood counts.

What might cause the centers of these hemorrhages to be pale? Little is known about the white centers of retinal hemorrhages in any of the several conditions wherein they occur. Focal accumulations of leukocytes have been found in some pale-centered hemorrhages of leukemia,[12] bacterial endocarditis,[13-15] and pernicious anemia.[5] Those of aplastic anemia and aleukemic leukemia have not yet been examined histologically.[5] Leinfelder[10] has proposed four possible mechanisms for a white center in a retinal hemorrhage: a nest of leukocytes, a group of cytoid bodies, a collection of serum, or a central clearing of a previously homogenous hemorrhage. If the retinal hemorrhages in the two cases described here were produced by a sudden increase in venous pressure, according to the theory of Ballentyne,[3] it is difficult to imagine how any of these four mechanisms would occur.

## Summary

Pale-centered retinal hemorrhages were found in the eyes of two children with intracranial bleeding. Neither child had septicemia or a blood dyscrasia, the usual causes of pale-centered retinal hemorrhages. Although retinal hemorrhages commonly accompany intracranial bleeding, pale centers of the hemorrhages have not been previously described. The pathogenesis of the pale centers is unknown.

# RHEGMATOGENOUS RETINAL DETACHMENT AND CHOROIDAL MELANOMA

DENNIS M. ROBERTSON, M.D., AND VICTOR T. CURTIN, M.D.
*Miami, Florida*

This report describes an eye with retinal breaks and a retinal detachment containing two separate malignant melanomas.

## CASE REPORT

A 62-year-old white woman was referred to the Bascom Palmer Eye Institute because of recent findings of a retinal detachment in association with a probable tumor of her right eye. The patient gave a history of progressively decreasing visual acuity for two years. The past history, including a systems review, was otherwise normal. Examination revealed vision of 20/400 in the right eye and 20/20 in the left eye; a superior field defect to finger counting was present on the right. The right pupil reacted normally to consensual light but incompletely to direct light. Extraocular movements and slit-lamp examination of the anterior segments were normal. Applanation tensions were 20 mm Hg in each eye. Pigment particles were scattered throughout the vitreous in the right eye. Fundus examination showed a near total retinal detachment in the right eye and a large horseshoe tear within the area of detachment superotemporally (Fig. 1). In addition, there was a round retinal break with an overlying operculum superotemporally in an area of attached retina. A large solid-appearing mass extended inferiorly from the posterior pole toward the ora serrata. Though seen indistinctly, its surface appeared to be smooth and mottled with pigment. A defect to transillumination was present. The clinical diagnosis was malignant melanoma of the choroid, retinal detachment, and retinal breaks. Enucleation was advised and performed.

Grossly, the eye was normal. On cross section, the retina was almost totally detached and contained two breaks, superotemporally. A 10 by 10 mm elevated gray-brown mass involving the choroid was visible inferiorly under the detached retina. A pigmented plaque-like choroidal lesion that was distinctly separate from the main lesion was situated temporally in the region of the ora serrata, with extension into the posterior half of the pars plana of the ciliary body.

Microscopically, the anterior segment was normal. A large choroidal tumor near the disk extended inferiorly to the ora serrata. Its cells were predominantly of medium size with oval vesicular nuclei, prominent nucleoli, and scanty eosinophilic cytoplasm arranged in places in dense whorls. Many epithelioid cells with irregular nuclei and abundant cytoplasm were also present (Fig. 2). A moderate amount of pigmentation was irregularly distributed within the tumor. Bruch's membrane was intact over the tumor. Tumor cells extended along the intrascleral vascular channels beneath the mass. A vortex vein extending outside the eye contained an intraluminal mass of tumor cells.

The smaller temporal tumor contained small, relatively uniform cells with hyperchromatic nuclei and scanty cytoplasm and larger fusiform cells with elongated vesicular nuclei. Nucleoli and nuclear chromatin bars were present in variable distributions. Scanty pigmentation was present in the posterior half of the tumor, but the more anterior and internal regions were heavily pigmented. Detachment of the retinal pigment epithelium demonstrated hyperplasia and irregularity in this area. Large drusen were present in Bruch's membrane in the same region. The choriocapillaris was absent in some areas, whereas in others it appeared normal (Fig. 3 and 4).

The retina was detached over both tumors and elsewhere. Superotemporal sections showed a retinal horseshoe tear with vitreous attached to the anterior flap (Fig. 5).

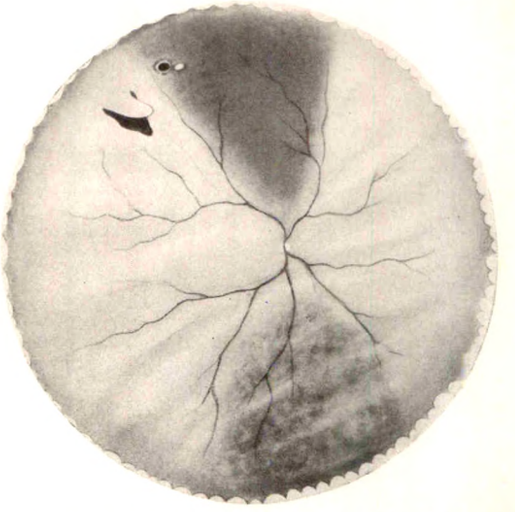

Fig. 1 (Robertson and Curtin). Drawing of fundus showing large choroidal melanoma partially camouflaged deep to a retinal detachment. A horseshoe tear is located superotemporally in area of detached retina and a round hole with operculum can be seen in the sector of attached retina.

From the Bascom Palmer Eye Institute, Miami, Florida.

Reprint requests to Dennis M. Robertson, M.D., Department of Ophthalmology, Mayo Clinic, Rochester, Minnesota 55901.

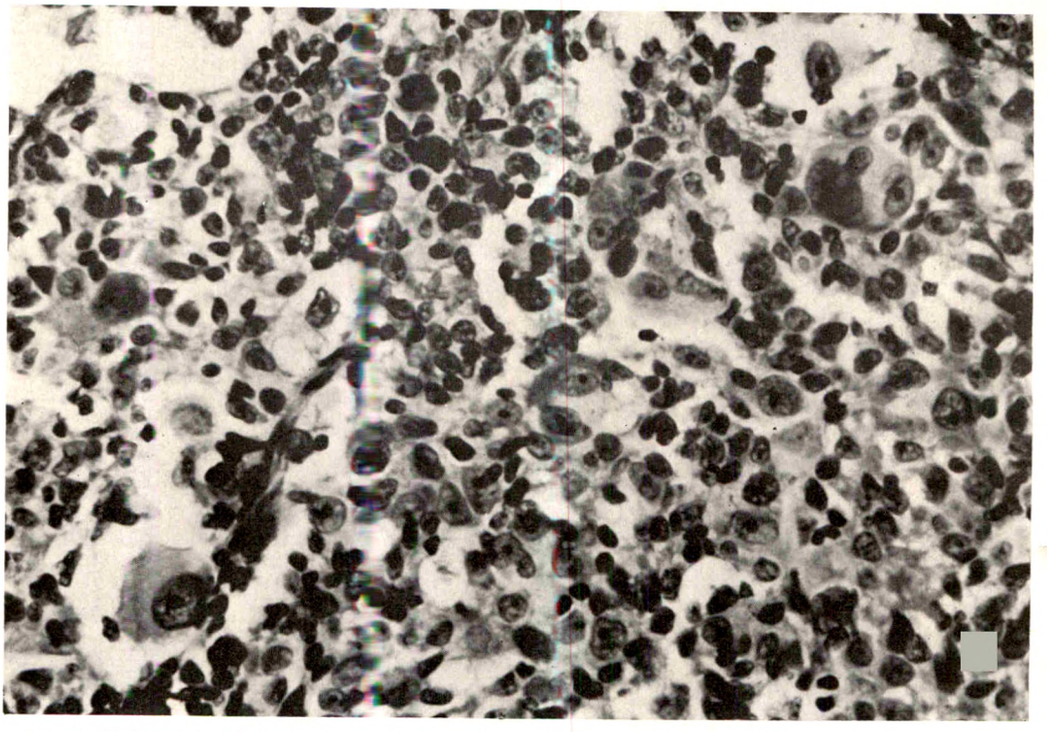

Fig. 2 (Robertson and Curtin). Larger tumor has epithelioid and spindle cells (hematoxylin and eosin, ×440).

Pathologic diagnoses were malignant melanoma of the choroid, mixed type; malignant melanoma of the choroid and ciliary body, spindle cell type; retinal detachment; and retinal horseshoe tear.

## Comment

The association of malignant tumors of the choroid and retinal breaks with or without retinal detachment only recently has been documented in literature. Although several articles have reported this relationship,[1-3] only four cases have been reported which include the histopathology of both the tumor and the retinal break.[3-6] Boniuk and Zimmerman[3] reported a case of choroidal melanoma in which an incidental retinal break was discovered histologically. Manschot[4] re-

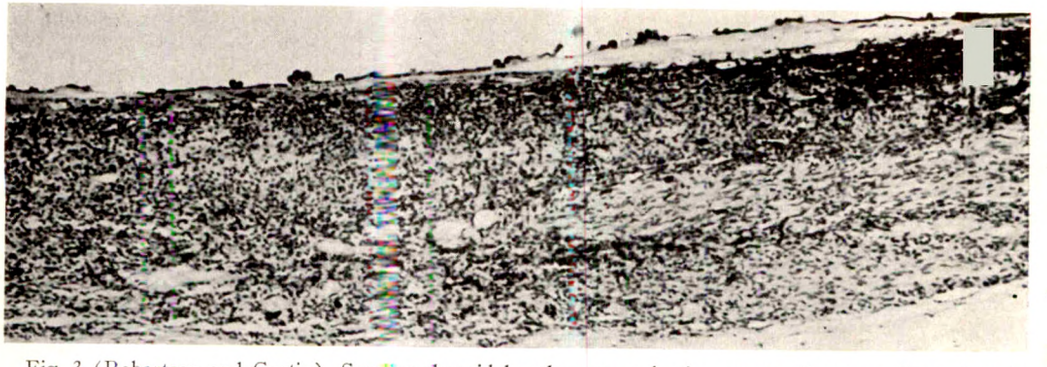

Fig. 3 (Robertson and Curtin). Smaller choroidal melanoma under low power (hematoxylin and eosin, ×70).

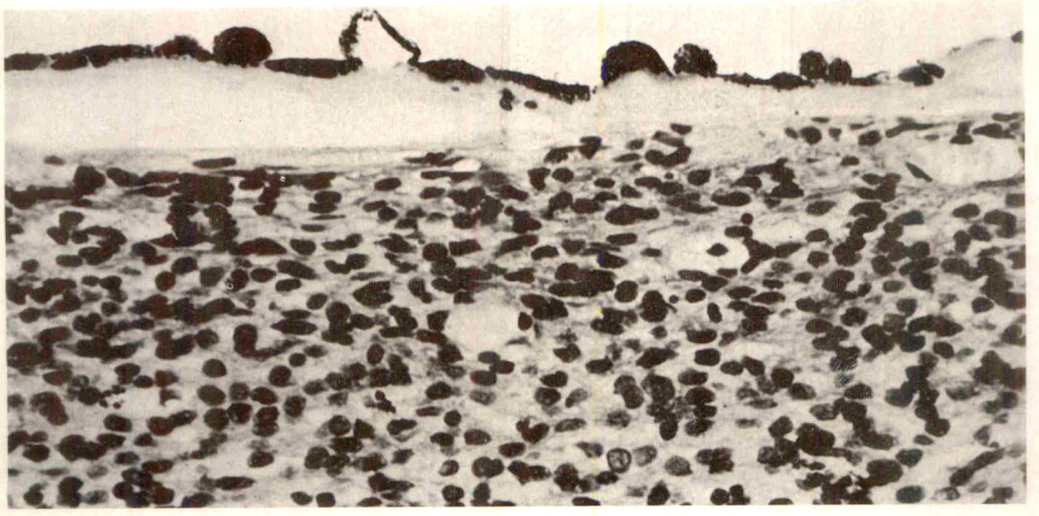

Fig. 4 (Robertson and Curtin). Same lesion as in Figure 3, showing variable cellular morphology, irregular pigment deposition, and area where choriocapillaris is absent (hematoxylin and eosin, ×440).

ported a case in which a hole overlying a melanoma in the histologic specimen was believed to have evolved from a degenerated retinal cyst. In the case reported by Berson and associates,[5] a round retinal break was found in the superotemporal quadrant within the detached retina remote from a clinically recognized malignant melanoma. Howard[6] reported a case in which a choroidal metastatic lesion from an adenocarcinoma of the colon was associated with a retinal detachment and a small "fish-mouth" tear.

In the cases reported by Berson's group and by Howard, the retinal detachments might be explained on the basis of the observed hole. In the case reported by Berson and associates, the tumor was recognized and the eye was removed. In the case reported by Howard (the only one with a horseshoe tear), the tumor was not recognized until after unsuccessful retinal detachment surgery was performed. In the present case, a horseshoe tear in the detached retina superotemporally could easily have explained the retinal detachment.

Because 5 to 8% of eyes contain retinal breaks,[7,8] these circumstances of retinal breaks, a retinal detachment, and intraocular tumor will occur by coincidence in rare instances. What are the best ways of avoiding errors in diagnosis? First, the characteristics of the detachment itself should be carefully evaluated. Does the location of the retinal breaks satisfactorily explain the geography of the detachment? Does subretinal fluid readily shift when the patient's head is changed from the vertical to the horizontal position? If the answer to the first question is "no" and the answer to the second is "yes," the ophthalmologist should be particularly alert that the problem is other than a rhegmatogenous retinal detachment. Second, the part of the eye that is behind the detached retina must be appraised. Indirect ophthalmoscopy greatly facilitates the examination because its greater illumination (when compared with direct ophthalmoscopy) gives the examiner a clearer view beneath detached retina. Consequently, an underlying mass is less likely to be camouflaged and overlooked. Third, any area that looks suspicious should be transilluminated. This can be most simply accomplished with the aid of a Finnoff head and an indirect ophthalmoscope. Similar to the scleral depressor, the illuminated Finnoff head is placed behind the region of the eye to

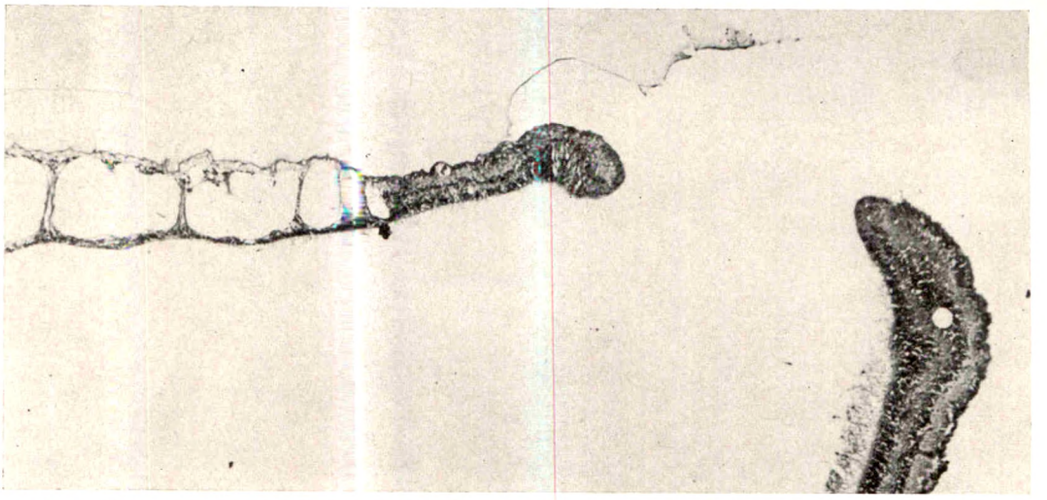

Fig. 5 (Robertson and Curtin). Horseshoe tear showing vitreous attachment to anterior flap (hematoxylin and eosin, ×44).

be studied, while the examiner views this region through the optics of the nonilluminated indirect ophthalmoscope. A mass such as a choroidal melanoma will likely be revealed by a transillumination defect that appears dark against the surrounding illuminated tissue. Hopefully, these considerations will help the ophthalmologist avoid operating for detached retina in the presence of an underlying tumor and thus obviate the complications that have been described by Boniuk and Zimmerman.[3] In our case, the limits of the detachment could have been easily explained by the superotemporal horseshoe tear. Though shifting fluid was somewhat exaggerated, detachment surgery would likely have been recommended had the tumor not been recognized by indirect ophthalmoscopy and further defined by retroillumination in the manner described.

An additional and unusual finding was the discovery on gross pathologic examination of a second small malignant melanoma in the eye of our patient. This tumor was well circumscribed and distinctly remote from the larger tumor. Because of its small size and its cellular structure, the lesion appears to have been relatively inactive. Nevertheless, the cellular characteristics and the changes in the choriocapillaris and pigment epithelium justify classification of this lesion as a malignant melanoma which developed from a separate focus. In referring to multiple origins of melanomas, Reese[9] stated that any malignant melanoma might be accompanied by benign melanomas elsewhere, but he questioned whether two malignant melanomas had ever developed separately in the same eye. Kurz,[10] however, reported a case in which two melanomas arose independently 180 degrees apart in the ciliary body and iris. The present report serves to demonstrate that malignant melanomas also may arise from separate foci within the posterior uveal tract.

## Summary

A case is reported in which the patient's eye contained a rhegmatogenous retinal detachment and two apparently separate choroidal melanomas. Though the geography of the detachment could have been easily explained by the superotemporal horseshoe tear, clinical recognition of one of the tumors underlying the elevated retina led to the correct diagnosis and enucleation. Photomicrographs of the specimen show sections through both tumors and the horseshoe tear.

ACKNOWLEDGMENTS

We thank G. Brock Magruder, M.D., and Stuart N. Willner, M.D., for their referral and treatment of this patient.

OPHTHALMIC MINIATURE

When ordinary people were told by the dogmatic propagandists of Charles Darwin's theory of evolution that so complex a thing as an eye had come into existence by some vague force known as natural selection, acting on chance minor structural variations, their credulity was taxed to the utmost. Their faith would probably have failed them completely had they been asked to believe that this random and mechanistic process had produced the vertebrate eye and the invertebrate eye in complete independence and more than that, had permitted the invertebrates to originate at least three different kinds of eyes in independence, within the limits of their own phylum.

# EXPERIMENTAL RETINAL DETACHMENT IN THE OWL MONKEY

## VIII. Photoreceptor Protein Renewal in Early Retinal Reattachment

Arnold J. Kroll, M.D., and Robert Machemer, M.D.

*Miami, Florida*

It has been demonstrated that the degeneration of photoreceptor outer segments, the alterations of the pigment epithelium, and the extinction of the electroretinogram (ERG) produced by experimental retinal detachment can be quickly reversed by surgical reattachment of the retina.[1-4] In addition, autoradiography has demonstrated that the normal renewal of outer-segment protein is changed by experimental retinal detachment.[3] This report describes the effect of reattachment of the retina on the protein renewal of photoreceptor cell inner and outer segments.

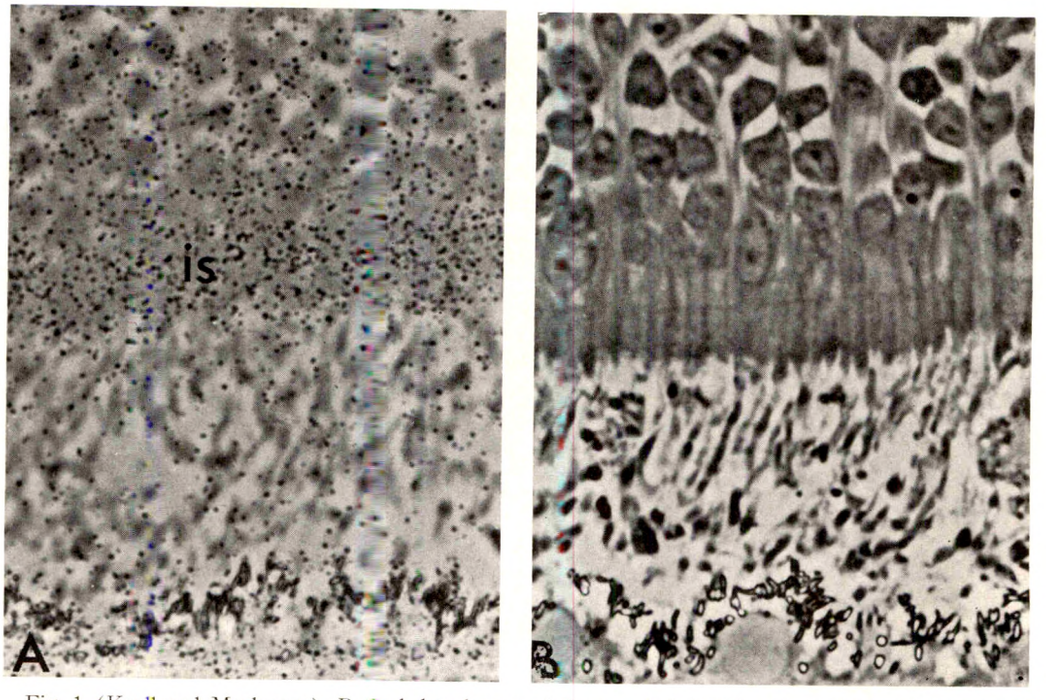
### Materials and Methods

In a series of three owl monkeys (Aotus trivirgatus), each weighing between 600–800 g, retinas were experimentally detached,[6] allowed to remain detached for four weeks, and then were surgically reattached, using a



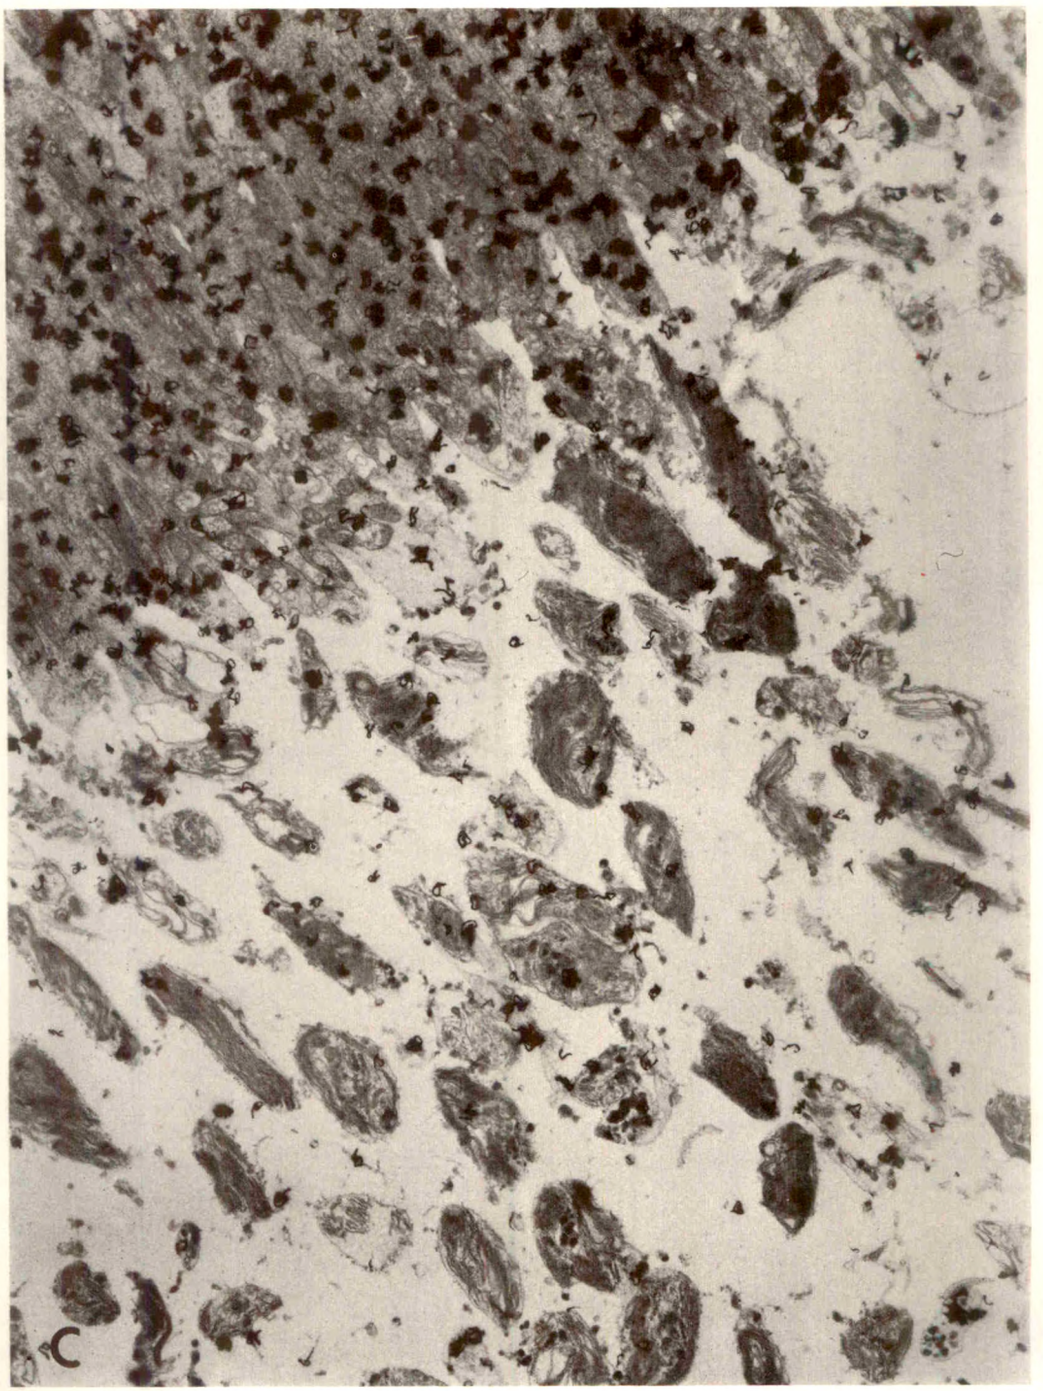


Fig. 1 (Kroll and Machemer). Retinal detachment of four weeks' duration, three hours after surgical reattachment, and two hours after injection of tritiated amino acids. There is extremely heavy labeling of the inner segments (is) compared with the control (Fig. 4). Note close apposition of the retina to pigment epithelium.

C

modification of methods previously described[1-6]: The anesthetized animal was placed in a box with the head projecting. A lateral canthotomy and lateral orbitotomy were done and the conjunctiva opened circumferentially. No diathermy or cryocoagulation was used. The retinal break was localized and appropriate sutures for a radially placed silicone sponge scleral buckling were placed. A drainage site was prepared posterior to the retinal break in the meridian of the planned scleral buckling and subretinal fluid was released using a diathermy needle puncture through choroid and pigment epithelium. A 27-gauge needle on a syringe containing air was passed through the pars plana anterior to the retinal break and into the vitreous cavity. Care was taken to position the eye and head so that both the drainage site and the pars plana injection site were at the lowest part of the eye. With alternating gentle aspiration and injection, the liquified vitreous was entirely replaced by air. The subretinal fluid was thus forced out of the drainage site by the pressure of the intravitreal air. With this method, fluid could be completely drained. The silicone sponge was then placed beneath the sutures and the sutures were tightened and tied. The intravitreal air was finally replaced by saline using gentle aspiration of air and injection of saline.

Each animal then received 55 mc of a tri-

The label has moved diffusely into the outer segments, but is more evenly distributed between inner and outer segments than in Figure 1.

M

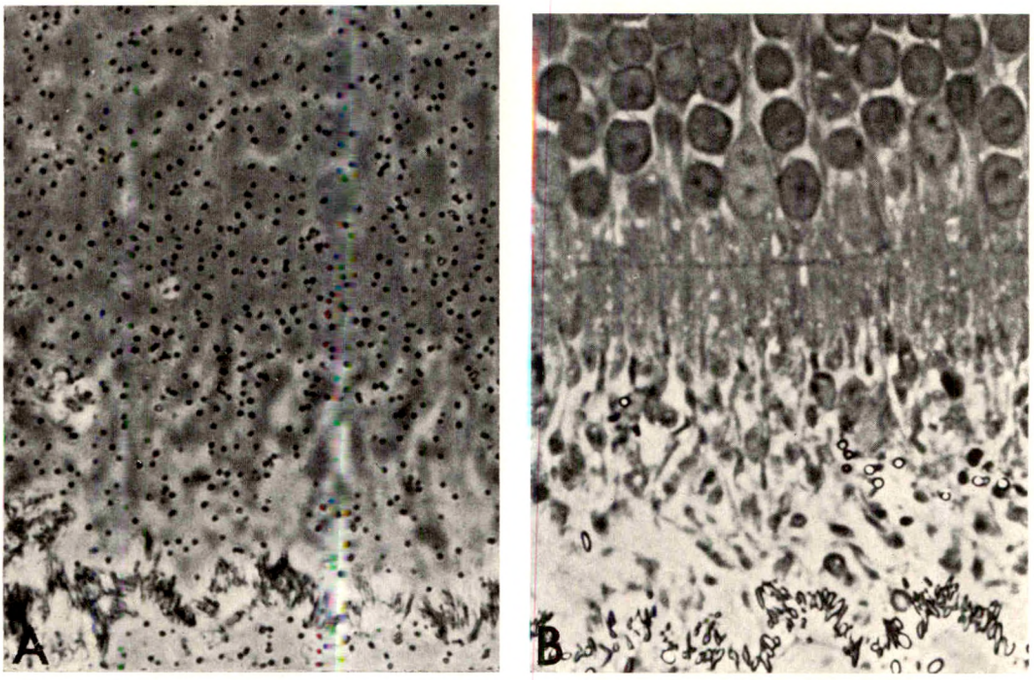
tiated amino acid solution (50 mc of L-phenylalanine and 5 mc of L-leucine), injected into the ipsilateral internal carotid artery as previously described.[5] Three control animals had similar ipsilateral intracarotid injections. Each control animal had an experimental retinal detachment of four weeks' duration, but in them, no attempt had been made to reattach the retinas. The intracarotid injections were started one hour after reattachment of the retina, and the eyes were enucleated at two hours, eight hours, and two days after the start of the intracarotid injections. Fixation, dehydration, embedding, and preparation for phase-contrast and electron microscopic autoradiographic studies were similar to previous work.[5,7-12] The retina and pigment epithelium situated away from the region of scleral buckling was selected for study.

## Observations

The surgical technique described above permitted immediate reattachment of the retinas with essentially complete drainage of all subretinal fluid (Figs. 1-3). This was accomplished without the use of cryotherapy or diathermy.

For each eye illustrated, a pair of phase contrast micrographs (autoradiography and histology) is accompanied by a representative electron microscope autoradiograph (Figs. 1-5).

The most striking autoradiographic finding was that within three hours of retinal reattachment, there was an extremely heavy labeling of the photoreceptor inner segments as compared with the label of detached retinas (compare Figs. 1 and 4). Nine hours after retinal reattachment (Figs. 2 and 3),



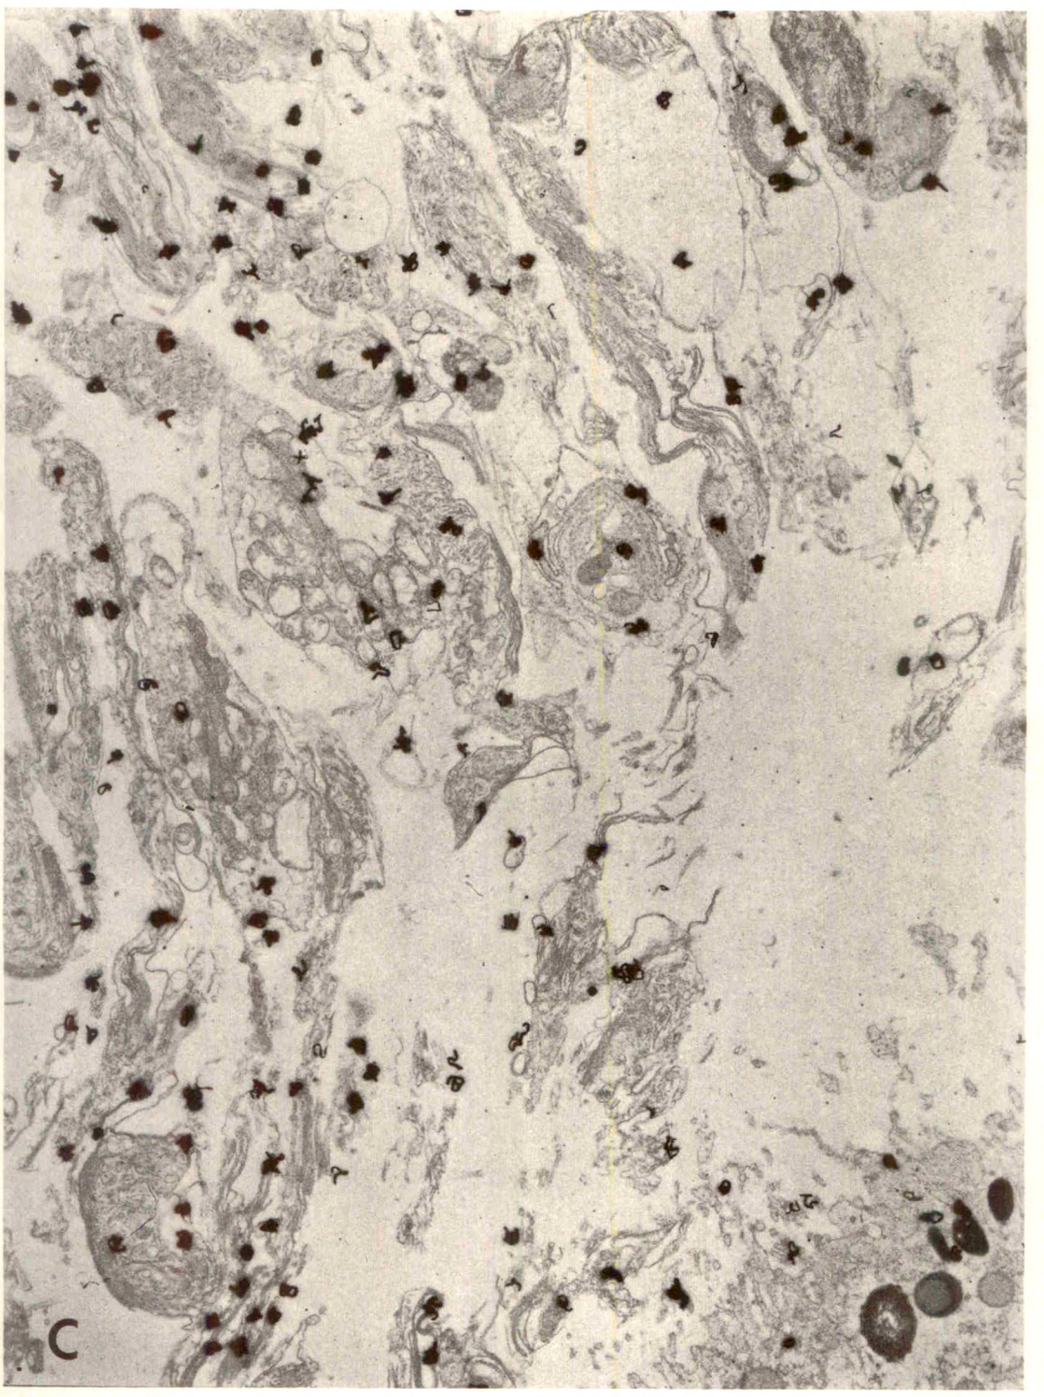


Fig. 3 (Kroll and Machemer). Retinal detachment of four weeks' duration, two days after surgical reattachment, and two days after injection of tritiated amino acids. (A) Autoradiography and (B) histology (phase-contrast photomicrograph, 400). (C-facing page) Electron photomicrograph (×6000). There is no significant change in the distribution of label compared with that shown nine hours after reattachment (Fig. 2). However, the label remains diffuse and heavier than in detached retina (Fig. 5).

C

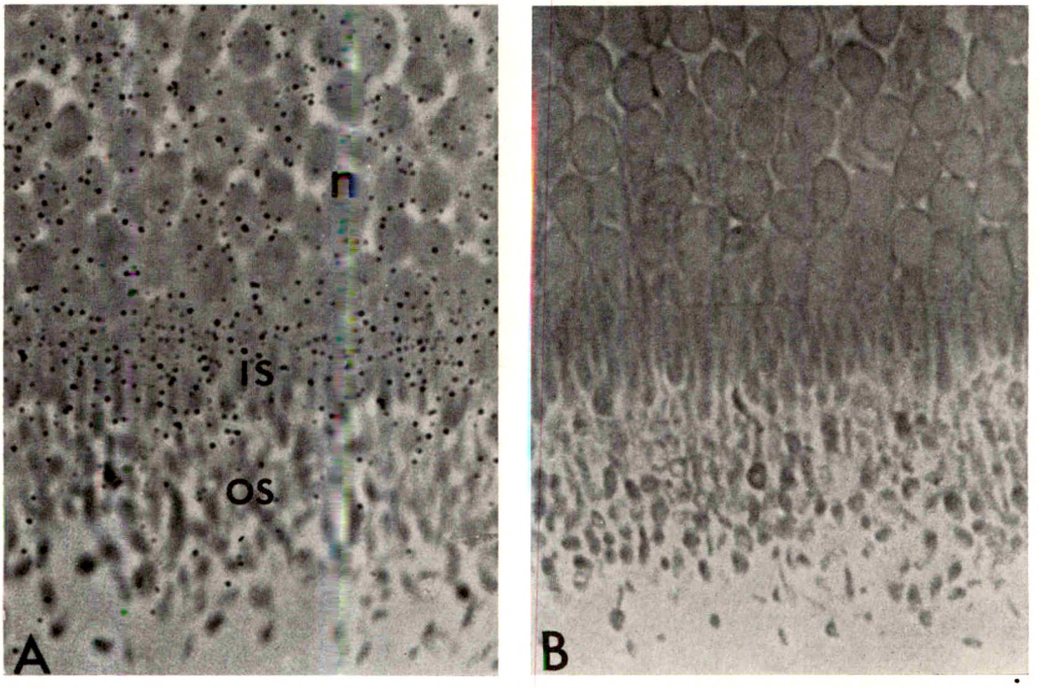
much of the label had moved diffusely into the outer segments, but unlike normal retina, no banded pattern appeared in the outer segments at that time.[5] Two days after reattachment, one could see heavier labeling of all portions of the photoreceptors than was observed in detached retinas (compare Figs. 3 and 5).

## Comment

The use of intravitreal air tamponade was very effective in removing essentially all subretinal fluid during surgical reattachment of the retina. It was thought essential to drain all of the fluid so as to remove the experimental variable of differing amounts of residual subretinal fluid being present postoperatively. Complete retinal reattachment was histologically confirmed in all cases—in some, as early as three hours postoperatively (Figs. 1-3). The intravitreal air was replaced by saline during the scleral buckling surgery so as to remove the air itself as another variable in the subsequent autoradiographic studies of photoreceptor protein renewal. In addition, so as not to interfere with choroidal or retinal metabolism, no cryotherapy or diathermy applications were made. Despite the lack of cryotherapy or diathermy, all retinas remained reattached during the experiment.

Autoradiographic studies[7-12] have emphasized that normal photoreceptor outer-segment protein is constantly renewed by a process of incorporation of amino acids into protein in the inner segments, a migration of the newly formed protein into the outer segments toward the pigment epithelium, and eventual phagocytosis of the protein by the pigment epithelium.

In a previous study done under identical conditions, the incorporation of radioactive



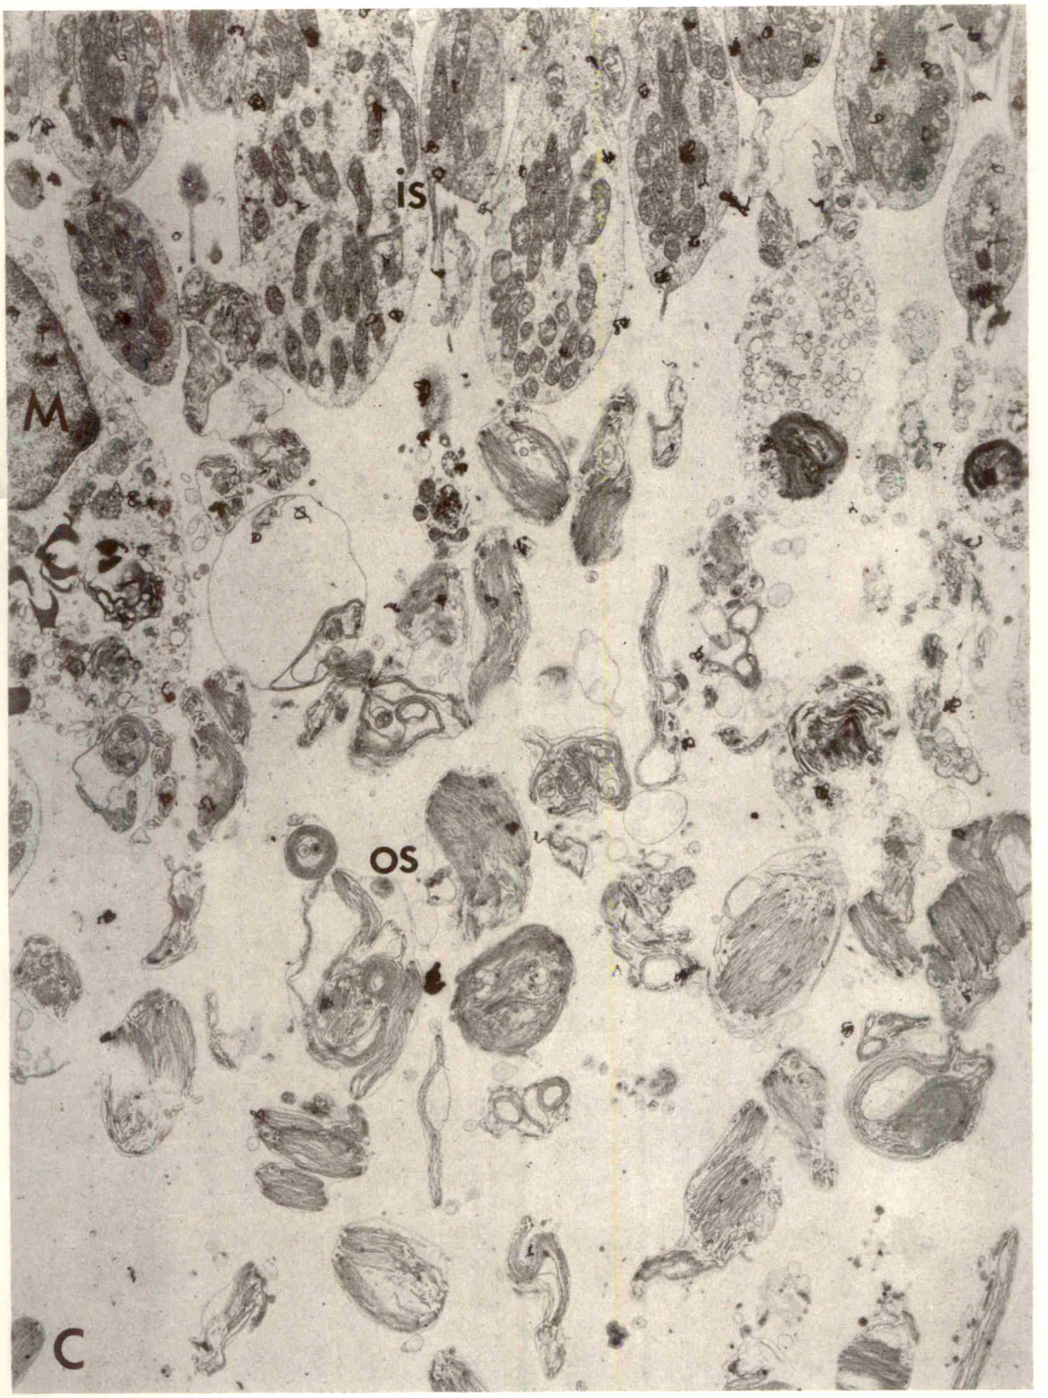


Fig. 4 (Kroll and Machemer). Retinal detachment of four weeks' duration, two hours after injection of tritiated amino acids. (A) Autoradiography and (B) histology (phase-contrast photomicrographs, ×400). (C-facing page) Electron photomicrograph (×6000). The inner segments (is) and nuclei (n) of the photoreceptors are labeled. The outer segments (os) are sparsely labeled. A macrophage (M) also is labeled. This retina serves as a control for the surgically reattached retina seen in Figure 1.

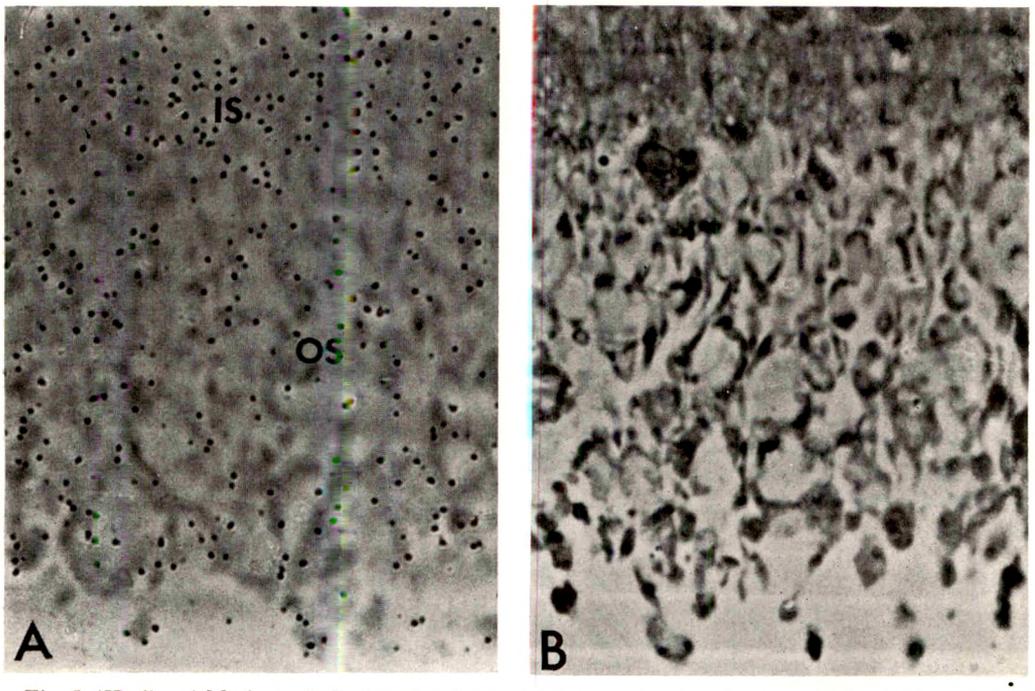
IS
M
OS
C

amino acids in normal and detached retinas was demonstrated, and it was shown that retinal detachment does not prevent incorporation of amino acids and the transportation of newly formed protein into the outer segments.[5]

The present study shows that retinal reattachment produces a rapid and marked increase in amino acid incorporation in the photoreceptor inner segment. This incorporation is higher than in the normal, attached retina.[5] Why this occurs is not known; however, the data suggest that, with reattachment, some factor causes amino acid to become more utilized in the photoreceptor inner segment, and triggers this metabolic resurgence. This resurgence probably originates in the pigment epithelium and the triggering factor is either produced or accumulated in these cells. It may be vitamin A, retinene isomerase, or some other substance.

As expected, some time later radioactive protein appears in the outer segment. In the normal eye, there is a band formation with migration from the inner to the outer part,[5,8,12] whereas in the reattached retina, the labeled protein is diffusely distributed all over the outer segment. Even two days after reattachment, there is no hint of a label-free zone in the inner part of the outer segment which one would expect if the protein was deposited in the normal manner. An explanation is difficult, but it is possible that the newly formed protein, after it is exported from the inner segment, can spread widely throughout the relatively "empty" outer segments, whose contents have degenerated during retinal detachment. It is highly unlikely that actual synthesis of outer-segment protein takes place within the outer segments themselves because they lack the synthetic and distributive organelles, the ergastoplasm,



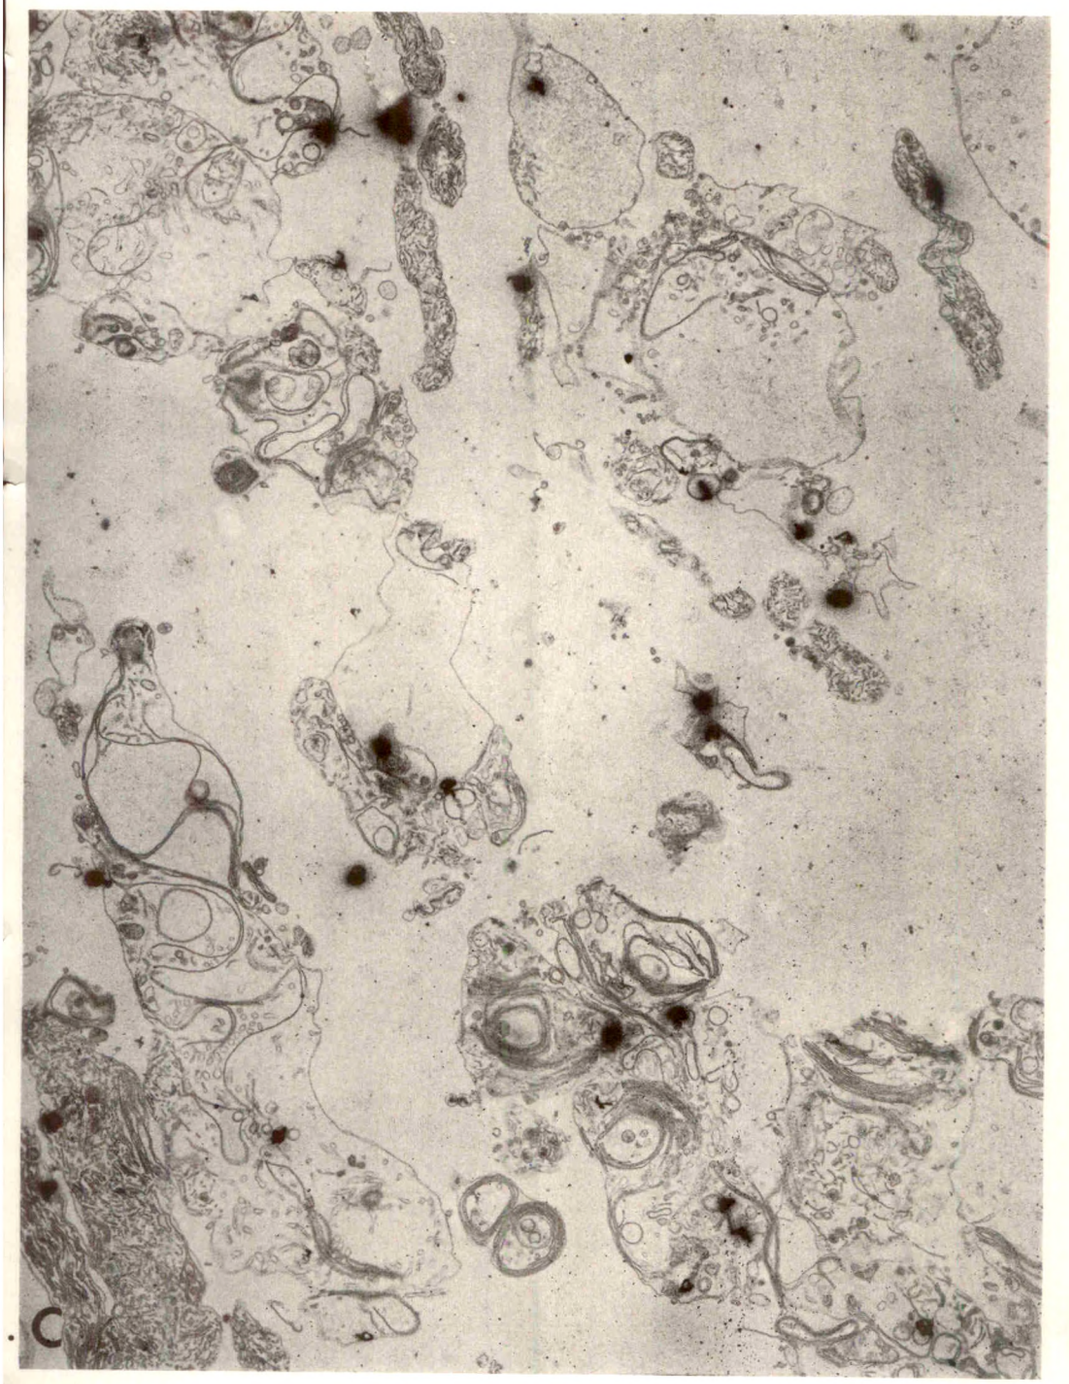


Fig. 5 (Kroll and Machemer). Retinal detachment of four weeks' duration, two days after injection of tritiated amino acids. (A) Autoradiography and (B) histology (phase-contrast photomicrographs, ×400). (C-facing page) Electron photomicrograph (×6000). There is fairly uniform labeling of both inner (is) and outer (os) segments. This retina serves as a control for the surgical reattached retina seen in Figure 3.

and Golgi apparatus, which are in the inner segments.[9] It is unlikely, as well, that the protein—most of which is normally bound to the saccules—should diffuse unbound in the outer segments at a time when abundant sacule material reappears in the outer segment.

Once the outer segment is refilled with saccule material, the random arrangement of saccules will slowly disappear, and after about two days, the normal pattern of stacks of saccules begins to be visible.[2] This suggests a return to normal band formation in the radioautogram, with labeled saccules starting near the inner part of the inner segment.

The high protein metabolism in the photoreceptor layer of the retina after reattachment correlates well with the speed with which the retina recovers functions measured by ERG; the ERG can be recorded as early as five hours after reattachment of the retina.[4]

## Summary

Protein renewal by retinal photoreceptor cells in early retinal reattachment in the owl monkey was studied by phase-contrast and by electron microscopic autoradiography. Compared with detached retina, reattachment produced a rapid, heavy labeling of the photoreceptor inner segments followed later by diffuse labeling of the outer segments. The marked increase in photoreceptor protein metabolism immediately after retinal reattachment correlates well with previous morphologic and electrophysiologic observations of photoreceptor recovery.

## Acknowledgments

We thank Mr. B. Davis who prepared the autoradiographs and provided technical and photographic assistance, and Dr. H. Buettner and Mrs. M. Halley, who assisted with the animal surgery, and Miss O. Levy who did the secretarial work.

# POSITIVE AND NEGATIVE DEFLECTIONS IN THE OFF RESPONSE OF THE ELECTRORETINOGRAM IN MAN

KAZUO KAWASAKI, M.D., YUTAKA TSUCHIDA, M.D., AND JERRY H. JACOBSON, M.D.
*New York, New York*

The electroretinogram (ERG) is a complex electrical waveform generated by the retina, the start of which, the early receptor potential (ERP), follows almost immediately upon the commencement of a light stimulus. This entire response to onset of illumination —ERP, and a-, b-, and c-waves that follow— is a result of the interaction of the electrical activities of several processes, first described as P-I, P-II, and P-III by Granit[1] in 1947, and since then, further defined[1–7] as to their individual sites of origin and significance.

When the stimulus light is discontinued there is a change in the electrical activity of each of the several processes which make up the total response. The interaction of these processes produces a deflection in the waveform recorded at the surface of the retina or eyeball. This phenomenon, called variously the "off effect," "d-wave," or "off response," has been relatively ignored in the development of electroretinography as a clinical instrument, much greater emphasis having been placed on those responses generated by onset of stimulation. In this paper, we shall use the terms, "on response" and "off response" to mean the alteration in total recorded waveform engendered by onset and cessation of light stimulation.[5]

The off response of the ERG begins with a negative-going deflection in predominantly rod retinas[1–7] and with a positive-going wave in cone retinae.[1–3,5,8]

The human dual retina would be expected to be subject to variation in its off response from the positive, cone type to the negative, rod type by manipulation of stimulus or adaptation parameters.

The human off response is negative in polarity with a dim stimulus.[9–12] The human off response becomes positive in polarity with increased stimulus intensity,[10,13–16] and is preserved in stationary congenital night blindness.[13,16]

This paper describes the characteristics of the negative and positive off responses in normal human subjects and the variations from normal of the responses in stationary congenital night blindness and rod monochromatopsia. Our goal, in this study, is to lead toward the ultimate utilization of the off response as a clinically useful parameter of the ERG.

## METHOD

Stimulus light from a 1 kw tungsten source was brought to a focus, after transmission through heat filters, at an electromechanical shutter, which controlled the light beam to provide rectangular flashes of 0.74 second duration at two- to 30-second intervals. The stimulus light then entered one of the two input ends of a Y-shaped glass fiber light guide.

Adapting light from an additional tungsten source (150 w) was focused upon the other input end of the light guide. The glass fibers carrying light from each source were mingled together at the output end (7 mm in diameter), which was held 5 cm from the cornea of the examined eye. Zero log unit intensities of stimulus and adapting light were $8.4 \times 10^3$ and $5.2 \times 10^3$ lux, respectively, at the cornea. Neutral density filters were interposed in the light path to decrease the luminance. Stimulus and adapting light

intensity was expressed in $\log_{10}$ units. No adapting light was present, unless noted.

ERG responses were led from a contact lens electrode[17] to a Grass electroencephalogram amplifier (7P511, time constant 0.25 second unless otherwise noted) and averaged by a Mnemotron CAT 400 computer. The combined earlobes served as the indifferent point. The pupil was dilated with 1% tropicamide. Upward deflection indicates positivity of the corneal electrode.

## Results

A very dim stimulus (−4.0) evoked a small b-wave (one of the on responses) and a negative off response (Fig. 1). The threshold of the negative off response was the same as that of the b-wave. With increasing stimulus intensity (up to −2.0 log units), the b-wave amplitude rapidly increased, while the negative off response increased only slightly. Further increase of stimulus intensity decreased the amplitude of the negative off re-

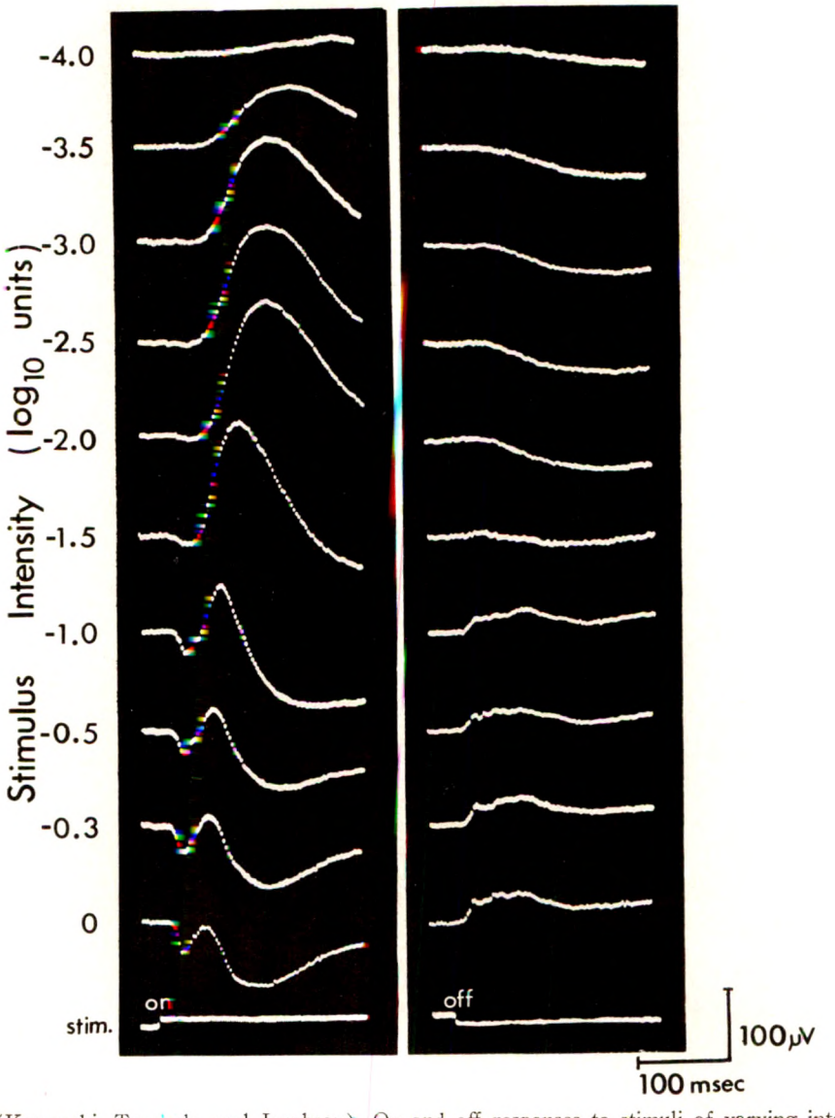

Fig. 1 (Kawasaki, Tsuchida, and Jacobson). On and off responses to stimuli of varying intensities in normal subject. Each trace is average of 20 responses. Stimulus frequency 0.5 Hz.

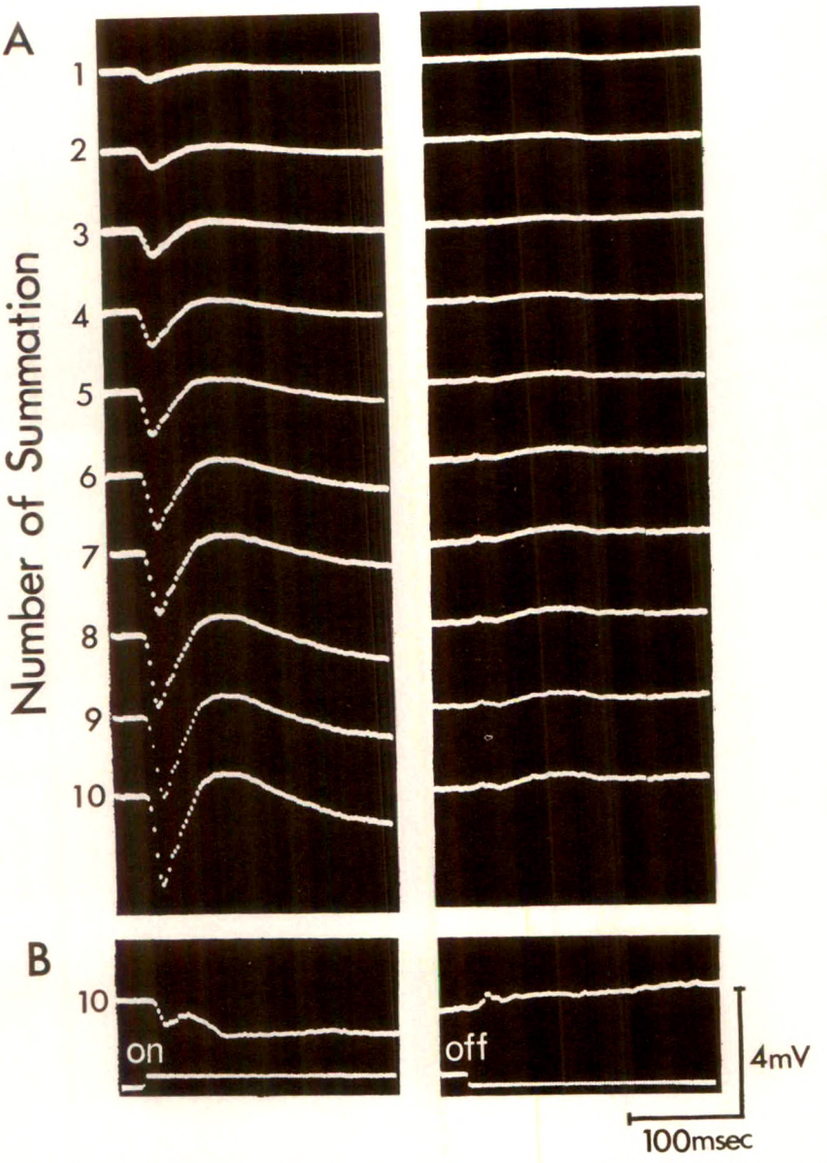

Fig. 2 (Kawasaki, Tsuchida, and Jacobson). On and off responses of normal subject to (A) intense stimulus (zero log unit) in virtually dark-adapted state and (B) in light adaptation induced by high frequency of stimulation. In A, after dark adaptation of 30 minutes, 10 stimuli were delivered at a rate of one flash per 10 minutes, with no background illumination between flashes. Responses to these 10 stimuli were successively summed. In B, 10 identical stimuli were presented once a second, with no preliminary dark adaptation. Summed response to these 10 stimuli shown. Vertical calibration relates to sum of amplitudes of responses.

sponse, which was now preceded by a small positive off response (−1.5, Fig. 1). With still brighter stimuli, the amplitudes of the a-wave and positive off response increased approximately linearly to log stimulus intensity, while the b-wave was suppressed. The positive off response was followed by a negative-going wave returning toward the baseline.

The apparently paradoxical reduction of

b-wave amplitude with increased stimulus intensity is partly due to the increased level of light adaptation consequent to the use of repetitive stimuli necessary for computer averaging. This light adaptation may also influence the positive off response. In an attempt to control this factor, the series of experiments illustrated in Figure 2 was conducted. The subject was dark-adapted for 30 minutes, then exposed to 10 single stimuli of maximum intensity, one flash every 10 minutes, with no background light between flashes. The summed a- and b-wave amplitude of these 10 responses was equal to 10 times the amplitude of the first dark-adapted response. Inspection of the individual responses (not summed) revealed no difference in a- or b-wave amplitude between the first and last responses. Since a- and b-wave amplitude is known to be sensitive to light adaptation, this would indicate that dark adaptation was not significantly affected by this set of stimulus parameters. In this situation the positive off response was very small (Fig. 2-A). In Figure 2-B, the stimulus of the same intensity as used in Figure 2-A, was repeated once every second. Light adaptation engendered by this frequency of stimulation—and indicated by the reduced a- and b-wave amplitude—was accompanied by an increase in the positive off response. Therefore, light adaptation induced by the repetitive stimuli augments the positive off response.

Figure 3 shows the effect of increasing light adaptation on responses to a relatively dim stimulus (−3.0). Increased level of light adaptation alone did not produce a positive off response unless the stimulus was sufficiently intense. Repetitive, intense stimuli, hence, are favorable to positive off response production.

The spectral sensitivity of the b-wave,

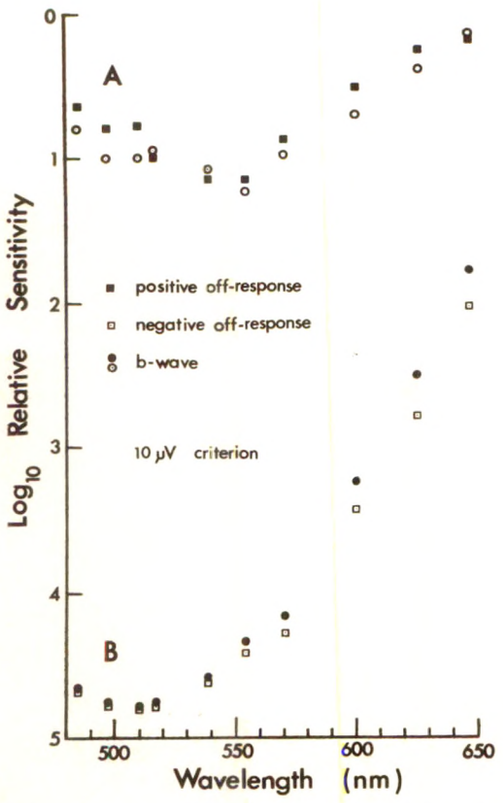

Fig. 4 (Kawasaki, Tsuchida, and Jacobson). Spectral sensitivity of b-wave, positive and negative off responses. (A) Eye was exposed to adapting light of —1.1 log unit. (B) No adapting light was used, but eye was dark-adapted for 30 minutes prior to recording. Stimulus intensity was increased in 0.5 log steps from sub-threshold level at each wave length of equal intensity monochromatic light. Ordinate is $\log_{10}$ reciprocal stimulus intensity required to evoke response of 10 μv criterion voltage. Data derived from average of 80 responses in A and of 20 responses in B. Stimulus was repeated every two seconds in A and 30 seconds in B.

positive and negative off responses was studied using a series of equal energy monochromatic stimuli obtained by use of interference filters and neutral density filters. The eye was dark-adapted for 30 minutes prior to the recording. Stimulus intensity was increased in 0.5 log steps from subthreshold level at each wavelength.

Precautions were taken to avoid disturbing dark adaptation during the recording: Relatively dim stimuli were used, the maximum intensity being not more than one log unit above the intensity producing a just discernible b-wave at each wavelength. Dark adaptation of 10 minutes was allowed between recordings at different wavelengths. Stimuli were repeated at low frequency (one flash every 30 seconds).

The amplitudes of the averaged responses were plotted versus log stimulus intensity at each wavelength. From such graphs we derived the stimulus intensity required to produce a constant (10 μv) amplitude response at each wavelength. The reciprocal of the resulting intensity value represents sensitivity. The spectral sensitivity curves thus obtained are illustrated in Figure 4. The low-threshold negative off response was as sensitive to monochromatic light as the dark-adapted b-wave, and its spectral sensitivity approximately fitted the C.I.E. scotopic sensitivity curve[18] in dark adaptation.

The spectral sensitivities of the positive off response and the b-wave were obtained similarly. The eye was light-adapted to white light of −1.1 log unit intensity so as to saturate the scotopic function.[19] Since, with this constant background illumination, light adaptation induced by repetitive stimuli became less significant, stimuli were repeated at high frequency (one flash every two seconds) for averaging. The positive off response and b-wave thus light-adapted were the most sensitive to light of a wavelength of about 550 nm (Fig. 4).

Figure 5 is the ERG of a 59-year-old white man with recessively inherited stationary congenital night blindness. His dark adaptation curve showed only the cone portion. Color vision was normal. He was myopic and corrected vision was 20/30 in each eye. The fundi showed peripheral retinal atrophy, myopic crescents, and narrowing of retinal arteries. Neither b-wave nor negative off response was evoked in this patient by −3.0 log unit stimulus, which was bright enough to elicit these responses in normal subjects. Intense stimuli evoked an a-wave and a

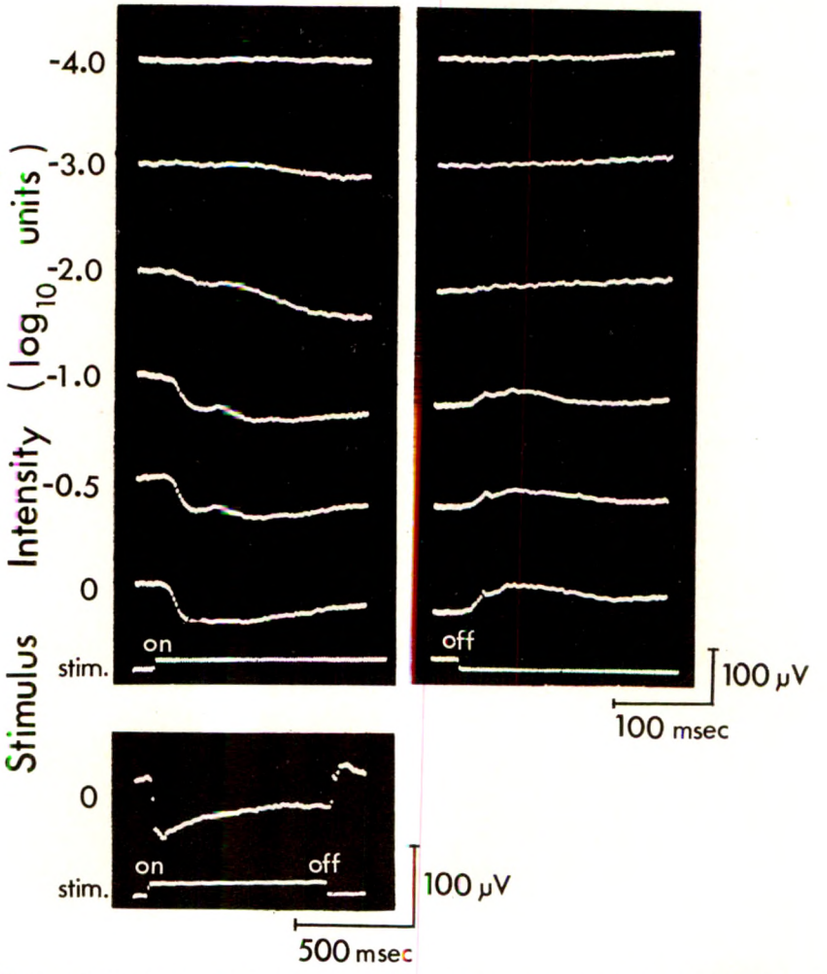

Fig. 5 (Kawasaki, Tsuchida, and Jacobson). ERG in stationary congenital night blindness. On and off responses absent with dim stimulus, a-wave and positive off responses present with bright stimulus. Average of 20 responses. Stimulus frequency 0.5 Hz. Amplifier time constant 0.6 seconds in lowest record in left column, 0.25 seconds in all other records.

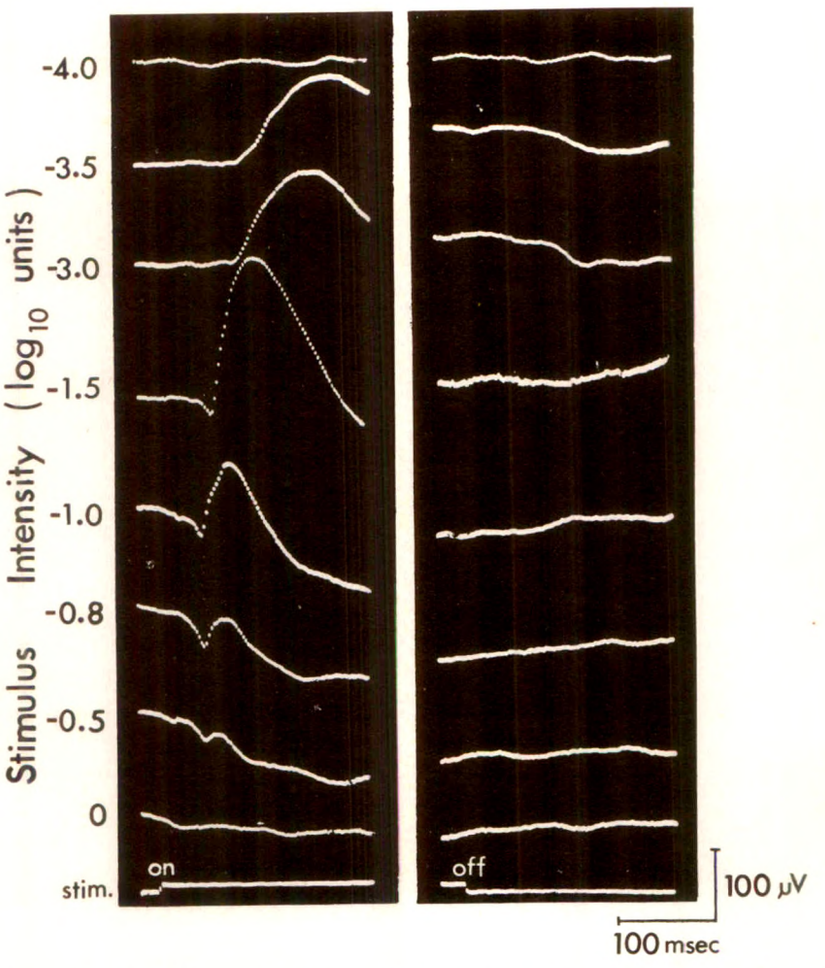

Fig. 6 (Kawasaki, Tsuchida, and Jacobson). ERG in rod monochromatopsia. Negative off response present, positive off response absent. Average of 20 responses. Stimulus frequency 0.5 Hz.

positive off response of normal amplitude, but b-wave amplitude was greatly decreased. The ERG, hence, appeared to consist of P-III[1] or the late receptor potential[2,3,5] (lowest record, Fig. 5).

The level of light adaptation induced by the repetitive stimuli of −3.0 log units (8.4 lux) should not exceed the level which is equivalent to continuous light adaptation of this intensity (8.4 lux), since dark periods intervene between repetitive stimuli. The level of adaptation produced by continuous light of 8.4 lux is below the saturation level of the human scotopic function.[19] Therefore, the absence of the low-threshold negative off response with this stimulus intensity in this patient is not due to the suppression of the scotopic function by light adaptation induced by the repetitive stimuli.

Figure 6 shows the ERG of a five-year-old white girl with poor vision (20/200 in each eye), photophobia, nystagmus, and poor color vision. The fundi were normal. Color tests, including Ishihara, H-R-R pseudo-isochromatic plates, and anomaloscopy, in conjunction with her symptoms, indicated that her color defect was rod monochromatic. We found the low-threshold negative off response present and the high-threshold positive off response unrecordable in this pa-

tient. The positive off response was absent in this case even with a stimulus bright enough to evoke a distinct a-wave in normal subjects. General anesthesia was used in this patient because she could not tolerate bright stimulus lights. The anesthesia was not responsible for the absence of the positive off response in this case, however, since a normal positive off response was found under identical general anesthesia in normal subjects.

## Discussion

If the analyses of animal ERGs[1-3,5,20] may be applied to the human ERG, the low-threshold negative off response would represent the termination of P-II[1] or the dc component,[20] and the initial ascending phase of the high-threshold positive off response the end of P-III or the late receptor potential.[2,3] Studies of animal ERGs[4,20] also suggest that the negative-going wave following the high-threshold positive off response is due to the end of P-II[1] or the dc component. A positive plateau potential, which seems to correspond to the dc component of the cat,[20] is also present in man.[12,21]

Evidence suggests that reduction of the amplitude of the negative off response at moderate stimulus intensities, similar to that seen at the transition from the negative to positive off effect in Figure 1, occurs in single flash studies,[11,12] indicating that this phenomenon is not due to light adaptation induced by repetitive stimuli. One of the possible explanations for this amplitude reduction of the negative off response is that the positive off response adds algebraically and results in an apparent decrease in amplitude of the negative off response.

Figure 4-B indicates that the low-threshold negative off response is mediated by the rod system in dark adaptation. The absence in night blindness and the presence in rod monochromatopsia (Figs. 5 and 6), of this low-threshold negative off response, favor this assumption.

The presence in night blindness, and the absence in rod monochromatopsia, of the positive off response (Figs. 5 and 6), suggest its close relationship with the cone system. This assumption is supported by its high threshold and spectral sensitivity. Our results do not exclude the possibility of the contribution of the rod system to the positive off response in the fully dark-adapted state.[22] Dark-adaptation should increase the amplitude of an ERG response related to the rod (scotopic) system. The positive off response is larger in moderate light adaptation than in dark adaptation[15,16] (Fig. 2). This suggests that the rod system does not greatly contribute to the high-threshold positive off response.

## Summary

When stimuli of relatively low intensity are used, the off response of the human electroretinogram consists mostly of a negative-going wave. With intense stimuli, the off response begins with a positive-going wave. The negative-going wave of the off response to dim stimulus is absent in stationary congenital night blindness and present in rod monochromatopsia. The positive-going wave of the off response to intense stimulus is present in stationary congenital night blindness and absent in rod monochromatopsia.

OPHTHALMIC MINIATURE

It is a widely spread belief that there is a strange power in the eyes of man. Mowgli was expelled from the wolf pack because they could not bear his gaze, and even his best friend, the panther, was unable to look him straight in the eyes. . . . Amongst themselves, animals only look at each other fixedly when they intend to take drastic measures or are afraid of each other. Consequently they conceive a prolonged fixed gaze as being something hostile and menacing and rate it in man as the expression of extreme malevolence. And this the whole secret of the "power of the human eye."

# BANDAGE LENSES IN THE TREATMENT OF BULLOUS KERATOPATHY

ANTONIO R. GASSET, M.D., AND HERBERT E. KAUFMAN, M.D.
*Gainesville, Florida*

In a previous paper[1] we reported that hydrophilic contact lenses provide a simple and often useful therapy for bullous keratopathy. These lenses* (Griffin) can be worn in cases of epithelial bullae and gross corneal irregularities without causing corneal ulceration. They generally relieve the pain associated with ruptured bullae and corneal ulcers without interfering with the healing process. Their use as an optical bandage for diseased corneas has improved vision and relieved pain in many cases where other sight-preserving techniques have failed or were not possible.

Since our original report, we have fitted a total of 528 corneas (normal and pathologic) with bandage lenses and have monitored an additional 1207 cases fitted by other clinicians. A review of these data corroborated our previous results and revealed that errors in fitting can cause poor results as well as unnecessary complications.

Our present fitting techniques are presented here, together with a summary of the clinical results of this therapy in 49 patients with varying degrees of bullous keratopathy.

## MATERIAL AND METHODS

Through studies of the Bausch and Lomb, the Griffin, and other types of lenses, we found that good visual results required the use of lenses available in various curvatures and diameters. Leibowitz and Rosenthal[2] similarly reported relief of pain without improvement of vision with the Bausch and Lomb lens. For this reason, only Griffin lenses were used as bandage lenses in this study.

*The lens*—A detailed description of the Griffin lens has been presented elsewhere.[1] Briefly, it is both flexible and hydrophilic, containing a high water content and reasonably good optical surface and a tear layer beneath the lenses. The Griffin lens potentiates the action of medication such as hypertonic saline, and it is available in a variety of diameters and curvatures, which may explain, in part, the superior visual acuity obtained with theses lenses.

*Fitting procedure*—Fitting patients with bullous keratopathy is much more difficult than fitting patients for simple refractive errors. However, experience in fitting patients for refractive errors is a significant asset in fitting pathologic corneas.

Trial lens fitting is the easiest and often only method by which these lenses can be fitted in patients with bullous keratopathy. Through such testing, the dimension, curve, and diameter that will give the best and most stable performance is determined. A properly fitted lens has both central and peripheral contact, so that it does not flex in the center with each blink, and it has sufficient diameter so that it will not move with each blink. However, it is difficult to verify this alignment for any given lens. Fluorescein is useless since it penetrates the lens instantly and does not delineate the form of the tear layer. In addition, keratometer readings are usually unavailable in patients with bullous keratopathy. Thus the first question is how to select a lens that will provide sufficient adherence to prevent movement without inducing too much apical clearance and, consequently, variable vision.

If the lens selected is not of the proper curvature and diameter, there are two possible difficulties: it may be too steep, or it may

From the Department of Ophthalmology, College of Medicine, University of Florida. This study was supported in part by Public Health Servie Grants EY 00266, EY 00446 and EY 00033 from the National Eye Institute.

Reprint requests to Herbert E. Kaufman, M.D., Department of Ophthalmology, College of Medicine, University of Florida, Gainesville, Florida 32601.

* Still available only for investigative use.

be too flat. If the lens is too flat (or too small), it will move up and down with each blink or will be displaced laterally on sideward gaze. If the lens is too steep, there is alternate blurring and clearing of vision with each blink. This may be somewhat difficult to evaluate initially in a patient with bullous keratopathy. However, if there is any doubt that the lens might be steep, one should proceed to the next flatter lens (or the one with the next smaller diameter). If the lens is too flat, it will move excessively. If the lens moves too much one can be assured that the proper lens is steeper. If the lens seem to center properly in the eye, one can try for a flatter lens to be certain that it is not too steep.

The following guidelines have been extremely helpful to us in selection of the proper combination of curve and diameter for any given patient:

1. A larger diameter increases adherence and may cause apical clearance.
2. A smaller diameter decreases adherence and may cause movement and lag.
3. A steeper curve increases adherence and may cause apical clearance and associated change in vision.
4. A flatter curve reduces adherence and will eliminate the changing vision caused by flexing of the lens.
5. Never rely on the results of a given test lens until the lens has been on the eye for a significant amount of time (15 to 30 minutes).

This last rule is most important in patients with bullous keratopathy. Large, single bullae usually disappear within a few days, and only diffuse epithelial edema remains. The constant wearing of these lenses also results in dehydration of the cornea and a significant change in corneal shape. The lens that fitted properly before is no longer satisfactory. This change usually results in a reduction in visual acuity, and it is not unusual to find a patient with an initial visual improvement from 20/200 to 20/40 in whom, after a few days, visual acuity decreases to 20/100 or 20/200. Biomicroscopy of the eye usually reveals a significant change in the cornea with disappearance of the big bullae and diffuse epithelial edema. When these cases are refitted and hypertonic saline used, visual acuity usually improves again. In some cases several changes in the lenses are required.

Once the proper curve and diameter are determined, the refractive power of the lens should be considered. For the beginner, plano lenses will simplify the procedure. The proper power can be prescribed by one of the following techniques:

1. By using the spectacle refraction and vertex distance and refining the refraction through a trial lens procedure.
2. By using plano lenses and refracting over.

The selection of the trial lens is mady by taking the spectacle refraction in minus cylinder form, ignoring the cylinder and correcting for the vertex distance when necessary.

Just as the base curve of the lens changes with changing corneal curvature, the required refractive power may change. Patients with bullous keratopathy must have over-refraction in each follow-up visit.

*Use of medications*—Pupils are dilated for the first few days in cases of chronic bullous keratopathy, especially with epithelial defects, because of the concomitant iritis present in almost every case. We have found it extremely useful, in many cases of chronic bullous keratopathy, to institute eyelid hygiene techniques. Hexachlorophene (pHisoHex) scrubs for five minutes once or twice a day have virtually eliminated minor infection and unrecognized blepharitis as causes of patient discomfort.

Antibiotics are used if secondary infection or chronic blepharitis is present at the time of fitting.

Five percent hypertonic saline without

preservative or methylcellulose is the single most important medication used in combination with the lenses. In most cases it produces a significant improvement in vision and is used three to five times a day, as necessary. However, it should be avoided initially in patients who have a significant amount of discomfort. In these cases, lens application and pupillary dilation should relieve the pain within a few days. At that time the patient should be refitted and hypertonic saline used for improvement of visual acuity.

The following variations in technique have been used:

1. In advanced cases of bullous keratopathy where a hazy subepithelial layer is present, the pathologic corneal epithelium and the underlying connective tissue are easily removed after application of local anesthetics with a cotton swab or a No. 15 Bard-Parker blade. Homatropine, atropine, or scopolomine is then applied to the eye. Neosporin ophthalmic solution is also generously applied to the eye. A pressure patch is not necessary in these cases where the lens is inserted immediately after the removal of the pathologic corneal epithelium. Visual acuity is usually much improved immediately after such procedures, but it will decrease one or two lines after a few days. This is due to the regrowth of the corneal epithelium, the thickening of the corneal stroma, and, in some cases, folds in Descemet's membrane. The lens must be refitted in all these cases and application of 5% hypertonic saline instituted once the eye is comfortable.

2. In patients with advanced bullous keratopathy and some subepithelial membrane, no effort should be made to fit with the proper refraction until several weeks after the lens is applied. In these cases, a plano lens of the proper diameter and base curve is used.

3. In patients with a large epithelial defect, such as after removal of an epikeratoprosthesis,[3] the pupil is dilated and a randomly selected, preferably steep lens and antibiotics are applied to the eye. The lens is left in the eye until re-epithelization has occurred. We prefer to allow two to four weeks before any attempt is made to improve visual acuity by refitting the patient.

4. If the proper lens dimension cannot be determined at the first visit, we have found that an 8.1 lens 14.0 mm in diameter with central thickness of approximately 0.3 mm gives the most satisfactory result until the proper dimension can be determined.

## Results

Between February, 1969, and July, 1970, a total of 49 patients with varying degrees of bullous keratopathy have been fitted with bandage lenses at the University of Florida.

Of these 49 patients, 41 are still wearing their lenses. In eight in whom use of the lens was discontinued, only one significant lens-related complication has occurred. One patient developed a purulent conjunctivitis. The lens was erroneously left in the eye for a week and a small corneal ulcer developed. This healed rapidly under treatment without visual loss, and lens wear was resumed. The most common reason for discontinuing the lenses was failure to improve the visual acuity to a reasonable level in patients who had no significant discomfort. Of the 41 patients still wearing the lenses for relief of pain and improvement in vision, 12 have now worn them for over one year; the other 29 have worn them from three to twelve months.

*Visual acuity*—In most cases visual acuity was counting fingers prior to bandage-lens therapy. A few patients had a visual acuity better than 20/100 and only one was as good as 20/60.

The improvement in visual acuity after treatment with the Griffin lenses is shown in Table 1. It is, however, based on the following considerations:

Visual acuity is often improved immediately after insertion of the lens and the application of hypertonic solution. However, in some cases, many fittings and several weeks or even months are necessary before the best visual acuity can be obtained.

TABLE 1

BEST VISUAL IMPROVEMENT AFTER BANDAGE-LENS THERAPY

| Visual Acuity | No. Cases |
|---|---|
| 20/20 | 9 |
| 20/40 | 12 |
| 20/60 | 2 |
| 20/80 | 1 |
| 20/100 | 9 |
| 20/200 | 5 |
| Less than 20/200 | 11 |

Visual acuity improves after the application of 5% hypertonic saline without preservative. An effective schedule for its application seems to be one or two drops on awakening and repeated applications at 10:00 A.M., 1:00 P.M., and 5:00 P.M. Hypertonic saline is most needed during the morning hours. In the afternoon, visual acuity clears somewhat even without the application of hypertonic saline.

Visual acuity may fluctuate. Therefore, the patient must make a hypertonic saline schedule that best fits his individual requirements. In bilateral bullous keratopathy cases under bandage-lens therapy, visual acuity fluctuates at different times in each eye, and these patients seldom complain of fluctuating visual acuity. In monocular cases, the variations are more noticable, but this is not a significant problem if the patient learns the proper use of hypertonic saline. It must be emphasized early in treatment that there is no limitation to the number of installations of hypertonic saline needed.

An unexplained decrease in visual acuity should be checked by over-refraction or refitting of the lens. In several cases, refraction and corneal curvature changed after several days or weeks of therapy. In all cases, refitting for the proper lens dimension and power has resulted in improvement of visual acuity. Post-cataract macular edema is seen in these patients. Fluorescein angiography has frequently indicated this explanation for vision which could not be improved.

*Relief of pain*—The combination of bandage-lens therapy and pupillary dilatation have resulted in rather uniform relief of the pain of bullous keratopathy. It must be emphasized, however, that in painful advanced cases there is always a concomitant ciliary spasm. The intelligent use of dilating drops is necessary.

In some chronic cases, it is not unusual for the application of hypertonic saline to be painful at first, and since this significantly disturbs successful lens wearing, it should be delayed until irritability has ceased and the patient is ready for refitting.

Elevation of intraocular pressure or glaucoma is often difficult to diagnose in cases of bullous keratopathy. We have found Goldmann and Schiøtz readings inaccurate and misleading in these cases; however, the MacKay-Marg electronic applanation tonometer provides clinically useful measurements and has proven a valuable tool in controlling pressures in these cases.[4]

*Wearing time*—Although 24-hour, continuous wearing time seems to be preferable in most cases of bullous keratopathy, every patient should be individually managed. The full-time wearing of the lenses generally affords the most comfort, and in the beginning we had many cases in which patients experienced pain from ruptured bullae at night when the lens was not in place. In addition, insertion and removal of the lens by unskilled hands seems to produce a significant amount of discomfort and sometimes trauma to the epithelium. Most patients wear the lens for at least a month at a time, and need not manipulate the lens themselves at all. Despite this, however, every patient must be able to remove the lens or have the lens removed in case conjunctivitis develops or the eye becomes red.

## DISCUSSION

Well-planned basic laboratory research is generally easy to interpret. In this type of clinical research, however, there is always the possibility that in spite of the most stren-

uous attempt to avoid it, some prejudice may affect results. The findings of this investigation are as objective as we could make them. As a control, several investigators with different backgrounds were asked to study the effect of Griffin lens therapy in bullous keratopathy.[5] They obtained generally similar results.

The fact that most patients who were fitted a year ago are still wearing the lenses with complete comfort and a sustained improvement in visual acuity indicates that this mode of therapy is clinically useful. Although the improvement of visual acuity is unpredictable in cases of advanced bullous keratopathy, there are few contraindications to trying this simple therapy. If it proves unsuccessful, lenses can be easily removed without risk of permanent damage or great expense to the patient; in our hands, this therapy has proved almost risk free.

The unique synergistic effect of the hypertonic saline and the Griffin lenses appears to stem from the absorption and gradual elution of drugs from these lenses.[6] Other hydrophilic contact lenses such as the Bausch and Lomb lens do not seem to have the same properties.[6] It is possible to treat bullous keratopathy with flush-fitting lenses, but in our experience, the use of such lenses requires complicated and laborious fitting techniques and results in less predictable visual improvement. More important, they represent a significant hazard in that if they rotate or become displaced in any way, serious corneal ulceration can result. Our experience suggests that bandage-lens therapy is much easier and safer than either the molded methacrylate lenses or the epikeratoprostheses. In our clinic we try the bandage lenses in virtually every patient with bullous keratopathy. In cases where the degree of visual acuity is not sufficient for the patient's needs, the lenses are removed and a penetrating keratoplasty performed.

## Summary

Bandage lenses were used to treat 49 patients with varying degrees of bullous keratopathy and proved successful in 41. These cases have been followed from two to 24 months. In eight cases, the lenses were discontinued because of failure to improve vision to a reasonable level in patients who had no significant discomfort. The remaining patients continue to wear their lenses in comfort with significantly improved vision. One corneal ulcer developed, but responded well to treatment and no loss of vision occurred.

Bandage-lens therapy shows considerable promise as a simple, effective method for the treatment of bullous keratopathy. The type of lens and the availability of a variety of powers, radii of curvature, and diameters, are important for optimal visual acuity, as is meticulous refitting after an initial period of adjustment.

# MICROCYSTIC DYSTROPHY OF THE CORNEAL EPITHELIUM

JESSE M. LEVITT, M.D.
*Brooklyn, New York*

In 1964, Cogan, Donaldson, Kuwabara, and Marshall[1] described a new entity, microcystic dystrophy of the corneal epithelium, characterized by groups of tiny, round or comma-shaped, greyish-white, superficial corneal opacities in the pupillary zones of both eyes. Histologic studies showed intraepithelial cysts containing keratinized debris and extensions of the basement membrane forming an anomalous membrane within the epithelial layer of the cornea. All of the five reported patients were healthy adult women, with negative family histories. The corneal opacities disappeared without leaving scars, and over the years other opacities appeared. Although a temporary reduction in visual acuity and mild irritation was occasionally noted, most patients were free of complaints.

In 1965, Guerry[2] reported seven cases which conformed to the clinical and histologic findings of Cogan and his associates. Of the seven, two were males. In addition to the typical corneal opacities, Guerry observed in every case a maplike dystrophy over the entire corneal surface as a constant clinical sign (Fig. 1). Guerry added that cataract extraction can be performed in these cases without disturbance to the cornea.

In 1966, Wolter and Fralich[3] reported still another case that confirmed the clinical and histologic observation of Cogan and his group and it was their belief that the origin of the cysts was from the basal epithelium.

The two cases which are now reported show both the characteristic corneal opacities of Cogan and associates, and the maplike opacification of Guerry.

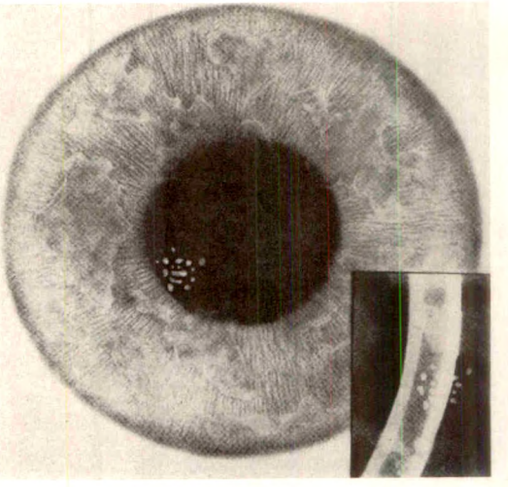

Fig. 1 (Levitt). Artist's composite drawing of two lesions on biomicroscopy: Cluster of superficial corneal opacities (cysts), easily seen, and diffuse maplike opacification visible only in oblique illumination (courtesy of D. Guerry III).

## CASE REPORTS

*Case* 1—A white woman, 51 years of age, was first seen in May, 1963, and has been re-examined at intervals to date. She complained of blurred vision of one or the other eye on at least three occasions. Each time, groups of discrete, irregularly-shaped greyish opacities were observed in the pupillary zone, suggesting a peculiar epithelial disturbance that could not be categorized. Each time the corrected visual acuity of the affected eye was reduced to 20/70 or 20/50, and within several months improved to normal, with disappearance of most of the opacities. At no time was the eye inflamed. The corneal sensation, tested with a cotton wisp, was normal. In September, 1965, I first noted a diffuse, lacy film in the epithelium of both eyes of this patient which seemed to become more pronounced with each succeeding examination. Dilatation of the pupil made it easier to discern the opacification. The appearance suggested an oil slick in water (Fig. 2).

In 1960, this patient's left kidney was excised because of a large, palpable tumor which proved to be a renal cell carcinoma. She has enjoyed good health since, and yearly physical examinations and chest x-ray studies are negative. Electrophoresis of blood serum and urine are negative. Family history is non-contributory. In December, 1969, the patient was examined by Dr. Frederick Theodore, who suggested microcystic dystrophy of the corneal epithelium as a possible diagnosis.

At the last examination, in May, 1970, corrected visual acuity was RE: 20/25 with —3.25 sph. ⌒ —0.75 cyl. ax. 135°, and LE: 20/30 with —3.50 sph. ⌒ —0.75 cyl. ax 180°. Only a few scattered white opacities were seen in the corneas, but the diffuse maplike film was very apparent in each eye. She also had incipient peripheral opacities

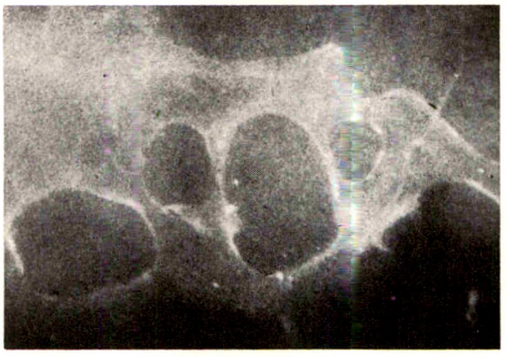

Fig. 2 (Levitt). Slit lamp view of diffuse, maplike changes in the epithelium, resembling an oil slick in water.

of both lenses. The fundi were essentially normal in appearance.

*Case 2*—A white woman, 67 years of age, was examined in December, 1969. She had no complaints. Corrected visual acuity was RE: 20/30 with −1.50 cyl. ax. 45°, and LE: 20/40 with −1.50 cyl. ax. 180°. Both eyes looked grossly normal. On biomicroscopy, clusters of discrete, spherical white opacities were visible in the lower pupillary zones (Fig. 3). These spots could not be seen with the naked eye, but were easily visible with an eight diopter magnification hand loupe. With oblique illumination the same "oil slick in water" opacification was observed in both eyes as in Case 1. In addition, yellowish-green branching lines (Hudson-Stahli) were observed in the corneas.

In 1958, a benign tumor of the colon was excised; the patient has been in good health since. At her last visit, in May, 1970, there were no marked changes in the eye findings.

## Discussion

These two cases present evidence that the maplike dystrophy described by Guerry is part of the syndrome first reported by Cogan and associates.

The evidence so far indicates that microcystic dystrophy of the corneal epithelium is a purely epithelial disturbance. The disease does not extend beyond the basement membrane. Removal of the epithelium is curative, since the newly formed epithelium remains normal.

The two salient findings of superficial white spots and diffuse opacification are quite distinctive and cannot be mistaken for anything else, once one is aware of this entity. For differential diagnosis the reader is referred to a tabulated list compiled by Falls[4] of numerous disease entities involving the corneal epithelium.

## Summary

Microcystic dystrophy of the corneal epithelium is characterized by groups of tiny round or comma-shaped, greyish-white superficial corneal opacities in the pupillary zone of each eye. These findings are described in two patients, one, a 50-year-old white woman, had a transient decrease in vision to 20/70. Vision improved to normal with disappearance of most of the opacities. The second patient, a 67-year-old white woman, had corrected vision of 20/30 and 20/40. Epithelial changes of the cornea were similar to those seen in the first patient and resembled an oil slick on water.

# CORNEAL THICKNESS DURING CORNEAL HOMOGRAFT REJECTION AND UVEITIS IN RABBITS

JOSEPH A. CAPELLA, M.S., AND STEPHEN R. WALTMAN, M.D.
*Gainesville, Florida*

Corneal thickness measurements are valuable in predicting the short-term outcome of penetrating keratoplasties.[1] Changes in thickness result from an interaction between the factors that affect corneal endothelial function. The present study was designed to determine the effects of graft rejection, uveitis and other factors on corneal thickness. The following categories of corneal involvement were studied: (1) normal cornea, (2) uveitis in unoperated eyes (normal), (3) "normal" autografts, (4) uveitis in autografts, (5) "normal" homografts, (6) homografts with skin grafts (second set), and (7) uveitis in homografts.

We wanted to determine if changes in thickness occurred before clinically detectable graft rejection or uveitis and what effect these events had on corneal thickness. The results indicate that pachometry is a useful quantitative tool when used to assess keratoplasty.

## MATERIAL AND METHODS

Adult (2 to 3 kg) albino rabbits of both sexes were used in all experiments. Under intravenous pentobarbital anesthesia, 7 mm penetrating corneal grafts were exchanged between animals (day 0) as previously described.[2] Running 7-0 black silk sutures were used, and operated eyes were treated daily with Neosporin ointment and 1% atropine drops until suture removal (day 10). To induce corneal homograft rejection, abdominal skin grafts were exchanged between the same animals on day 14. In a second group, 7 mm corneal autografts were rotated in situ and sutured with 7-0 black silk.

Uveitis was induced in normal and grafted eyes by an intravitreal injection of 2 ml of egg albumin in 0.1 of sterile saline solution. A 27-gauge needle was used to introduce the albumin into the vitreous.[3] Control animals received intravitreal saline alone.

Animals were examined and corneal thickness measurements made daily by independent observers who were unaware of which animals had homografts and which autografts. An arbitrary scale was established to evaluate changes. The following list of descriptive changes was graded on severity based on a scale of 0.1 to 1: limbal flush, iris rubiosis, cells in the anterior chamber (flare), corneal haze, corneal vascularization, and graft clouding.

The central corneal thickness measurements were made on various days (Table 1), using a modified Haag-Streit pachometer,[4] and at the termination of the experiment, clinical observations and thickness measurements were correlated.

## RESULTS

In the normal cornea, thickness ranged from 0.35 to 0.48 mm, with thin corneas occurring in very small animals. In most of the rabbits, thicknesses ranged between 0.40 and 0.45 mm. Day-to-day variations in thickness were 0.02 mm or less, with the two eyes of each animal never varying by more than 0.01 mm from each other. The correlation of thickness and clinical results are found in Table 1.

*Uveitis in unoperated eyes*—A mild uveitis was induced in one eye of 11 animals (day 0). The course of the uveitis was described previously.[3] The uveitis was apparent by the fifth day in all animals, but corneal thickening did not occur until the sev-

| Clear | .416 ± .020 | .523 ± .023 | 19* | Cells in anterior chamber,† graft clouding corneal vascularization | 4 |

* This time represent days after challenge.
† The degree of clinical signs was not as marked as in those that clouded.

enth day (Fig. 1). Corneas eventually thickened 20% and then returned to near normal thickness as the uveitis subsided (day 15). By the 25th day, corneal thickness was completely normal in all animals and no change in thickness was noted in the fellow eyes (Fig. 1). The clinical signs of uveitis (represented by the shaded area of Fig. 1) appeared earlier than the observable thickening and peaked at the fifth day. There was no change in thickness in animals receiving intravitreal saline.

*Autografts*—Nine animals had successful corneal autografts (Fig. 2). Following surgery, corneal thickness gradually increased until suture removal on day 10. Five animals had peak values on this day and a drop in thickness of 0.16 mm or less after suture removal. By day 20 the average thickness was 0.47 mm and dropped to 0.40 mm one week later. It is obvious that this postoperative changes in thickness in both these autographs and the later homografts are due largely to the wound trauma and possible manipulation of the endothelium. All normal auto- and homografts returned to average normal thickness by day 30.

*Uveitis in autografts*—On day 45, uveitis was induced using intravitreal albumin in four autografted eyes. All developed a mild uveitis with 25% increase in graft thickness (Fig. 3). Thickness increases were maintained longer than in nongrafted eyes and measurements did not return to normal until day 75. Clinical signs occurred earlier than in normal eyes (shaded area in Fig. 3).

*Normal homografts*—Successful corneal homografts were performed in 20 rabbits, and six of these who did not receive skin grafts did not reject their corneal grafts (Fig. 4). The pattern of change in thickness in the animals without skin grafts was the same as in autografted animals, and by day 20 all had normal thickness.

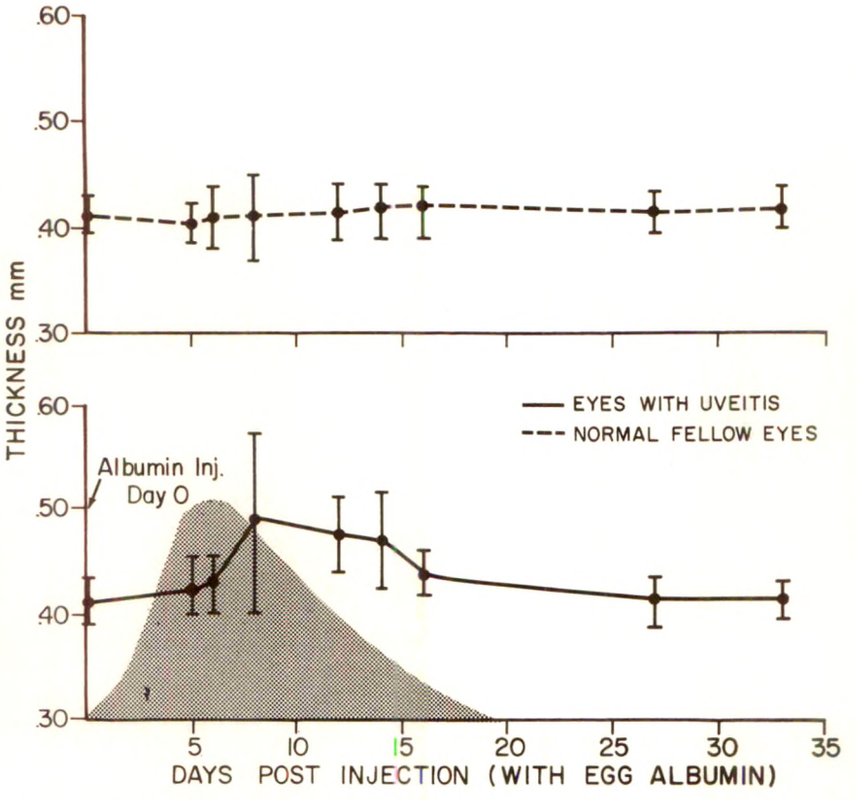

Fig. 1 (Capella and Waltman). Changes in corneal thickness with albumin induced uveitis. Experimental eyes are shown below by solid line, control fellow eyes are shown above with interrupted line. The shaded area in the lower graph represents the appearance of clinical symptoms as described.

*Homografts with skin grafts*—Fourteen animals received skin grafts from their corneal donor animals on day 14. On day 20, all had clear corneal grafts, and while the mean corneal thickness of the grafted eyes was slightly greater than the other groups, it was only 10% higher (0.49 vs 0.45 mm) than their untreated control eye (Fig. 5). This thickness difference between groups was due in part to the use of larger animals. Homograft rejections began 12 days after skin grafting (day 26). A limbal flush with dilatation of iris vessels and engorgement of corneal vessels leading to the graft occurred.[2] A fine line of keratic precipitates appeared on the peripheral graft endothelium and then progressed centrally. No changes in corneal thickness occurred until two days following clinical signs of rejection (approximately day 28) (shaded area of Fig. 5) Definite evidence of rejection was always present at least 24 hours prior to thickness changes.

*Uveitis in homografts*—Approximately 25 days after keratoplasty, six animals received intravitreal albumin injections (Fig. 6). Within one week, a 25% increase in thickness was noted in all animals. Three animals maintained this increased thickness for four weeks, and then their corneas gradually thinned to near normal levels at two months. The other three had a continued rapid increase in thickness to 0.90 mm during the fifth week and their grafts became clouded.

When clinical rejection was first observed, both eyes of six additional homografted animals were treated for 10 days with 0.1% dexamethasone drops twice daily. In grafted eyes, the rejection phenomenon regressed

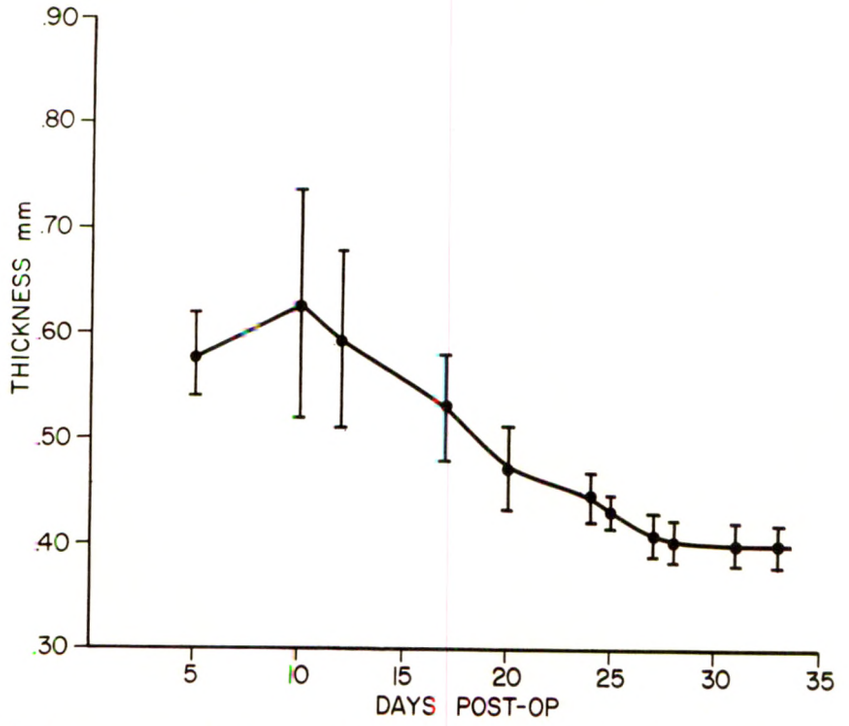

Fig. 2 (Capella and Waltman). Postoperative corneal thickness of full-thickness corneal autograft. The 95% confidence intervals are shown.

and there was no change in corneal thickness. When the corticosteroids were discontinued, corneal thicknesses increased and rejection occurred. In the six nongrafted eyes, no change in corneal thickness was noted during or after corticosteroid therapy.

## Discussion

Corneal thickness is a useful clinical parameter for predicting the prognosis of donor tissue following penetrating keratoplasty.[1] In clinical studies, however, the considerable variation in both donor material

and postoperative course make it difficult to evaluate the influence of other factors on endothelial function and thickness. In this regard, several interesting observations have arisen from our studies.

The pattern of corneal detumescence and resumption of normal thickness in rabbits after keratoplasty was similar in corneal autografts and nonrejecting homografts. Maximal thickness was reached just before or just after suture removal. Thin grafts became temporarily thicker and thick grafts thinned following suture removal, suggesting that mechanical factors affecting endothelial alignment are important. In thick grafts, less than optimal suture placement may prevent defects between donor and host endothelium from closing until after suture removal. In thin grafts, the trauma of suture removal may cause a temporary disturbance of endothelial function. Within 10 days after suture removal, however, all grafts returned to normal thickness.

The increase in thickness during the first 10 postoperative days is undoubtedly due in part to surgical trauma and postoperative uveitis. In otherwise normal eyes, induced mild uveitis caused a 20% increase in corneal thickness. In all cases, the uveitis was clinically detectable at least 24 to 48 hours prior to changes in thickness, although no quantitative value could be put on the degree of corneal involvement. Previous studies revealed that endothelial damage occurred in uveitis and led to increased thickness.[5] Logically, the anterior chamber flare was evident before changes in thickness. These eyes regained normal thickness in about two and one-half weeks. Uveitis in well-healed autografts created a 25% increase in thickness with a prolonged recovery period of one month. The only obvious reason for this prolongation is the trauma induced by the surgery. Homografts also thickened by 25% following uveitis and recovery was delayed for two months in those grafts that did not cloud. This is most likely due to the increased loss of endothelium brought about by the uveitis. Fifty percent of the homografts with uveitis clouded and doubled in thickness and by day 10 it was possible to predict which homografts would eventually recover. It is safe to assume that the clouded homografts lost the entire endothelial sheet due to some immunologic process resulting in their immediate clouding. The remaining 50% that cleared

possibly had some immunologic tolerance and therefore were able to recover.

In second-set rejecting homografts, thickness reached a minimum at day 21 and stayed there for an additional week. There were no definite signs of rejection by thickness changes prior to obvious clinical signs. Rejection could be reversed and thickness changes prevented if corticosteroids were given prior to an increase in thickness. However, once there was sufficient endothelial damage to cause central corneal swelling, topical corticosteroids could not reverse the rejection process. In our animals, corneal thickness usually doubled and the entire endothelium and graft were rejected within 48 hours. In more smoldering rejections, where endothelial damage and thickness changes are more gradual, the use of immunosuppressive agents may allow for recovery. Finally, it is noteworthy that the untouched normal fellow eyes of all our animals were not affected by graft rejection, uveitis, or therapy in the experimental eye.

The alterations in thickness in these various categories studied are unquestionably linked to those clinical parameters described previously. However, the use of thickness measurements as an index of the degree of corneal involvement can and has proven to be a significant factor in post-keratoplasty follow-up.

## Summary

Corneal thickness was measured following penetrating corneal autografts and homografts and induced uveitis in rabbits. Normal grafted tissue regained normal thickness approximately three weeks after surgery. Thickness increased rapidly during homograft rejection, but not until rejection was clinically apparent. Topical corticosteroids could reverse the rejection process if instituted prior to thickness changes.

Albumin induced uveitis caused a 20 to 25% increase in thickness in both normal and grafted eyes. Uveitis was easily detected prior to changes in corneal thickness. After uveitis induction, nongrafted corneas regained normal thickness in two and one-half weeks, while autografts required a month and homografts two months. Fifty percent of the homografts became opaque after induced uveitis and by pachometry were apparent by the 10th day after uveitis induction.

# INTEGRITY AND POSITION OF THE ANTERIOR HYALOID MEMBRANE FOLLOWING CATARACT EXTRACTION

GEORGE P. LANDEGGER, M.D.
*Los Angeles, California*
AND
NILES ROTH, PH.D.
*Forest Grove, Oregon*

Observations of the hyaloid membrane, made over a period of years following surgical extraction of the crystalline lens, reveal that in some eyes the integrity and location of this membrane seem totally unaffected. In a significant number of eyes, however, the membrane may show changes that probably result from the surgical procedure itself, from absence of the lens as a supporting structure, or from other as yet undefined causes.

This study reports the frequency of various observed changes in the hyaloid membrane after intracapsular cataract extraction. A few observations were made on eyes in which cataracts had been removed by the extracapsular method.

## MATERIALS AND METHODS

Data were obtained on 75 eyes in 56 patients examined over a period of about five years. All eyes were operated on by the same surgeon (G.P.L.). The surgical procedure for 69 of the eyes was intracapsular cataract extraction with some variation in the types of iridectomy performed. The remaining six cataracts were extracted extracapsularly.

Observations were begun approximately one month following the operation; during the first year, subsequent observations were spaced three months apart. Thereafter, an attempt was made to space the observations at four-month intervals.

At each examination, the hyaloid membrane was inspected with a slit lamp for discontinuities or breaks in its structure. Moreover, data obtained with a Zeiss anterior chamber depth micrometer was used to calculate relative protrusion of the membrane into the anterior chamber. Relative protrusion, or prolapse, is defined as the amount (in percent of anterior chamber depth) the axial part of the hyaloid membrane moves toward the cornea. Prolapse (%P) is calculated as follows: $\%P = ACD-VL/ACD \times 100$, where ACD is anterior chamber depth, and VL is vitreous location, i.e., distance from the axial part of the hyaloid membrane to the posterior corneal surface. For example, a vitreous location of 3 mm in an anterior chamber 4 mm deep yields a vitreous prolapse of 25%.

In most of the observed eyes, it was evident that the anterior hyaloid membrane was not rigidly fixed in position, so a membrane appearing to have a certain location relative to the iris plane at one moment might show a measurable change of position on subsequent measurement. Before analyzing the data, therefore, it had to be decided how large a vitreous protrusion would be considered significant. Examination of data from successive observations led to the decision that an apparent vitreous prolapse of less than 10% is not significant. Thus, in a given case, variation of the extent of vitreous prolapse would be significant only if it exceeded 10% (±) when compared with mean values obtained earlier. We recognize that, in a given instance, factors other than chance movement of the vitreous contribute to the variability of the prolapse extent. Two of these factors are uncontrolled changes of position of the observed eye and inherent errors in the measuring procedure. The accu-

racy of the measuring procedure, which utilizes the Zeiss anterior chamber depth micrometer, has been discussed elsewhere.[1]

## Results

The findings revealed several distinct groups: In Group 1, the 53 eyes of this group all had intact anterior hyaloid membranes during the five year study. Among these eyes, however, there were the following subgroups: (A) Fairly constant vitreous prolapse existed for 24 eyes, 13 of which had an average prolapse of 37%, ± 10, while 11 had essentially zero prolapse throughout the five years. (B) Vitreous prolapse decreased with postoperative time in 29 eyes. Prolapse decreased gradually for 22 of these eyes from an initial value of 53%, ±22, to a final mean value of 22%, ±14, at an average rate of 5.8%, ±4.7, per year. In the remaining seven eyes of this subgroup, prolapse decreased less linearly than in the other 22, and approached zero after four or five years following an initial value of 29%, ±14.

In Group 2, the anterior hyaloid membrane in these 16 eyes was either lacking entirely at first examination (12 eyes), or lost its integrity within two and one-half to three years, exhibiting one or more holes or disappearing entirely (four eyes). In Group 3, because extracapsular extraction was employed on the six eyes of this group, it is in a different class from the preceding ones. Measurements on these eyes pertained to location of the lens capsule remnant and not to hyaloid membrane location. As would be expected, the anterior surface of the lens capsule showed no significant protrusion into the anterior chamber over the five years. In fact, the average long-term location of the anterior capsule surface tended to be slightly behind the iris plane (negative prolapse) with extreme values of + 11% and − 25% at specific times during the five years.

## Discussion

In Group 1-B, the significant prolapse reduction observed over a period of years is supported by the findings of Goswami and associates[2] who believe the vitreous body shrinks in the course of time. This view, however, is open to question because the observed prolapse decrease could be explained just as easily by a movement of the entire vitreous body toward the retina after a prior detachment from the posterior fundus. In line with this reasoning, the unchanging but significant vitreous hernia found in 13 eyes of Group 1-A could be explained by the occurrence of a detached vitreous after the operation and by failure of the vitreous to move backward. Obviously, this matter can be settled only by future observations of the posterior vitreous soon after the operation and for a period of years thereafter.

Results of the present study point to the following possibilities after intracapsular cataract extraction: (1) the hyaloid membrane may protrude more than a third of the way into the anterior chamber and remain there for several years with no rupture of the membrane. (2) The membrane may protrude at least halfway into the chamber, then gradually recede to about one quarter of the distance from iris to cornea, remaining intact for an indefinite time. (3). The membrane may prolapse significantly to about a third of the anterior chamber depth, then recede to the iris plane in four or five years and remain intact indefinitely. (4) Herniation may be small immediately postoperatively, become negligible in a few months, and show no change thereafter. (5) Finally, at the time of or soon after the operation, the membrane may disappear—an occurrence more likely to be associated with rupture of the hyaloid membrane, either at the time of operation or within the following month. (6) In a few instances, the membrane may remain intact for as long as three years after the operation, followed by a late rupture or a disappearance of the membrane.

With regard to the special category (Group 3) in which extracapsular extraction was performed, results suggest—even though the sample size was small—that the

lens capsule remnant retains its firmness over a period of years following the operation. If significant loss of capsule rigidity had occurred, it would have shown up as a gradual protrusion of the capsule surface into the anterior chamber during this five-year study.

## Summary

A five-year study of 69 aphakic eyes, operated on intracapsularly, showed 53 eyes with intact anterior hyaloid membranes throughout the entire period of study. In 16 others the membrane ruptured or disappeared during the five years. Six additional eyes, operated on extracapsularly, showed no change in location of the lens capsule remnant.

Among the 53 eyes with intact membranes, 24 showed fairly constant vitreous prolapse over the test period. Thirteen of these had an average prolapse of 37%, ±10, and 11 had nearly zero prolapse. In the 29 eyes with changing prolapse, 22 were characterized by gradual reduction from 53%, ±22, to 22%, ±14, at an average rate of 5.8%, ±4.7, per year. The remaining seven eyes of this group had almost zero prolapse at the end of four or five years after a postoperative value of 29%, ±14.

## Ophthalmic miniature

"I am half distracted, Captain Shandy," said Mrs. Wadman, holding up her cambric handkerchief to her left eye, as she approached the door of my Uncle Toby's sentry box, "a mote—or sand—or something—I know not what, has got into this eye of mine. Do look into it—it is not in the white—"

In saying which, Mrs. Wadman edged herself close in beside my Uncle Toby, and squeezing herself down upon the corner of his bench, she gave him an opportunity of doing it without rising up. "Do look into it" said she.

"I protest, Madam," said my Uncle Toby, "I can see nothing whatever in your eye."

"It is not in the white," said Mrs. Wadman. My Uncle Toby looked with might and main into the pupil.

# LASER IRIDECTOMIES

HUGH BECKMAN, M.D., ROBIN BARRACO, B.S., H. SAUL SUGAR, M.D.,
ERNEST GAYNES, O.D., AND ROBERT BLAU, M.D.
*Detroit, Michigan*

In 1956, Meyer-Schwickerath[1] described the use of a xenon arc photocoagulator to produce iridectomies. He reported a high incidence of corneal and lenticular opacities and recommended that this procedure be performed only in aphakic eyes. In 1958, McDonald and Light[2] used copper-covered carbon arcs as a source of high intensity light for the same purpose, but they, too, found that they had produced corneal and lenticular opacities. Similar undesirable burns were described by Hogan and Schwartz[3] in 1960, and by Burns[4] in 1965.

The probable cause of lenticular and corneal burns during photocoagulation of the iris is the heat conducted from the surface of the photocoagulated iris. The longer the time required to perform the iridectomy, the greater the burn to the adjacent tissues. Iridectomy with a xenon are photocoagulator requires an exposure of several seconds. It was hoped that with a laser, which produces large amounts of energy in a shorter time, iridectomies could be produced without damage to lens or cornea.

In 1964, Flock and Zweng[5] reported their inability to create iridectomies using a 0.1 joule ruby laser. In 1967, Snyder,[6] using a 0.3 joule ruby laser on the iris of Dutch Chinchilla rabbits, could not produce a penetrating hole with a single burst. He did succeed in penetrating the iris with multiple bursts of laser energy on the same target and described late hole formation in the iris at the site of a single burst as a result of iris atrophy. He observed that retinal burns occurred in a large number of eyes on which multiple laser bursts were used to produce an iridectomy. No lenticular or corneal opacities were noted. Campbell and co-workers[7] used a focused neodymium laser beam of up to 8 joules and reported the creation of severe burns of the iris without hole formation, but with corneal and lenticular opacities. Zweng and his associates[8] recently reported the successful creation of iridectomies in brown eyed rabbits using a single burst of ruby laser energy. The results with approximately equal amounts of energy were for some reason, not consistent. Iridectomies were also created in monkey irises using long-pulsed and Q-switched ruby energy. These iridectomies closed off and either opened by atrophy or were reopened by additional bursts of energy. Holes were created in brown irises using repeated applications of argon laser energy. Iridectomies could not be created in blue or light brown irises.

To study the factors producing iridectomy in rabbit iris using a single burst of laser energy, a laser with interchangeable ruby and neodymium rods was used.

## MATERIALS AND METHODS

*Laser equipment*—A biomedical laser system consisting of a solid-state laser head with interchangeable ruby and neodymium rods is used. The laser head is joined to a modified Zeiss operating microscope (Fig. 1). Binocular viewing through the microscope is along the line of the laser beam (Fig. 2). At the time the laser is fired, a shutter swings across the viewing system, completes the firing circuit, and triggers the laser (Fig. 2). The shutter protects the operator's eyes from possible reflections of the laser beam.

*Application*—The amount of energy di-

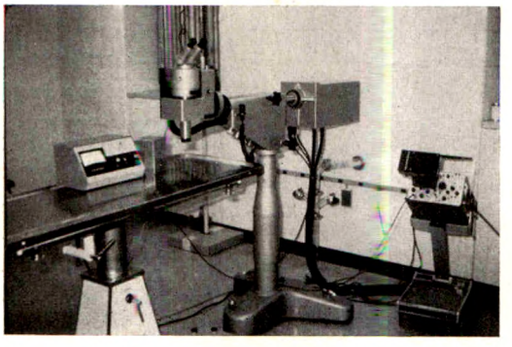

Fig. 1 (Beckman and associates). Laser combined with a Zeiss operation microscope.

rected at the iris is controlled by varying three factors: (1) the laser energy is increased directly and linearly with the amount of voltage used to excite the xenon flash lamps; (2) the amount of energy is increased directly and linearly by increasing the number of capacitor and inductor banks used (i.e., with three banks the pulse lasted 3.0 msec, and with six banks, 6.0 msec); (3) the laser beam was passed through one of eight apertures, decreasing in width from ½ to 1/16 inch in 1/16-inch steps. The energy directed at the iris decreased directly and linearly as the width of the aperture chosen diminished in size. Varying combinations of voltage, capacitor banks and apertures were used in iridectomy attempts.

Over 300 iridectomy attempts were performed, both on enucleated rabbit eyes, and on the eyes of living albino and brown-eyed rabbits. When live animals were used, they were anesthetized with an intravenous injection of sodium nembutal.

High-speed color cinematography, using a Hycam camera (400-10,000 frames per second) and 16 mm Kodak Ektachrome EF film, was employed to record iridectomy formation.

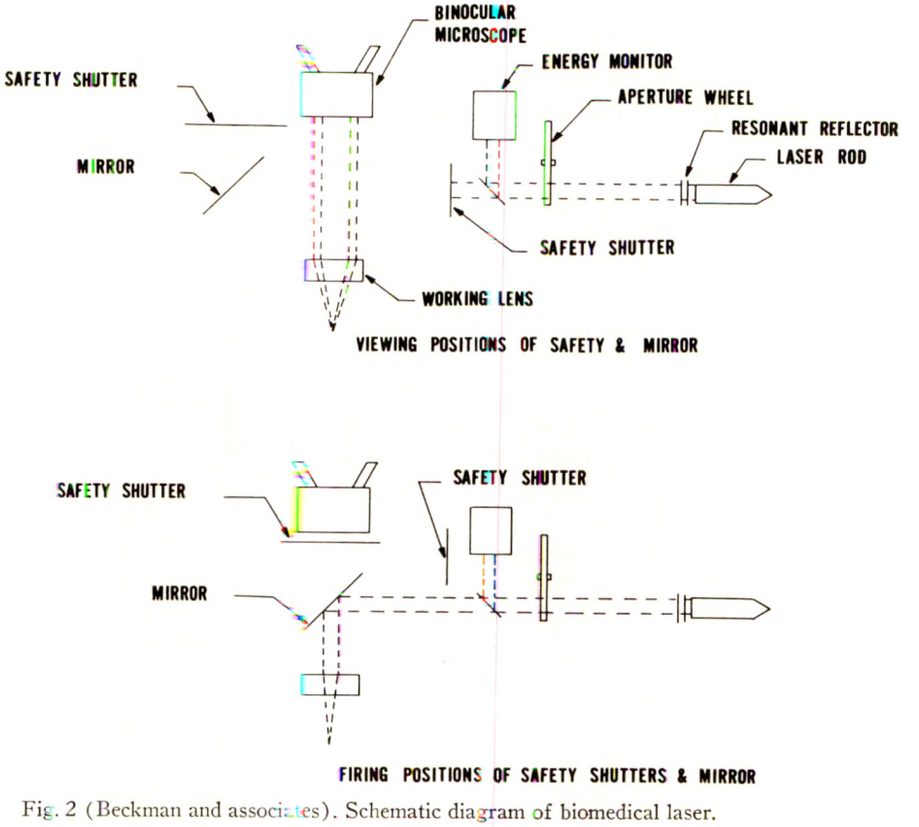

Fig. 2 (Beckman and associates). Schematic diagram of biomedical laser.

## Results

### Energy factors

When the number of capacitor and inductor banks used remain constant, any combination of aperture size and voltage sufficient to allow iridectomy threshold energy to become incident on the iris will result in a penetrating iridectomy. On brown irises this was found to be 3.2 joules for ruby, and 3.8 joules for neodymium laser energy. On albino irises it was found to be 12 joules for ruby energy. No iridectomies could be created in albino irises using neodymium energy.

When the number of capacitor and inductor banks was varied while maintaining constant energy levels on the iris, 6.0 msec bursts were found to be much more efficient in creating iridectomies than bursts of shorter duration.

### The distribution of laser energy and its absorption by iris pigment

The lesions produced on a brown iris could be divided morphologically into three zones (Fig. 3). When super-threshold iridectomy energy levels are used, the central zone is a hole through the iris. We refer to this as the vaporized zone. It measures approximately 0.4 mm in diameter regardless of the aperture used. The hole is surrounded by a light grey crater wall ring 0.3 mm wide —the subvaporization zone. The width of the subvaporization zone does not vary with the size of the aperture used. Surrounding the two central zones is a large variable ring of hyperpigmented burned iris tissue—the charred zone. It varies in size directly with the width of the aperture through which the laser beam passes. Typically, the hyperpigmented ring is 1.1 mm wide using a 3/16th inch aperture, and 1.4 mm wide using a 1/4 inch aperture.

All iridectomies produced with ruby energy in brown irises are temporarily closed by stromal fragments and pigment-laden macrophages, two weeks postoperatively.

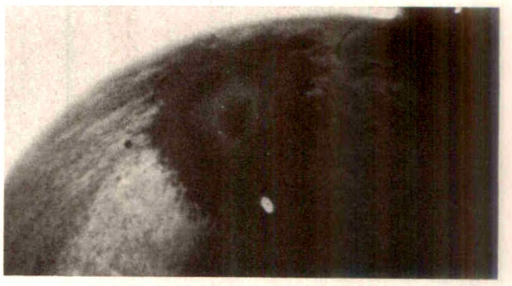

Fig. 3 (Beckman and associates). A ruby laser iridectomy in a brown iris demonstrating the central vaporized hole, the surrounding grey subvaporized crater area and the large hyperpigmented burned zone.

However, a week later, an iridectomy results after atrophy.

When the neodymium laser is used on a brown iris, a 0.3 mm vaporized area is formed (Fig. 4). No visible subvaporization zone is seen and the hyperpigmented burned areas are one-half the size of those created with ruby energy and the same aperture. The majority of these iridectomies remain open.

When albino irises are irradiated with ruby energy, no subvaporization or charred area is seen—only a hole (Fig. 5). All of these iridectomies remain open.

When albino irises are irradiated with neodymium energy, no hole is produced. A subvaporization area is seen since the iris is incompletely penetrated, and no charred area is found.

In attempts to enhance absorption of both ruby and neodymium energy, solutions of 5% fluorescein or Cardiogreen were given intravenously to albino rabbits. Cardiogreen absorbs much more neodymium and ruby energy than does fluorescein. Larger holes were produced in albino rabbits (Fig. 5) with the ruby laser when fluorescein was used. No subvaporization or hyperpigmented zones were seen. When albino rabbits were injected with Cardiogreen and ruby energy was focused on the iris, larger holes were created than without the colorifacient, and subvaporization and hyperpigmented charred zones appeared. When fluorescein was injected and neodymium energy was directed

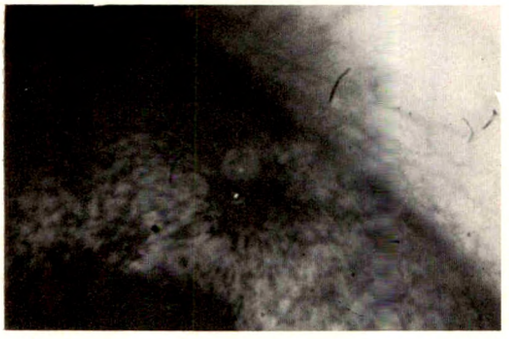

Fig. 4 (Beckman and associates). A neodymium laser iridectomy in a brown iris. Note the full-thickness penetration burn of the cornea and the small area of hyperpigmented burned iris.

into albino irises, no holes could be created but small burns of the iris appeared. When Cardiogreen was injected into albino rabbits, no holes could be created with neodymium energy but very large hyperpigmented burns were found.

Irradiating with either ruby or neodymium energy resulted in massive hyperpigmented burned areas when either fluorescein or Cardiogreen were given to brown-eyed rabbits.

### Transmission of laser energy to the iris through the transparent ocular media

Neodymium energy is absorbed to the extent of 7% by the cornea[7] while almost no ruby energy is absorbed. When vaporization energies are used at the neodymium wavelength, full-thickness burns of the cornea are created (Fig. 5). No such burns occur with ruby energy, but when excessive charring of the iris occurs, endothelial burns result from heating of the aqueous. Laser energy absorption by the cornea does not seem to have a significant effect on the formation of iridectomies.

No lenticular opacities were noted following either ruby or neodymium-created iridectomies.

While keeping energy levels constant, some threshold laser pulses resulted in iridectomies, while others resulted only in burns of the iris. If the target site on the iris was parallel to the axis of the laser rod, the incidence of hole formation was increased, while the incidence of hole formation decreased when the iris target site was perpendicular to the laser rod (Fig. 6). This phenomenon occurred when ruby energy was used, but not with neodymium energy.

*Cooling effect of aqueous*—When the depth of the anterior chamber was decreased by withdrawal of aqueous humor from the eye, iridectomies could be performed in live brown-eyed rabbits using 0.3 joules of ruby or neodymium energy. As the depth of the anterior chamber was increased, increasing amounts of energy were required to create the iridectomies.

In a deep-chambered human eye with a blue iris, about to be enucleated for malignant melanoma, no iridectomy could be created using maximum ruby energy levels. In another blue-eyed patient, with a very shallow anterior chamber due to iris bombe, an iridectomy was created using 7 joules of ruby energy.

High-speed cinematography during the performance of laser iridectomies showed that after the initial vaporization took place, incandescence occurred at the edge of the hole and was much more marked in eyes without aqueous. When aqueous was present, the incandescence was smothered and the hole did not enlarge in size. We feel that aqueous causes a suppressive effect on iris

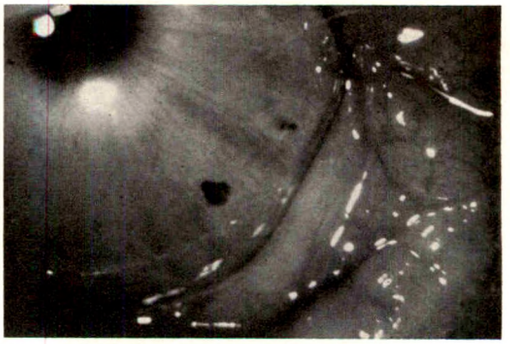

Fig. 5 (Beckman and associates). Ruby laser iridectomies in an albino iris. The laser iridectomy was created using intravenous fluorescein as a colorifacient.

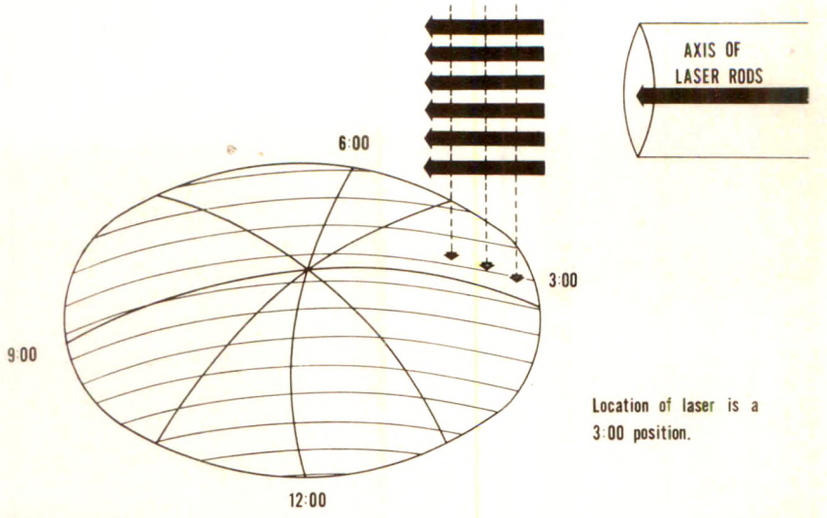

Fig. 6 (Beckman and associates). This shows the relationship between the polarity of the laser rod and the cytomolecular architecture of the cornea.

burns and that the thicker the aqueous layer, the more difficult it is for burning to take place, requiring more energy to create a hole.

*Cooling effect of iris circulation*—A penetrating iridectomy in enucleated brown rabbit eyes required a third less energy than in living eyes. High-speed cinematography showed a shorter period of incandescence at the edge of the hole in living eyes than in the enucleated eyes. This suppression of the incandescence is due to the conduction of heat from the target site by the iris circulation and results in an increased energy requirement for production of iridectomies in live animals.

*Thickness of iris*—If the pupil is dilated, the iris folds upon itself. This presents thicker tissue to penetrate and exposes more surface to the beam. Generally, more energy was found to be necessary to create iridectomies when the pupil was not constricted. With dilated pupils, larger areas of hyperpigmented burns occurred. During our early experiments, miotics were used to control the size of the pupil. Since we felt that this probably contributed to postiridectomy iritis, we later caused miosis by directing a bright beam of light into the eye.

*Length and pigmentation of the eye*—The focal length of the rabbit eye is approximately 8 mm. Since the depth of focus of our laser is 7 mm, it is quite understandable that in over 50% of the eyes in which penetrating ruby laser iridectomies were performed, retinal lesions were found. In all instances, these were white areas approximately 1 disk diameter in size. No retinal hemorrhages were seen. No retinal lesions were found with penetrating neodymium iridectomies, since less neodymium energy is absorbed by the pigment epithelium of the retina and choroid, and more energy absorbed by the lens and vitreous.

## Discussion

We must spectulate as to why 2 and 3 msec pulses were less efficient than longer pulses in forming iridectomies. A laser pulse, although of short duration, is made up of a myriad of much shorter pulses (Fig. 7). We postulate that possibly a "jackhammer" effect is necessary to create the penetration (i.e., the pulse must be of sufficient duration that the energy is available to penetrate the deeper layers of iris tissue after the more superficial layers are vaporized).

The amount of iris charring appears to be directly related to the closing off of the iri-

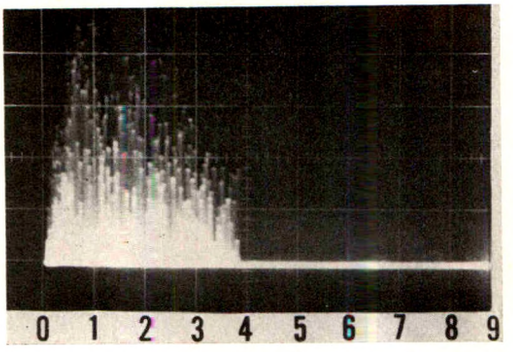

Fig. 7 (Beckman and associates). Oscilloscope recording of laser pulse (scale in msec).

dectomies. We believe this charring is related to the distribution of laser energy onto the target site and the absorption of these energies by the pigment of the iris. To eliminate charring of the iris, all the laser energy should ideally be confined to the vaporization zone. This can be achieved only by *avoiding secondary reflections* of laser energy. We have been able to create iris lesions with smaller hyperpigmented charred zones by locating additional apertures within the laser system at varying points (Fig. 8). We have studied four other possible reasons for aberrant energy falling on the iris outside the vaporization zone with resultant charring:

1. *Focus of the laser beam*—The laser is designed so that the focus of the beam is parfocal with the viewing optics. The depth of focus of the laser beam is 7 mm. Using the 16-power objective of the Zeiss microscope, the depth of focus of the viewing system is more critical than that of the laser beam. For practical purposes, whenever the target site is in focus, the laser beam is also in focus and the minor variations in focusing *would not* account for variations in the size of the lesion produced on the iris or changes in the morphology of these lesions.

2. *Spherical aberration by the delivery lens system*—The lens analysis is shown in Figure 9. The vertical scale represents half apertures. It should be noted that at a $\frac{7}{16}$-inch aperture and smaller, the lens system is diffraction-limited. The magnitude of spherical aberration at a $\frac{7}{16}$-inch aperature is only 0.0076

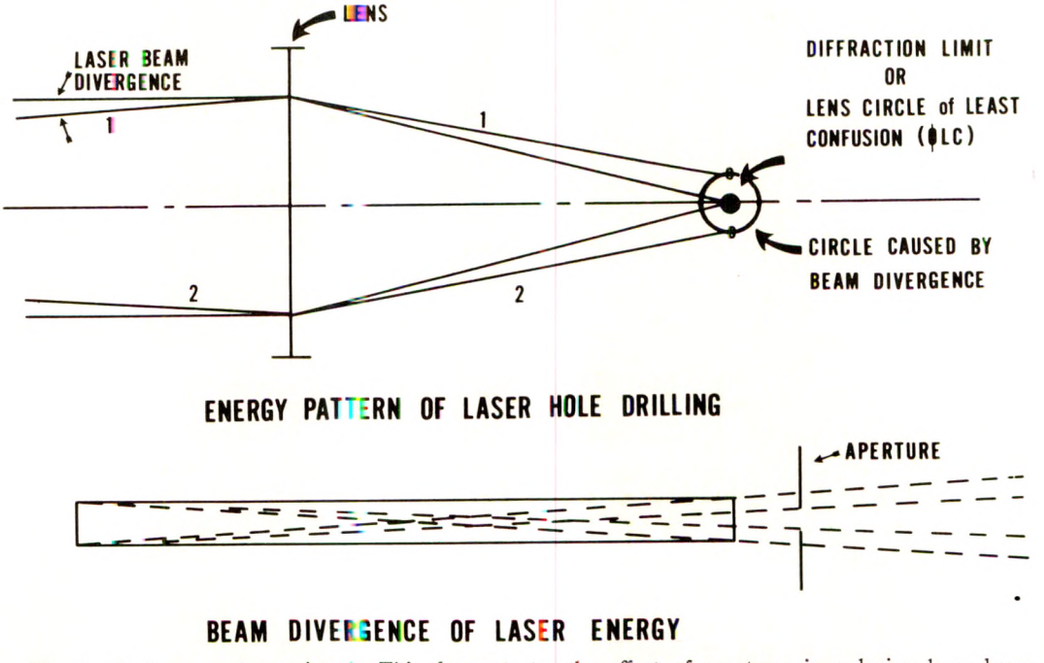

Fig. 8 (Beckman and associates). This demonstrates the effect of apertures in reducing laser beam divergence. It also demonstrates that the circle of laser energy created by laser beam divergence is larger than the circle of least confusion caused by the spherical aberration of the delivery lens.

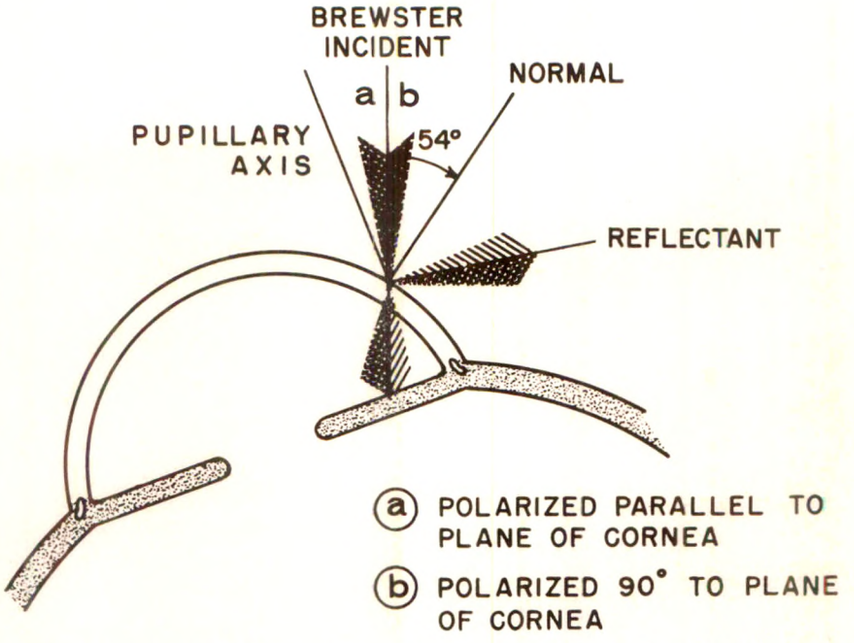

Fig. 11 (Beckman and associates). The rays polarized parallel to the plane of the cornea are better transmitted through the cornea onto the iris at Brewster angle (this angle calculated to be 54° for anterior surface of cornea). The rays polarized 90° to the plane of the cornea are less transmitted and more reflected by the surface of the cornea. (Ruby laser.)

Experimental evidence supports this theory, as shown by Figure 12. Identical energy was used for all four iridectomy attempts in this experiment. The two holes on the left were near Brewster's angle, and the two burns on the right were not. When threshold laser energy is focused on the iris near Brewster's angle, iridectomies are created with ease. On the other hand, when the laser energy incident on the cornea deviates from Brewster's angle significantly, no iridectomies can be created. A shift in the aiming angle towards an angle perpendicular to the iris plane allows less transmission than does an equal deviation towards a horizontal angle (Fig. 10).

The cytomolecular architecture of the cornea seems to result in a polarizing effect in which two axes are represented as geometric opposites in relation to the plane-polarized ruby laser beam. Along one axis, the corneal hemisphere will act with maximum geometric relation to the laser vector allowing Brewster's angle to have maximum effect; while along the other axis, conditions are minimal for Brewster angle effect. Our ruby laser is polarized in such a plane that the corneal hemisphere running from 3:00 to 9:00 o'clock (parallel to the laser rod) allows the Brewster angle to have its maximal effect. Along the 12:00 to 6:00 o'clock axis of the cornea (perpendicular to the laser rod) this effect is minimized (Fig. 6).

## Summary

A laser with interchangeable ruby and neodymium rods was fired through a modified Zeiss operating microscope to study the creation of iridectomies in brown-eyed and albino rabbits.

A pulse duration of 6.0 msec was more efficient in causing the formation of penetrating iridectomies than were shorter pulses. Any combination of voltage input and beam aperture sufficient to give threshold energies of 3.2 joules for ruby laser, and 3.8 joules

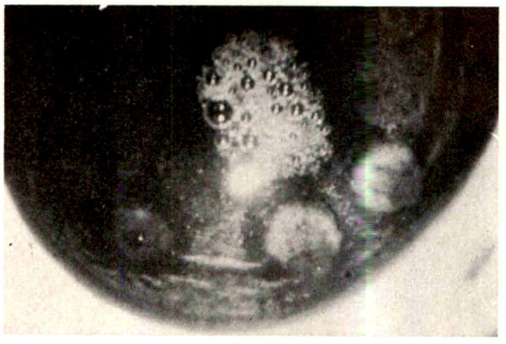

Fig. 12 (Beckman and associates). This demonstrates four attempts at iridectomy formation using identical energy levels. The two penetrating iridectomies on the left were made at Brewster angle while the two incomplete iridectomies on the right were created under identical conditions, except that the laser beam was aimed perpendicularly to the plane of the iris.

for neodymium on brown irises was sufficient for penetrating iridectomy. Ruby energy of 12 joules was required to create penetrating iridectomies in albino irises. No iridectomies could be produced in albino irises using neodymium energy. The iridectomies created in brown irises contain three zones: the vaporized zone, the light grey subvaporized crater, and the hyperpigmented charred zone.

The degree of charring appears to be directly related to the incidence of iridectomy closure. The charring can be decreased by eliminating secondary reflections of laser energy within the delivery system.

Ruby energy is more readily absorbed by iris pigment than is neodymium. Ruby energy would appear to be more optimal for less pigmented eyes since it is better absorbed while neodymium is more satisfactory for brown eyes because charring from aberrant rays of energy is reduced.

Colorifacients enhance absorption of these laser energies.

Ruby wavelength is less absorbed by the ocular media than neodymium energy. Corneal entry burns occurred when neodymium energy was used at iridectomy threshold levels, but not with ruby energy.

No lenticular opacities were noted with either laser source.

Polarized ruby energy is best transmitted through the cornea when its incident angle to the cornea approximates 54 degrees (Brewster's angle) to the normal. No such optimal angle is found for neodymium, since the non-crystalline neodymium rod does not emit plane polarized radiation.

The greater the depth of aqueous overlying the iris, the greater the laser energy required to produce a penetrating iridectomy.

### Acknowledgments

We thank Mr. Douglas Linn and Mr. David Matthews of Laser Systems Corporation, Ann Arbor, Michigan, and William Ginsberg, Ph.D., of the University of Michigan, for their help in this investigation.

room, a large space divided by portable partitions to accommodate postoperative patients (Fig. 2).[2] Adult postoperative patients remain on the surgical stretcher, protected by side rails, while infants and children are transferred to cribs in the recovery room. All positions adjoin sources of oxygen and suction; monitoring and emergency equipment are available; and a station for specially-trained recovery room personnel is provided.

Observation galleries in the outer support zone overlook two especially equipped ophthalmic operating rooms (Fig. 3). Admission is regulated at the control desk, but observers in street attire may view surgery without entering the inner operating room zone. A curved wall of tempered glass plate between the gallery and the operating room insures soundproofing and provides an unobstructed view.

The observation of surgery is greatly aided by closed circuit, high resolution television (Figs. 4).[11] One television camera is mounted above the surgical field on the Zeiss twin lamp, and a second camera is incorporated into the optical system of the surgical microscope (Fig. 5). Images on both cameras are viewed on small monitors by surgical personnel, displayed simultaneously on a 21-inch screen in the operating room and on a 14-inch screen in the gallery, and recorded on television tape for future educational use. If desired, the image may be transmitted to other parts of the institute by closed-circuit television.

An audiocommunication system between operating room and gallery, controlled in the surgical area, can permit one-way communication or a two-way conversation. Control of the system insures an uninterrupted concentration on the surgical procedure and prevents any disturbance of a patient under local anesthesia.

*Operating room zone*—Two major operating rooms furnished with equipment especially developed for the Institute occupy the operating room zone (Figs. 4 and 5). Each room is more than 400 square feet in area. Special surgical equipment includes a main column and an auxiliary column suspended from the ceiling and a pedestal anchored to the floor; an equipment cabinet and control console recessed in the side wall are con-

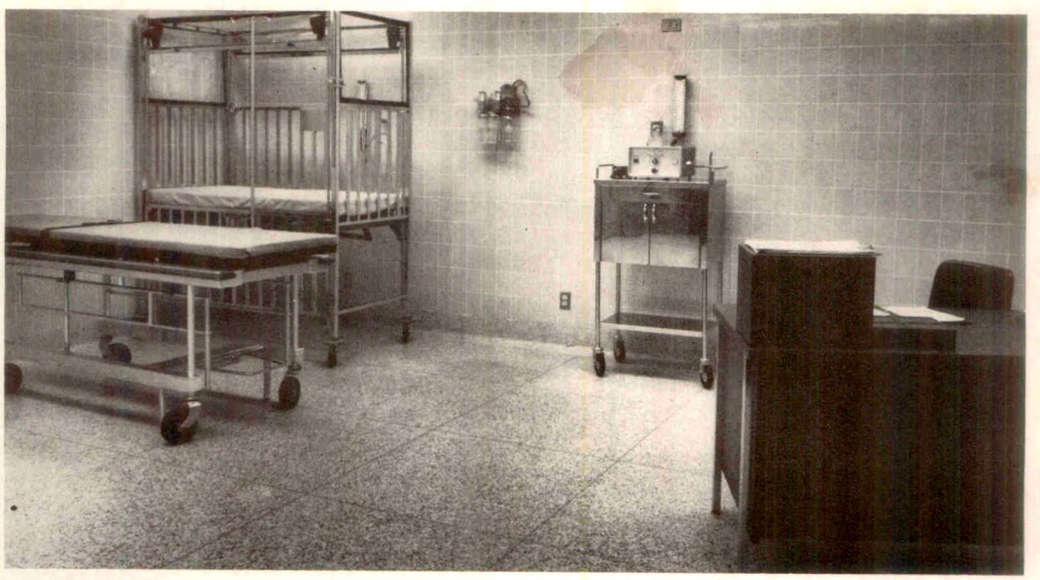

Fig. 2 (Christensen and Straatsma). Recovery room. Adult patients remain on special surgical stretchers; children are transferred to completely enclosed stainless steel cribs.

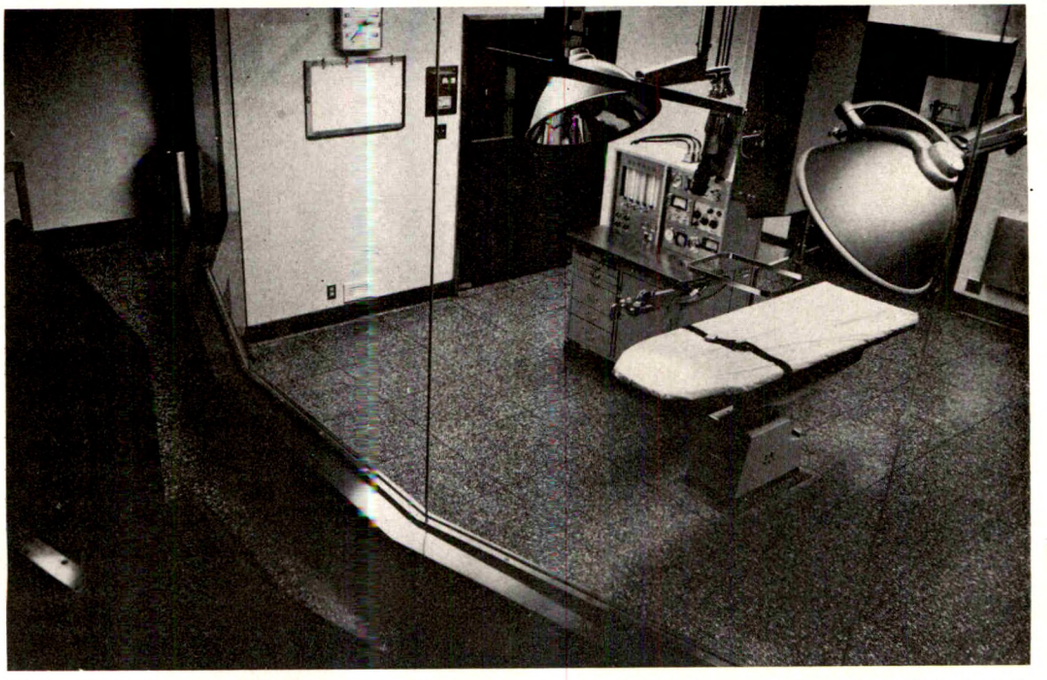

Fig. 3 (Christensen and Straatsma). Observation gallery. For optimum viewing the gallery floor is elevated; two rows of couches are arranged in tiers. Curved wall behind gallery and operating room is tempered plate glass.

Fig. 4 (Christensen and Straatsma). Observation gallery television. High resolution television cameras are mounted on the twin light and surgical microscope. The image of both cameras is viewed on monitors (upper right), recorded on television tape, and displayed simultaneously on a 21-inch monitor in the operating room and on a 14-inch monitor in the gallery (foreground).

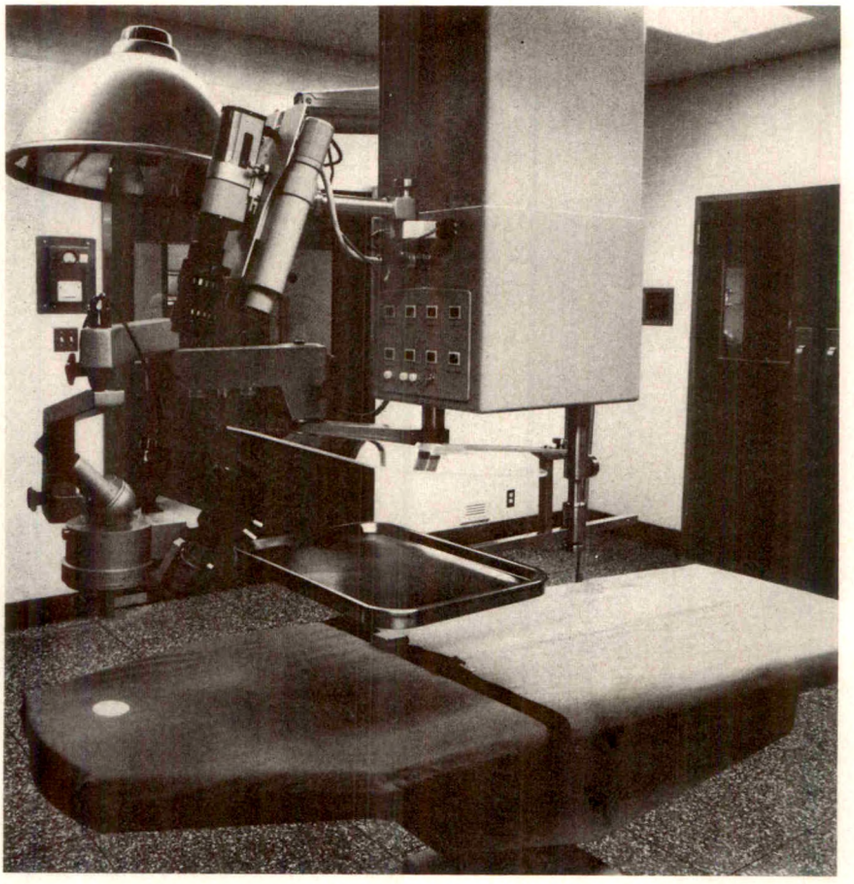

Fig. 5 (Christensen and Straatsma). Equipment column. Main column is adjustable and provides support for the surgical instrument tray with canopy, twin light and coaxial television cameras, and the surgical microscope. On the front of the column are outlets to which sterile surgical instruments may be attached and illuminated indicators to inform the surgeon of foot control settings.

nected with both the columns and the pedestal (Fig. 4).

The main column, which may be raised or lowered, supports the surgical instrument tray with its sterile transparent canopy, the high-intensity twin light and coaxially-mounted television camera, and the surgical microscope. The microscope is independently mounted so it can be focused or adjusted up and down and the "zoom" magnification varied by the surgeon's foot controls, which extend from the fixed surgical pedestal (Fig. 5).

On the front of the column facing the surgeon are outlets to which sterile surgical instruments for cautery, diathermy, vacuum, and the erysiphake lens extractor may be attached (Fig. 5). These items are contained in a recessed equipment cabinet and control console connected to the main column and to the pedestal by concealed conduit and cables (Figs. 4 and 6). The control-console selectivity connects the units and the operating microscope with the foot controls, regulates television transmission to the tape recorder, and monitors and adjusts audiocommunication with the gallery (Fig. 6).

On the side of the column are connections for television cameras attached to the twin light and to the operating microscope, a 16-mm movie camera, a 35-mm still camera, and microphones for use by the surgeon. On the

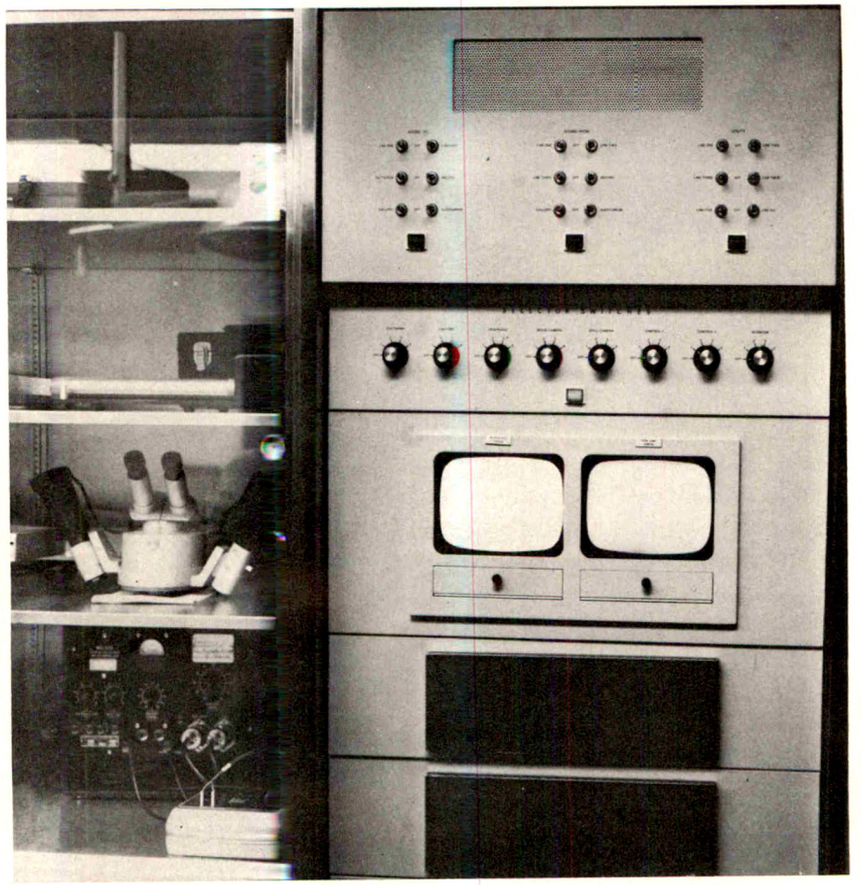

Fig. 6 (Christensen and Straatsma). Equipment cabinet and control console. Connected with the equipment column and the fixed surgical pedestal are a cabinet for surgical equipment (left) and a control console (right). The latter connects the equipment with the foot controls preferred by the surgeon, regulates the television system, and adjusts audiocommunication with the gallery.

back of the column are switches for the twin light, ceiling lights, and paired Castle surgical lights, controls to adjust the elevation of the main column, auxiliary column, operating table, and the head of the operating table (Fig. 7).

One control automatically adjusts all the elements needed to transfer a patient to or from the special wheeled stretcher to the pedestal. All controls operate by simple pressure, so they can be activated by the circulating nurse or depressed by the scrub nurse without contamination.

A safety device incorporated into the system prevents the theoretical possibility that a patient might be inadvertently compressed between the operating table and the column. Upon the exertion of one pound of pressure on the lowest projection of the column, the column moves up automatically as the table simultaneously moves down. Until the safety is reset, this control for position of the column and the table is preponderant over all controls.

The pedestal also incorporates electrical outlets, electrical ground circuits, a source of suction for surgery and anesthesia, and built-in sources of compressed air, oxygen, and nitrous oxide (Fig. 7). On the upper surface of the pedestal, two locking pins engage the contoured surgical table top, and four electromagnets hold it firmly in place

(Fig. 4). With the table attached, the pedestal may be adjusted by using controls on the main column, allowing the surgeon to sit or stand and the patient to be placed in Trendelenburg or reverse Trendelenburg position.

Movement of the pedestal and the columns is controlled by a hydraulic system located beneath each of the elevated observation galleries. An interlink between the two units permits the equipment in both special operating rooms to be operated by either hydraulic system.

The surgeon's chair is an integral part of a system in which foot controls are used and surgery is performed under high magnification (Fig. 8). The chair is designed to move easily when unoccupied and to be extremely stable when in use. The large base plate and unique pivot point enable the surgeon to rotate the chair to left and right through an arc greater than 90 degrees, while remaining concentric with the surgical field. The chair height is adjustable, and each arm support can be adjusted up, down, in and out, or removed entirely. When in use, the arm supports are covered completely with sterile drapes. When not in use, the surgeon's chair is stored beneath the observation gallery (Fig. 7).

Recessed in the wall opposite the corridor are the control console, surgical equipment cabinet, racks of sterile instruments, sutures and supplies, and cabinets containing surgical packs, as well as waste containers, low-intensity floor lights, and a wall-mounted stool and writing board for use by the circulating nurse (Fig. 7). On other walls of the room are x-ray view boxes, a clock with sweep-second hand, a stainless steel drop-leaf table on which surgical gowns and

Side wall contains (from right to left) the control console, equipment console, racks of sterile instruments, sutures, and complete surgical packs. Also visible are recessed containers for waste, low intensity floor lights, and a wall mounted stool and writing board for the circulating nurse.

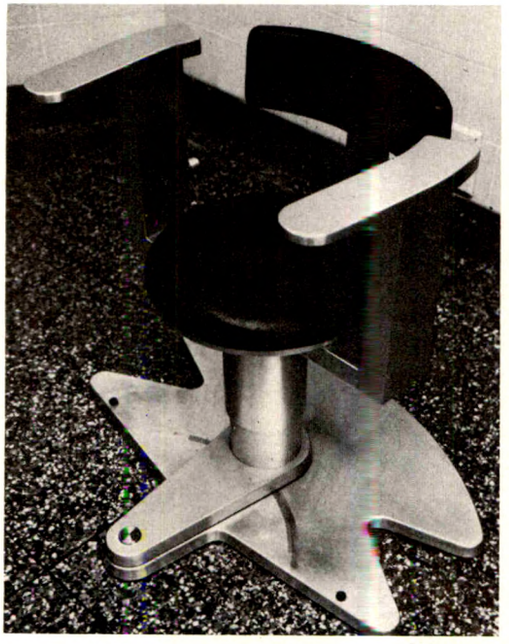

Fig. 8 (Christensen and Straatsma). Surgeon's chair. A large base plate and unique pivot point enable the surgeon to rotate this chair through an arc of more than 90 degrees while remaining concentric with the surgical field. Chair height may be varied with a built-in hydraulic control and each arm support may be adjusted up, down, in and out, or removed entirely.

gloves are placed at the beginning of each procedure, and doors connecting the operating room with the anesthesia induction room, surgical scrub area, and main corridor (Fig. 4).

The ceiling plan is of increasing importance in the design of an operating room. In this operating room, the ceiling incorporates the main column, the auxiliary column, ceiling outlets for oxygen, nitrous oxide and suction, and three sets of lights (Figs. 4 and 7). Supplementing the high-intensity Zeiss twin lamp on the main column are a pair of Castle surgical lights suspended from recessed ceiling tracks, two banks of fluorescent lights designed to provide optimum overall level of illumination in the room, and two recessed battery-operated emergency lights. The latter are designed to receive electrical energy from large, constantly charged storage batteries and to turn on automatically upon simultaneous failure of the regular power source and the stand-by hospital generator.

Anesthesia gas flows in from the ceiling or from the fixed pedestal attached to an anesthesia console developed for the Institute (Figs. 3 and 9).[5] This machine connects to built-in gas supplies and contains anesthesia gas-flow meters; stand-by tanks of oxygen, nitrous oxide, and medical compressed air; vaporizers for halothane and methoxyflorane; a carbon dioxide absorption system with bacteria filter; suction equipment; and a Bird automatic ventilator.

The unit contains an operation timer and equipment to monitor the patient's blood pressure, pulse rate, electrocardiogram, and blood oxygen saturations. Drawers of the console contain syringes, medications, and supplies; a voice-actuated tape recorder for educational and forensic purposes; and a writing surface for anesthesia records.

Augmenting the specially equipped ophthalmic operating rooms is a standard operating room, 400 square feet in size, for procedures which do not require special equipment. Photocoagulation therapy with the Zeiss zenon arc photocoagulator and the ruby laser (American Optical Co.) is carried out in this space. Space allocated for a fourth operating room is currently unfurnished.

Between the present and future operating rooms are anesthesia induction rooms and surgical scrub areas (Figs. 10 and 11). The anesthesia induction areas are equipped with wall-mounted anesthesia units. Through a large glass window, the surgical team can observe induction of general or local anesthesia, preparation of the surgical area, and placement of some or all surgical drapes, from the adjacent surgical sbrub area (Fig. 11). In the event of an emergency during induction of anesthesia, this observation permits immediate response. The surgical scrub area also contains a high-speed autoclave for resterilization of an instrument, if necessary, during a surgical procedure.

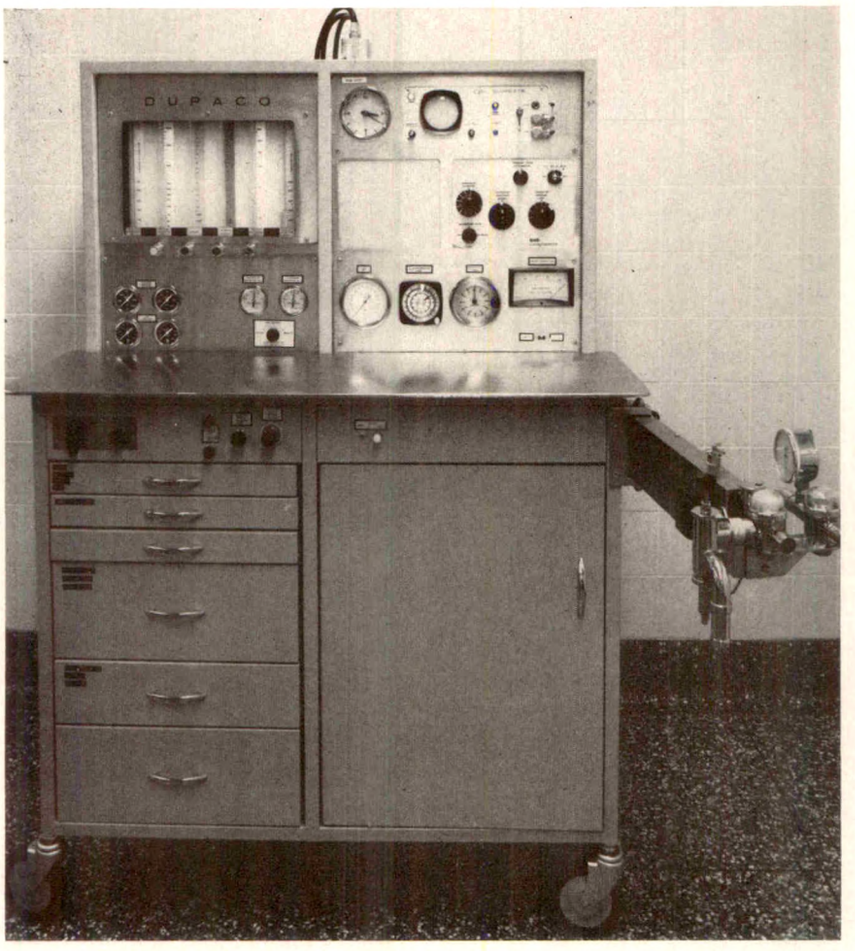

Fig. 9 (Christensen and Straatsma). Anesthesia console. The anesthesia unit connects with built-in gas supplies (top) and contains anesthesia gas flow meters (top left); patient monitor and timing equipment (top right); drawers and pullouts for syringes, medications, record keeping, and a voice-actuated tape recorder (bottom left); plus standby gas tanks, absorption system suction equipment, and ventilator (bottom right). The anesthesia bag and connecting tubes are attached to the arm that projects toward the patient (far right).

Equally accessible to all operating rooms is an instrument preparation room, divided into a "dirty" and a "clean" area (Fig. 1). Linen and waste used in a surgical procedure are transferred to the "dirty" area, placed in hampers, and removed through special doors that open directly into the outer support zone.

An ultrasonic cleaner-sterilizer that functions like a conveyor belt transmits surgical instruments to the "clean" area, where they are inspected and combined with other items to make up complete packs for specific surgical procedures.

*Surgical patient transportation*—The system for the transportation of patients consists of a commercially available Surgilift with break-apart conductive vinyl top, a specially designed stretcher with detachable top, and the fixed operating room pedestal.

The patient is moved from the hospital bed in the inpatient unit to the Surgilift[12] and transported to the surgical suite. In the corridor adjacent to the induction room, the

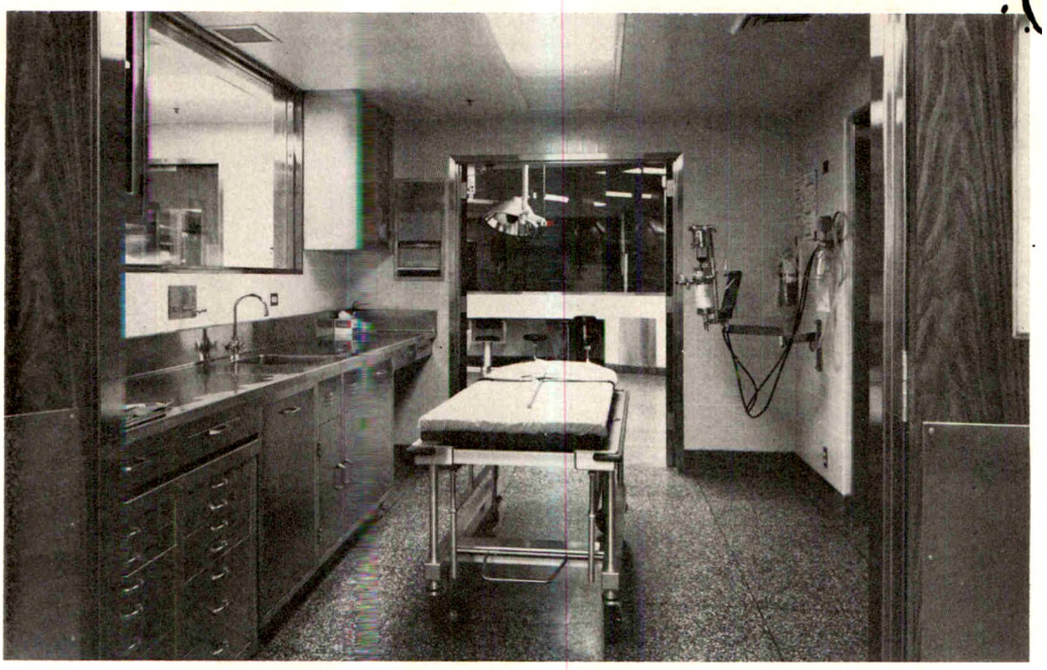

Fig. 10 (Christensen and Straatsma). Anesthesia induction room. Equipped with a wall-mounted anesthesia unit (right), the room is used for induction of local or general anesthesia, preparation of the surgical area, and placement of some or all surgical drapes.

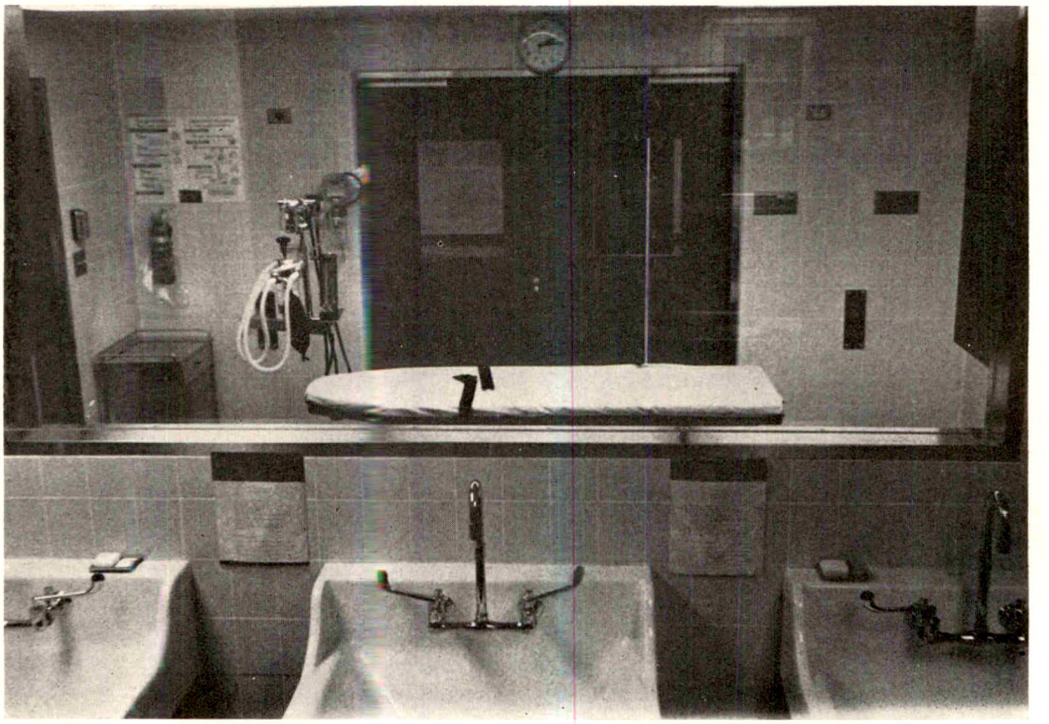

Fig. 11 (Christensen and Straatsma). Surgical scrub area. Through a large plate glass window, the surgical team can view the induction of anesthesia and the general preparation of the patient.

Surgilift is moved over the specially designed stretcher (Fig. 12) and the patient lowered onto the stretcher by means of a crank. When the straps on the circumference are released, the patient is precisely positioned on the stretcher.

The stretcher enters the induction room and, after the patient has received anesthesia induction, general preparation, and surgical draping, is moved into the operating room. The U-shaped stretcher (Figs. 10 and 12) is placed over the pedestal (Figs. 5 and 7), where the depression of a single control button transfers and firmly attaches the stretcher top to the pedestal (Fig. 4).

After the surgical procedure, the stretcher top is automatically replaced on the stretcher, side rails are attached, and the patient is transported to the recovery room. Except for the taper at the head, the stretcher is several inches wider than the usual operating table. Its two-inch pad of vinyl-covered conductive rubber enables the patient to remain comfortably on this unit in the recovery room.

When the patient is released from the recovery room, the Surgilift is reattached to the break-apart top (which has remained in place under the patient throughout surgery), and the patient is returned to the inpatient unit. Final transfer is made by lowering the patient onto his bed and releasing the circumference straps. When the center strip of the top is pulled out, the two sides are easily removed without disturbing the patient. This patient transport system avoids direct lifting of the patient by surgeon or assistants, eliminates physical strain by the patient in the immediate postoperative period, and is performed easily by one person.

Evaluation of a surgical system is a continuing process. The ophthalmic surgical system at the Jules Stein Eye Institute has increased patient safety, enhanced the precision of surgery, facilitated surgical training, and allowed for easy incorporation of equipment developed since inception of its design. Physicians with extensive experience in a variety of surgical methods have noted no significant defect in general design or in specially developed equipment. The response of nurses and paramedical personnel has been equally favorable.

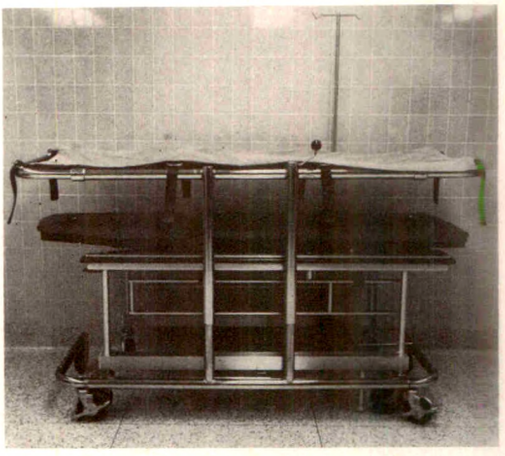

Fig. 12 (Christensen and Straatsma). The transfer from Surgilift to special surgical stretcher. After proper positioning, the Surgilift is lowered over the stretcher, the straps on circumference of break-apart top are released, and Surgilift frame is removed.

## Summary

The unique features of the ophthalmic surgery system at the Jules Stein Eye Institute include a support zone and two specially designed operating rooms. Hydraulic columns, pedestals, and equipment cabinets are interconnected by conduits. An adjustable hydraulic surgeon's chair rotates and remains concentric with the operative field. An anesthesia console provides gases and patient monitoring equipment. Closed circuit television and videotaping greatly aid observation of surgery in the operating rooms and galleries. The patient transport system includes a Surgilift, a stretcher with detachable top, and a fixed hydraulic operating room pedestal.

### Acknowledgments

Special operating room equipment was designed and constructed by Fred Storm Industrial Design, Inc., Los Angeles, California. The Surgilift is manufactured by Institutional Industries, Inc., 5500

Muddy Creek Road, Cincinnati, Ohio 45238. Mr. Michael Geoghegan made the photographs. Verona Pettyjohn provided editorial assistance.

# PERIPHERAL NASAL FIELD DEFECTS

RAYMOND P. LEBLANC, M.D.
*Quebec, Canada*
AND
BERNARD BECKER, M.D.
*St. Louis, Missouri*

In 1909, Rønne[1] introduced the concept that peripheral nasal step defects are a specific visual field change in glaucoma. It was a logical and well-founded extension of the arcuate fiber defect theory postulated by Bjerrum[2] and widely accepted soon thereafter in ophthalmic circles. For the next few decades, the literature contained reports, reviews, and discussions amplifying the frequency and importance of this type of field defect. In recent years, however, attention has been directed to central field studies, while only passing mention of the nasal step defect has appeared in textbooks and in the literature. Little attempt has been made to define the step as originally conceived by Rønne,[3-5] and the defect was considered of little value in the diagnosis of glaucoma.[6-9]

The purpose of this study was to determine the frequency of characteristic peripheral nasal field defects with step-like features in glaucoma patients.

## MATERIAL AND METHODS

*Selection of patients*—Fifty-one consecutive patients with primary open-angle glaucoma and documented field loss, seen in consultation in the Glaucoma Center, were selected for this study.

*Methods*—All patients had a complete ophthalmic examination which included general medical, family, and ocular history; visual acuity; refraction; tonometry; tonography; ophthalmoscopic examination; and visual field studies on the Goldmann perimeter, using both static and kinetic techniques. The static perimetry was carried out according to the circular method described by Ourgaud and Aubert[10] at 5, 15, and 35 to 45 degrees eccentricity, using various size test objects. All positive findings were then confirmed by meridional static perimetry.

## RESULTS

In the 51 consecutive patients (101 eyes) with glaucoma, there were 81 eyes with characteristic glaucoma field loss (Table 1). Twenty-one eyes (26%) showed peripheral nasal field defects with step features. In 12 of the 21 eyes this peripheral defect was accompanied by a central defect as well, but in nine eyes (43% of those eyes with nasal steps) the peripheral nasal defect was an isolated finding. Thus, an isolated nasal step occurred in 11% of the 81 eyes with glaucomatous field defects.

## CASE REPORTS

Cases 1 and 2, described below, are illustrative of primary open-angle glaucoma in which the peripheral nasal step was the initial and only field loss.

*Case* 1—This 13-year-old black boy was first seen at McMillan Hospital in January, 1966. His visual acuity was 20/20 in both eyes with myopic correction. Fundus examination revealed myopic crescents and a cup/disk ratio of 0.7 in both eyes. Applanation intraocular pressure (mm Hg) was RE:22, and LE:20, and the tonographic tracing demonstrated outflow facilities of RE:0.07, and LE:0.05. Slit lamp examination was normal and gonioscopy revealed Grade IV open angles. Tangent screen examination demonstrated normal visual

TABLE 1

PERIPHERAL NASAL FIELD DEFECTS IN EYES WITH GLAUCOMATOUS FIELD LOSS

| | Present Series | Aulhorn |
|---|---|---|
| Peripheral nasal field defects. | 21/81(26%) | 280/961(29.0%) |
| When accompanied with central defects | 12/81(15%) | 273/961(28.4%) |
| When isolated finding | 9/81(11%) | 7/961(0.7%) |

fields. The patient was classified as a glaucoma suspect on the basis of his pressures and outflow facilities and referred for further follow-up.

In December, 1967, Goldmann fields (Fig. 1) revealed an inferior nasal step of the right eye at 55 degrees using a I 4e test object and at 40 degrees when using a I 2e test object. In July, 1968, Goldmann field examination of the right eye was unchanged. Circular static perimetry, as well as meridional profiles above and below the horizontal meridian, confirmed the previously noted defects in the inferior nasal area of the right eye. The patient was classified as having primary open-angle glaucoma with field loss in the right eye and was begun on therapy.

*Case 2*—This 49-year-old black woman was found in 1961 to have high intraocular pressures and borderline facilities of outflow, but demonstrated no field loss at that time on tangent screen examination. Because of repeated intraocular pressures over 30 mm Hg, she was treated with antiglaucomatous therapy. In August, 1967, she was referred to the Glaucoma Center. Her corrected visual acuity was 20/20 in both eyes. Applanation pressures were RE:12, LE:13 mm Hg. Fundus examination revealed cup/disk ratios of 0.4 in the right eye and 0.7 in the left eye. Medication was discontinued. The patient returned three weeks later with applanation pressures of RE:18 and LE:28. Goldmann fields were normal in the right eye, but a nasal step was noted at 25 degrees eccentricity in the left eye, using a I 3e test object. Static quantitative perimetry was normal except for the superior nasal step in the left eye. The patient's visual fields were confirmed on repeated examinations on several occasions during the next few months (Fig. 2). The patient has been maintained on antiglaucomatous therapy with good control of pressure and no further deterioration in visual field function. The patient was classified as having primary open-angle glaucoma with asymmetrical pressures and field loss limited to the left eye.

Cases 3 and 4 illustrate primary open-angle glaucoma in which the visual field loss was a central defect accompanied by a peripheral nasal step.

*Case 3*—This 52-year-old white man was first seen on July 18, 1967, with a family history of glaucoma. Visual acuity with correction was RE: 20/20, and LE: 20/25. Applanation pressures were RE: 20, and LE: 18 mm Hg and outflow facilities were RE: 0.38, and LE: 0.33. Slit lamp examination was normal and gonioscopy revealed Grade IV open angles. Fundus examination showed myopic disks with a cup/disk ratio of RE: 0.1, and LE: 0.4. Visual field examination on the Goldmann perimeter was normal.

The patient returned one year later still asymptomatic. His applanation pressures were RE: 20, and LE: 21 mm Hg with outflow facilities of RE: 0.22, and LE: 0.20. Visual field examination was once again normal in the right eye. In the left eye, however, a nasal step at 40 degrees eccentricity extending to 50 degrees eccentricity was noted using the I 4e and the III 4e test objects. In addition, a superior Bjerrum scotoma was noted in the left eye using the I 2e test object (Fig. 3). Repeated visual field studies, using both kinetic and static techniques, confirmed the inferior nasal step as well as the superior Bjerrum scotoma in the left eye. The visual field has remained normal in the right eye. This patient has been followed on antiglaucomatous therapy.

*Case 4*—This 51-year-old white man was said to have glaucoma in 1951 and was treated intensively for three years. A maternal aunt had glaucoma. In July, 1954, visual acuity was RE: 20/20+, and LE: 20/20+. Tangent screen field examination showed minimal enlargement of the blind spots in both eyes to a 1 mm test object at one meter distance. Slit lamp examination was normal, as was

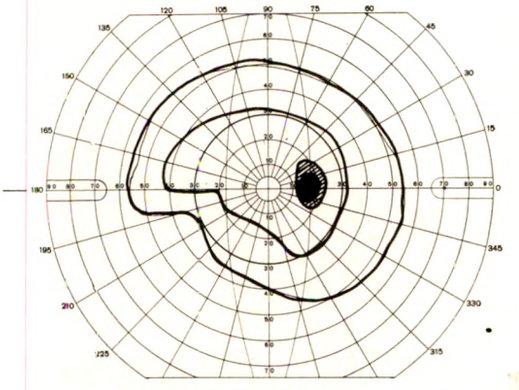

Fig. 1 (LeBlanc and Becker). Case 1. Visual field, right eye, showing nasal step.

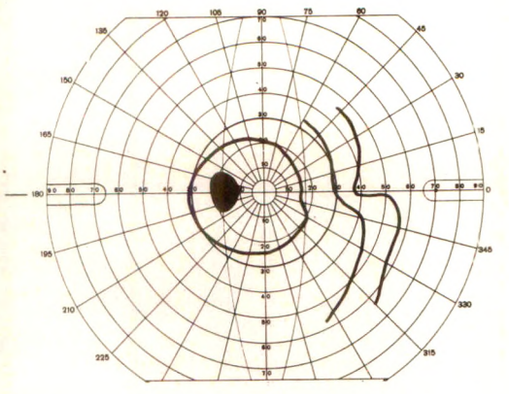

Fig. 2 (LeBlanc and Becker). Case 2. Superior nasal step in visual field of left eye.

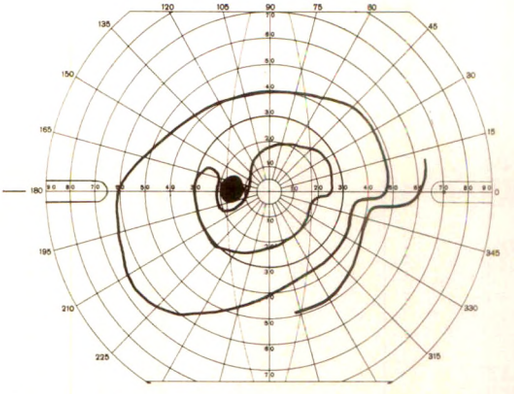

Fig. 3 (LeBlanc and Becker). Case 3. Superior arcuate scotoma accompanied by inferior nasal step.

the fundus examination. Gonioscopy revealed open angles. Applanation pressures were 38 mm Hg in both eyes with outflow facilities of RE: 0.04, and LE: 0.10. On maximum therapy his intraocular pressures could not be controlled. In October, 1963, his Goldmann field (Fig. 4) showed a sharp superior nasal step in the right eye with the I 2°, I 3°, and II 4° test objects. The patient also progressively developed marked glaucomatous cupping. Thermal sclerostomies were performed in the right eye in October, 1963, and in the left eye in January, 1964. In March of 1969, the visual acuity was RE: 20/300, LE: 20/200. Visual field examination of the right eye showed constricted isopters and a superior nasal step deformity present at 55 degrees eccentricity with a V 4° test object and at 50 degrees eccentricity with a II 4° test object. At 25 degrees eccentricity, the nasal step was present with a I 4° test object. To date, the left eye has demonstrated no nasal step. Applanation pressures were RE: 25, and LE: 10 mm Hg with outflow facilities of RE: 0.10, and LE: 0.31.

Cases 5 and 6 illustrate open-angle glaucoma with central visual field defects followed by late development of peripheral nasal steps.

*Case* 5—This 63-year-old white man was diagnosed as having primary open-angle glaucoma in 1955 on the basis of intraocular pressures. The patient was placed on antiglaucomatous therapy with fair control until May of 1966, at which time a relative Bjerrum scotoma in the left eye was found with a 1 mm test object on the tangent screen. In July, 1967, a Goldmann field showed the right eye to be normal, but the left eye showed a superior Bjerrum scotoma encroaching upon fixation with a I 2° test object. No nasal step deformity was noted at that time. His visual acuity in both eyes was 20/20 without correction. Slit lamp examination was normal. Gonioscopy revealed Grade IV open angles in both eyes. Fundus examination showed 0.3 cup/disk ratio in the right eye; the left eye showed a 0.5 cup/disk ratio with temporal pallor and a nasal shift of the vessels. The patient's investigation included ophthalmodynamometric studies and a neurologic work-up because of the asymmetrical field loss. All studies were normal. The patient's therapy was intensified. In May of 1968, visual field examination revealed further loss to the I 2° test object as well as the first appearance of a superior nasal step at 45 degrees eccentricity with the I 4° test object. Continued medical therapy since that time has prevented progression of the central field loss, but the superior nasal step has progressed (Fig. 5).

*Case* 6—This 48-year-old white man was diagnosed as having glaucoma in 1958 and placed on antiglaucomatous therapy. When referred in 1961, visual acuity was 20/20 in both eyes. Applanation pressures were RE: 31, and LE: 24 mm Hg, with facilities of outflow of RE: 0.06, and LE: 0.07. Slit lamp examination showed Krukenberg spindles and increased transillumination of the mid-periphery of the iris. Gonioscopy revealed Grade III open angles

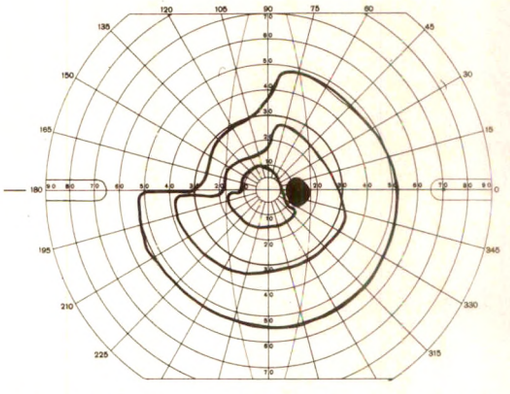

Fig. 4 (LeBlanc and Becker). Case 4. Chart shows both peripheral and central visual field loss and step feature.

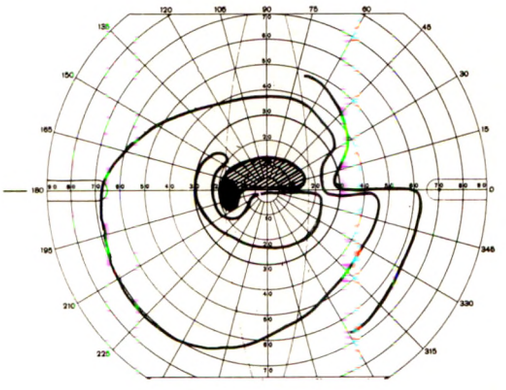

Fig. 5 (LeBlanc and Becker). Case 5. Well-developed arcuate scotoma and superior nasal field defect.

with heavy pigmentation of the trabeculum extending all the way to Schwalbe's line. Tangent screen examination demonstrated superior Bjerrum scotomas in both eyes. Fundus examination showed marked cupping with loss of the temporal rim of the disk in both eyes. A diagnosis of pigmentary glaucoma with marked field loss was made. The patient's therapy was increased and he was followed until 1964 at which time Goldmann fields demonstrated the marked superior Bjerrum scotomas in both eyes. In addition, in the left eye a superior nasal step at 40 degrees eccentricity with the I 4e test object and at 15 degrees eccentricity to the I 4e test object was noted (Fig. 6). The patient's antiglaucomatous therapy has been maintained and subsequent follow-up visits have shown good intraocular pressure control with no further changes in visual fields.

## Discussion

How does one explain the characteristic topography of the nasal step defect? The basic anatomy of retinal nerve fibers is the apparent key, a fact appreciated by Bjerrum and Rønne.[1,2] When an isolated peripheral bundle (fibers to the temporal retina) is selectively affected by disease, an isolated peripheral nasal step ensues. Similarly, involvement of a paramacular bundle leads to a central arcuate defect ending in a sharp step feature at the horizontal meridian. Combinations of these two mechanisms result in central and peripheral steps, alone or in combination. The variety of the presentations of the nasal step is illustrated (Figs. 1-6).

Our findings agree with the report of Rønne[1] and leave no question as to the importance of the nasal step defect. Since many ophthalmologists confine their visual field testing in glaucoma patients to an evaluation of the central field, it is important to appreciate the relative frequency of peripheral nasal steps.

A recent and widely quoted study by Aulhorn and Harms[8] reports the field changes in 1561 glaucomatous eyes with field loss. The authors report general concentric contraction as the most common finding, a change said to be nonspecific for glaucoma and of little diagnostic value. Of 961 eyes with specific glaucomatous defects (Table 1), 280 (29%) present peripheral nasal contractions. Peripheral contractions, specifically from the nasal side, are reported as an isolated finding in only seven of these cases (0.7%), while in 273 cases (28.4%) nasal defects are accompanied by paracentral defects. It appears then that the frequency of peripheral nasal field defects in our small series compares well with that in the extensive report of Aulhorn (i.e., 26 vs 29%). However, isolated nasal defects are very rare in the large series but constitute half of the nasal defects we find. This discrepancy may be explained on the basis of a higher yield of paracentral scotomas by the Aulhorn and Harms group. They use the Tübingen perimeter which allows a more scrupulous search of the central areas for minute scotomata. However, the Tübing-

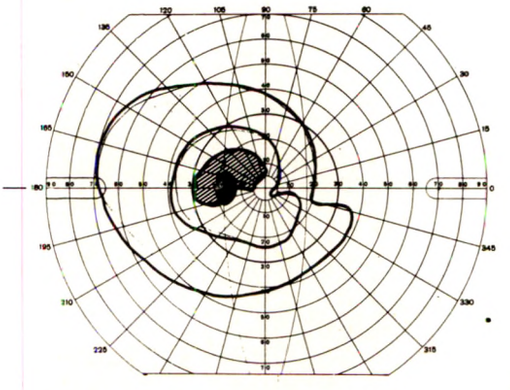

Fig. 6 (LeBlanc and Becker). Case 6. Superior arcuate defect with well-demarcated nasal step defect.

en perimeter is of limited availability compared to the more frequently used Goldmann and arc perimeters. In spite of intensive efforts with the Goldmann perimeter, using both static and kinetic techniques, we fail to demonstrate central defects in over 40% of patients with proved nasal steps. It is in this context that the importance of isolated peripheral nasal steps must be emphasized as a useful and early diagnostic sign in many cases of glaucoma.

## Summary

Fifty-one consecutive patients with primary open-angle glaucoma had 81 eyes with glaucomatous field loss. Peripheral nasal step field defects were found in 21 eyes (26%) and in nine of these the nasal step was the only demonstrable glaucoma field defect.

# LIGHT AND ELECTRON MICROSCOPY IN ABSOLUTE GLAUCOMA WITH PIGMENT DISPERSION PHENOMENA AND CONTUSION ANGLE DEFORMITY

TAKEO IWAMOTO, M.D., RUDOLF WITMER, M.D.
*New York, New York*
AND
ERNST LANDOLT, M.D.
*Zurich, Switzerland*

Pigment deposit on the trabecular region has long been noted in relation to glaucoma, and its possible derivation from the pigment epithelium of the iris has also been considered.[1,2] While there were those who apparently did not give much attention to the relation between Krukenberg's spindle and glaucoma,[3] Sugar and Barbour[4] delineated a disease entity called pigmentary glaucoma. Since then, many reports of similar cases have accumulated, as recently reviewed by Sugar.[5] Pigmentary glaucoma tends to occur bilaterally in eyes of young myopic males with symptoms of depigmentation of the iris, Krukenberg's spindle, pigment deposition on an open-angled trabecular area, and glaucoma. In regard to the pathogenesis, no clear agreement has yet been attained. Opinions concerning a causal relation between the pigment and the glaucoma are various:

(1) Atrophy of pigment epithelium of the iris, and probably the ciliary body as well, is the main source of pigment deposition and subsequent glaucoma.[5-7] (2) Some underlying factors other than pigment deposition may play a main role in causing glaucoma.[8-14] (3) This type of glaucoma may possibly be a variant of primary open angle glaucoma,[15,16] and pigment dispersion may not cause the pressure elevation.[16] (4) The relation is not yet clear.[17] Apart from pressure elevation, however, a main factor of this disease is a pigment dispersion syndrome or phenomena, which consists of atrophy of the iris pigment epithelium, Krukenberg's spindle, a dense trabecular pigment ring, and deposits of pigment on the iris and lens capsular surfaces.

On the other hand, a relation between monocular glaucoma and chamber angle deformities due to ocular contusion was emphasized recently by Wolff and Zimmerman,[18] and such a deformity with recessed chamber angle caused by blunt trauma was confirmed by many followers.[19-27]

This paper reports the electron microscopy of the trabecular meshwork, iris, and cornea of a patient whose left eye was enucleated because of pain and absolute glaucoma, and in which eye we saw definite signs of pigment dispersion phenomena superimposed on those of angle deformity due probably to old ocular contusion.

## CASE REPORT

A 52-year-old patient had a history of progressive visual loss in his left eye for about five years. This eye was totally blind, with a tension of 50 mm Hg by applanation. The cornea was clear, with much pigment deposition on the posterior surface in the form of Krukenberg's spindle. The chamber angle was open with heavy pigmentation of the trabecular meshwork. The iris was slighly atrophic and a year later showed neoformation of blood vessels; at this stage, the patient complained of great pain. The blind eye was, therefore, removed. The right eye was found to have normal vision with 0.75 D hyperopia, and a normal visual field, but gonioscopically there were the same changes as in the left eye. There was also a typical Krukenberg's spindle on the corneal endothelium, and a slight iris atrophy was noticed by transillumination. Ocular pressure of this eye without therapy was 26 mm Hg

Department of Ophthalmology, Columbia University, New York City, and the University Eye Clinic, Zurich, Switzerland. This investigation was partly supported by Public Health Service Research Grant 8R01 Ey 00190-15 from the National Eye Institute.

Reprint requests to Takeo Iwamoto, M.D., Department of Ophthalmology, Columbia University, 630 West 168th Street, New York, New York 10032.

at maximum, and could be kept around 15 mm Hg (applanation) with medication of one drop of adrenaline daily. The fundus showed no pathologic changes. An absolute pigmentary glaucoma of the left eye and beginning pigmentary glaucoma of the right eye was suspected clinically. As an early but important anamnesis, however, this patient had been hospitalized because of commotio cerebri due to a motorcycle accident about 26 years previously.

## Materials and methods

The enucleated left eye was immediately cut in half in a vertical meridian, and the temporal half with optic nerve was fixed in formalin and submitted to usual histopathologic study. Portions of the nasal half were fixed, either with 1% osmium tetroxide buffered with sucrose-containing Veronal acetate[28] or 2.5% glutaraldehyde in 0.05 M phosphate buffer (pH 7.4) followed by 1% osmium tetroxide,[29] dehydrated with graded alcohol and embedded in durcupan ACM (Araldite). Tissues were cut in meridional sections; 1-2 μ sections were stained with Giemsa for light microscopy and thin sections were doubly stained with uranyl acetate and lead citrate for electron microscopy as previous.[30] The LKB-Ultrotome and Porter-Blum microtome were used for cutting and the Zeiss EM-9 and EM-9S for electron microscopy. Normal human irises obtained by surgical enucleations due to malignant tumors were used as controls for the electron microscopy.

## Observations

### Light microscopy

Marked pannus was noted in the periphery of the cornea. A few scattered pigment granules were seen within the corneal endothelium. Although small pigment-clumps were occasionally attached to the posterior surface of the corneal endothelium, a large mass of such pigment granules was found in only one tissue block which was prepared originally for electron microscopy. This large accumulation was confined to a limited area of the central cornea, and believed to be clinical Krukenberg's spindle. The anterior chamber angle was open. Abundant pigment granules were deposited on the trabecular meshwork, which was sclerotic and degenerative. A hyaline membrane and an endothelium covered the entire inner surface of the trabecular region (Fig. 1-B), and the endothelium appeared to be continuous with that of the cornea. A deep recession of the chamber angle was seen in many areas (Fig. 1-A). The iris, ciliary body, and choroid were atrophic. In the iris both the stroma and iris epithelium* were far thinner than normal, and in the stroma there were many clump cells. Small pigment clumps were occasionally seen on the iris and lens capsule surfaces. The retina was atrophic. Atrophy of the ganglion cell and nerve fiber layer was significant. Glaucomatous cupping of the optic disk and thickening of the pial septum of the optic nerve were marked.

### Electron microscopy

The trabecular meshwork, iris, and part of the corneal endothelium were studied with the electron microscope.

*Trabecular meshwork*—The entire inner surface of the trabecular region was covered by an endothelium and a hyaline membrane (Figs. 1-C and 2-A). The endothelium was similar, structurally, to that of the normal corneal endothelium (Iwamoto and Smelser[31]), but there were some differences as follows: the thickness of the layer was irregular and, in general, thinner than that of normal central cornea (Figs. 1-C, 2-A and B). The tight junctions at the basal region of the intercellular spaces were often shorter or incomplete (Fig. 1-C). In the cytoplasm, there were more developed rough-surfaced endoplasmic reticulum, prominent filaments and some engulfed pigment granules (Fig. 2-B). A cilium-like structure was also occasionally found. The hyaline membrane varied in thickness and sometimes was very

* The iris epithelium consists of two pigmented layers: the anterior epithelial or myoepithelial (dilator muscle) layer, which is continuous with retinal pigment epithelium, and the posterior epithelial layer, or so-called iris pigment epithelium, which is a continuation of retinal neuroepithelium.

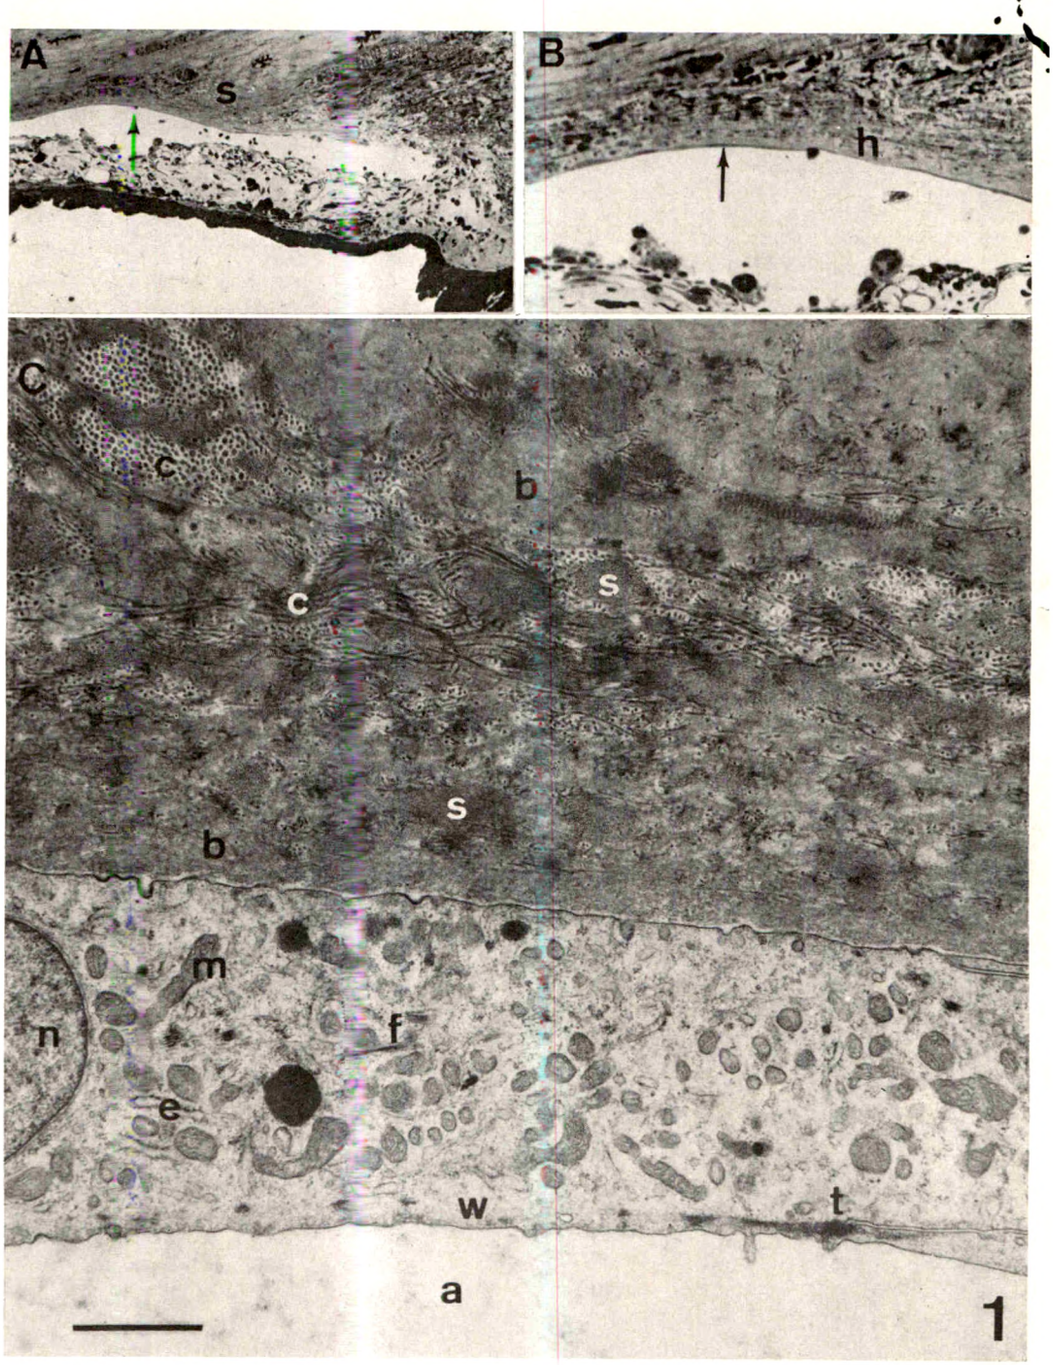

Fig. 1 (Iwamoto, Witmer, and Landolt). (A) Light micrograph of 2 μ section stained with Giemsa, showing the anterior chamber angle. Arrow indicates the trabecular region; (s) scleral spur. Note a deep recession of the angle (Giemsa, ×770). (B) Higher magnification of the trabecular region in A, showing the hyaline membrane (h) and endothelium (arrow) which cover the inner surface of the trabecular meshwork (Giemsa ×250). (C) Electron micrograph of the endothelium and hyaline membrane area. In the endothelium, nucleus (n), mitochondria (m), endoplasmic reticulum (er), terminal web (w), some filaments (f), and a tight junction (t), which is short, are seen. The hyaline membrane here is thick, and consists mainly of thin fibrils (s), thicker collagen fibrils (c), and basement membrane-like material, (b), (a) anterior chamber (×17,700). The line (bottom, left corner) in each electron micrograph (Figs. 1-7) represents 1 μ, unless otherwise indicated.

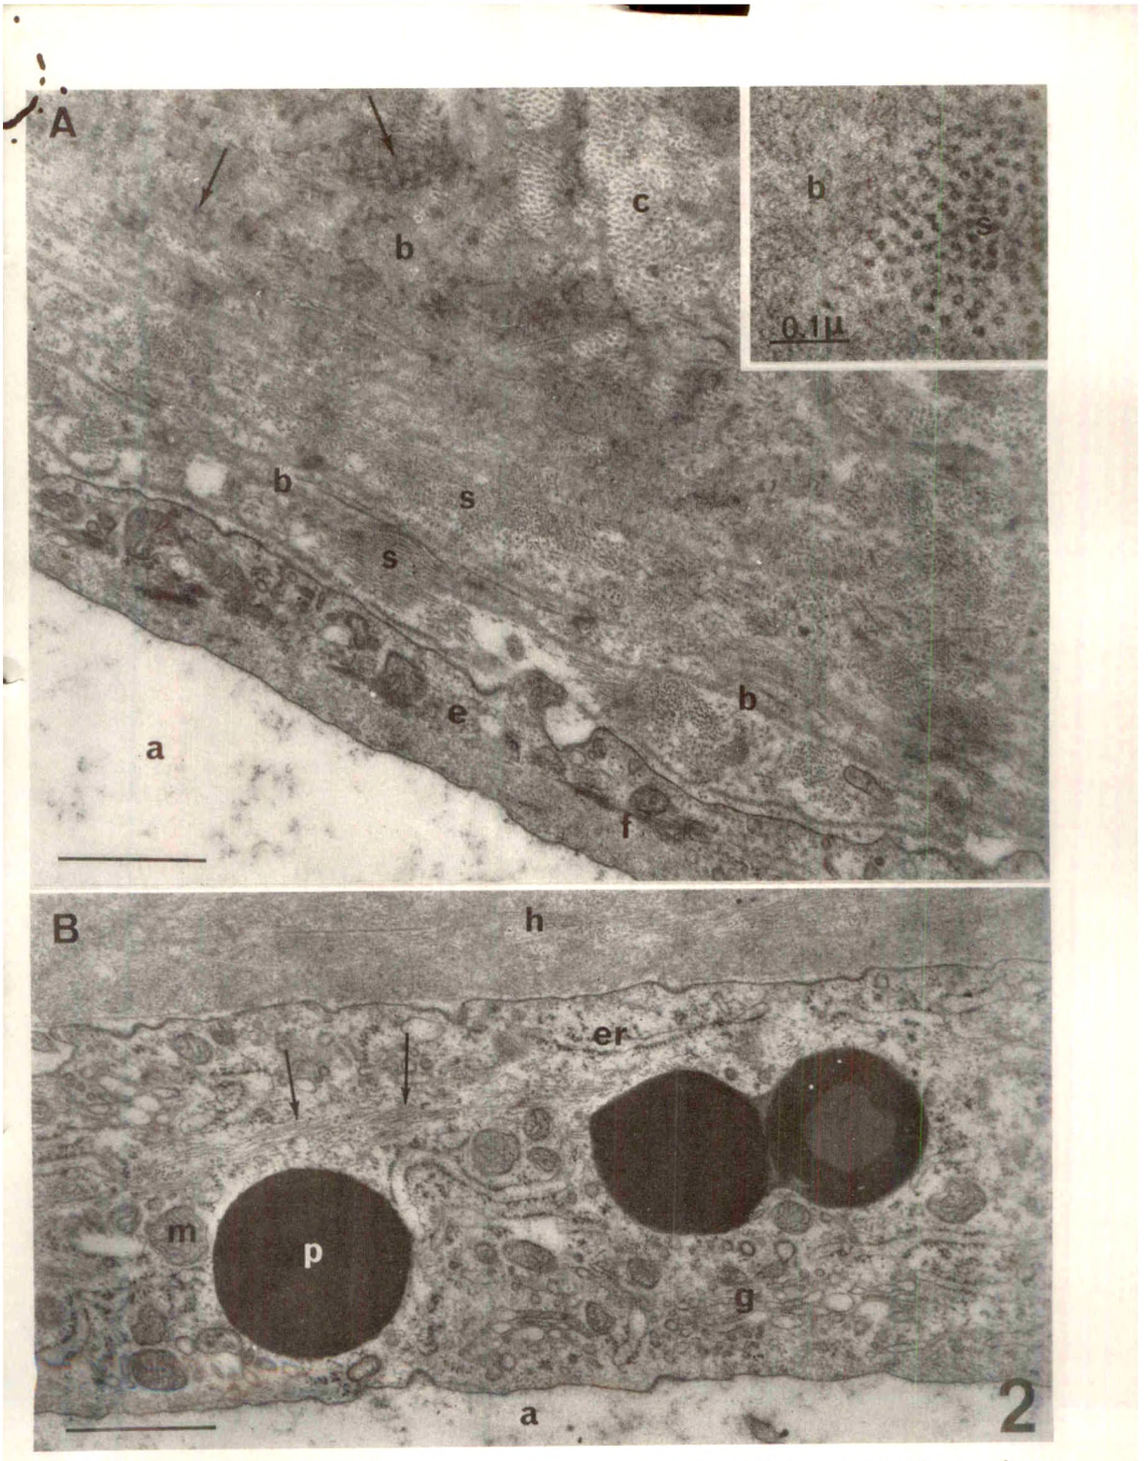

Fig. 2 (Iwamoto, Witmer, and Landolt). (A) Another region of endothelium and hyaline membrane covering the trabecular inner surface. The endothelium (e) is thin, and has filaments (f). The hyaline membrane consists of thin fibrils (s), thicker fibrils (c), basement membrane-like material (b) and some 100 nm banded material (arrows). This region is similar to abnormal Descemet's membrane of Fuchs' dystrophy (×20,000). Inset shows cross sections of the thin fibrils (s) and basement membrane-like material (b) at higher magnification (×108,000). (B) Another endothelial cell showing engulfed pigment granules (p), well developed rough-surfaced endoplasmic reticulum (er), and filaments (arrows), (m) mitochondria, (g) Golgi complex, (a) anterior chamber, (h) hyaline membrane (×20,000).

thick, as shown in Figure 1-C. It consisted of a mixture of basement membrane-like material, irregular groups of thin fibrils (10-15 nm in diameter), those of thicker collagen fibrils, and some 100 nm banded material. The basement membrane-like material was seen either as thin layers or widely spread areas. The hyaline membrane area made a transition into the innermost trabecular beams, which often lacked accompanying endothelial cells (Fig. 3-B).

In the uveal and corneoscleral meshwork, the individual beams or sheets contained abundant 100 nm banded material, mostly in the region called homogeneous matrix[32] or clear zone[33] (Fig. 3-A). The intertrabecular spaces were still open in some portions (Fig. 3-A), but in other areas the beams were closely apposed to each other, leaving a narrow space, or none, in between. In areas with no interspaces, either a single layer of endothelial cells separated the adjacent beams or the two beams fused without intervening cells (Fig. 3-B). The endothelial meshwork,[34] or juxtacanalicular connective tissue,[35] filled with cells and fibrillar elements often formed a thick layer (Fig. 4-A). No large vacuoles were observed in the endothelial cells lining the inner wall of Schlemm's canal. In some portions, the entire field of the trabecular meshwork was compactly filled with beams and other tissue elements without any space between the anterior chamber and Schlemm's canal (Fig. 3-B).

Cells containing pigment granules were frequently seen throughout the trabecular meshwork. They could roughly be divided into two types: In one type, pigment granules were distributed throughout the cytoplasm (Fig. 4-B); some of such cells resembled the clump cells seen in the iris, described below (Fig. 4-A). The other type of cells contained pigment granules aggregated in groups (Fig. 4-C), with each group clearly delimited from the surrounding cytoplasm. This type may be called macrophage.[36-38] The majority of these pigment granules observed in the trabecular area were of large, pigment-epithelial type, and the smaller granules, similar to those contained in the iris chromatophore or melanocyte, were only occasionally seen within the aggregates of the above macrophages (Fig. 4-C). Many of such pigment-containing cells covered the trabecular beams, at least in parts (Fig. 4-B).

*Iris*—Electron microscopy confirmed light microscopy in showing that both the stroma and the iris epithelium (dilator muscle layer plus iris pigment epithelium) were thinner than those of the normal control human irises. In the anterior border layer, so-called chromatophores, or uveal melanocytes, formed a relatively thick layer. The most significant finding in the stroma, however, was the presence of a large number of clump cells (Figs. 5-A and B). The majority of these belonged to the clump cells in the first phase, according to our tentative classification reported earlier (Iwamoto[38,39]). Most pigment granules contained in these cells were of the same size and structure as those of the iris epithelial cells, and were distributed throughout the cytoplasm. The other types of clump cells (Iwamoto[38,39]), were only occasionally observed (Fig. 5-C). In addition to these, clearly identifiable macrophages, as seen in the trabecular tissue (Fig. 4-C), were also found in the stroma.

Many of the myoepithelial or dilator muscle cells decreased or lost their anterior cytoplasmic (or muscular) processes, which are normally nonpigmented or only sparsely pigmented, and frequently, the whole cytoplasmic portions were filled with pigment granules. Various changes were seen in the iris pigment epithelial layer as well, while there were areas which appeared almost normal. These changes included: (1) apparent disintegration of the pigment granules (Fig. 6-A), seen also at the dilator muscle layer; (2) sparse distribution of the pigment granules in the cytoplasm (Fig. 6-B), and (3) destruction of the epithelial cell itself (Figs. 6-C and F), resulting in a release of the pig-

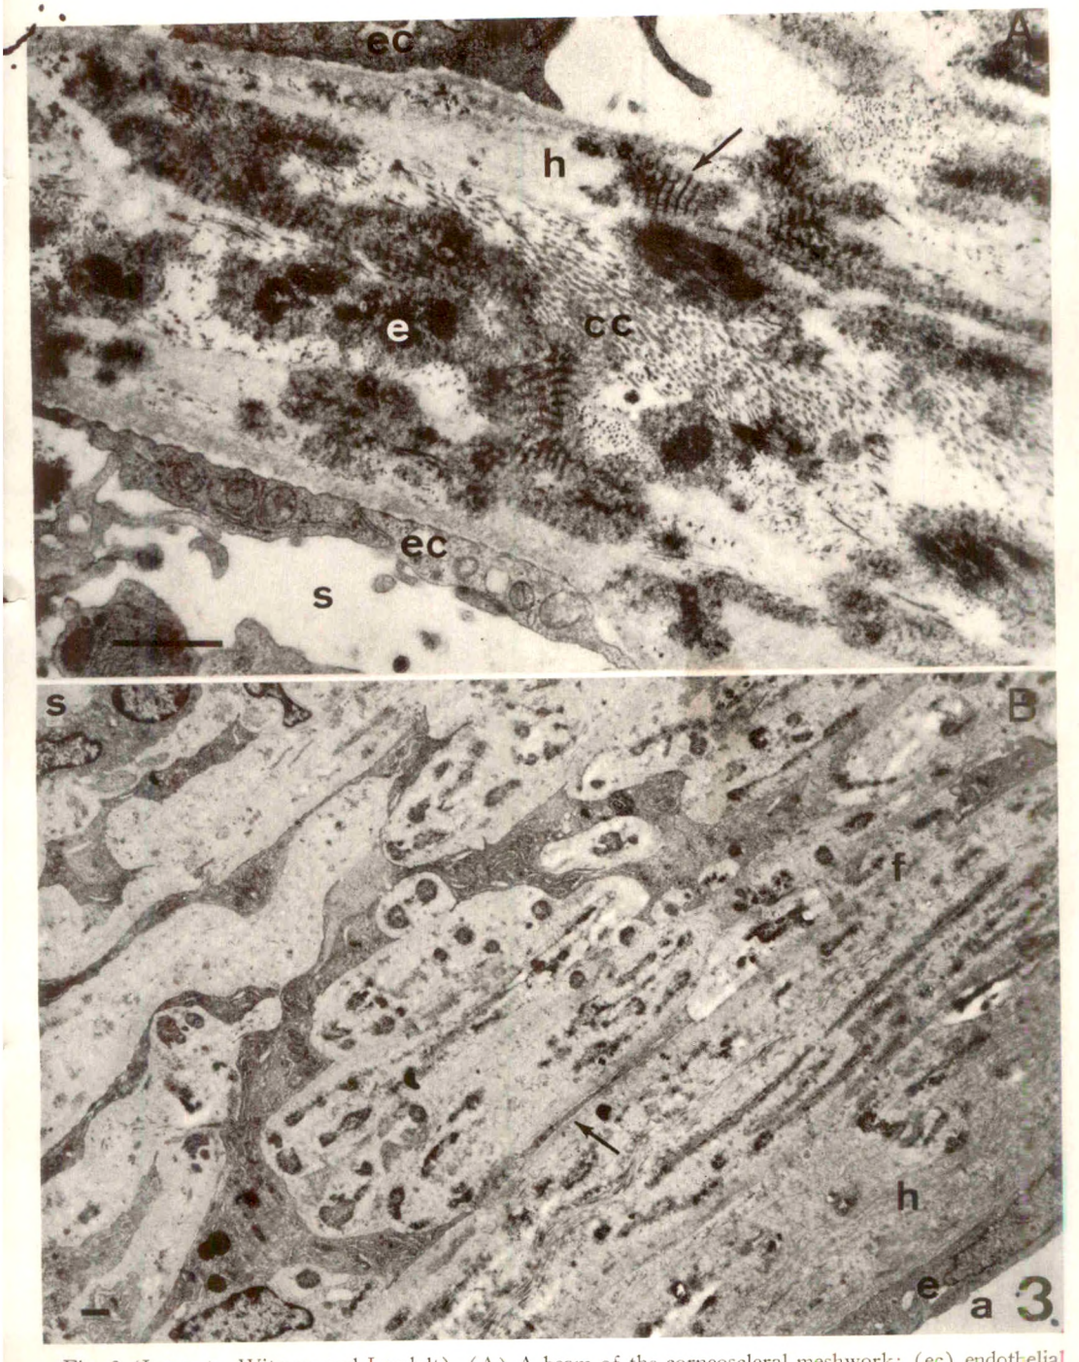

Fig. 3 (Iwamoto, Witmer, and Landolt). (A) A beam of the corneoscleral meshwork: (ec) endothelial cells covering the beam, (h) homogeneous matrix, (cc) central collagen core, (e) elastic component, (s) intertrabecular space. Note the abundant 100 nm banded material in the homogeneous matrix; the material appears to be located also in collagen core. (×14,700). (B) An area of the trabecular meshwork, where there is no intertrabecular space between the anterior chamber (a) and Schlemm's canal (s). A single thin layer of endothelial cells separates the adjacent beams at (arrow), and two beams are fused at (f). A hyaline membrane (h) which is covered by an endothelium (e) appears to make a transistion to the innermost trabecular beam. In this region only a few pigment granules are seen at lower left (×3750).

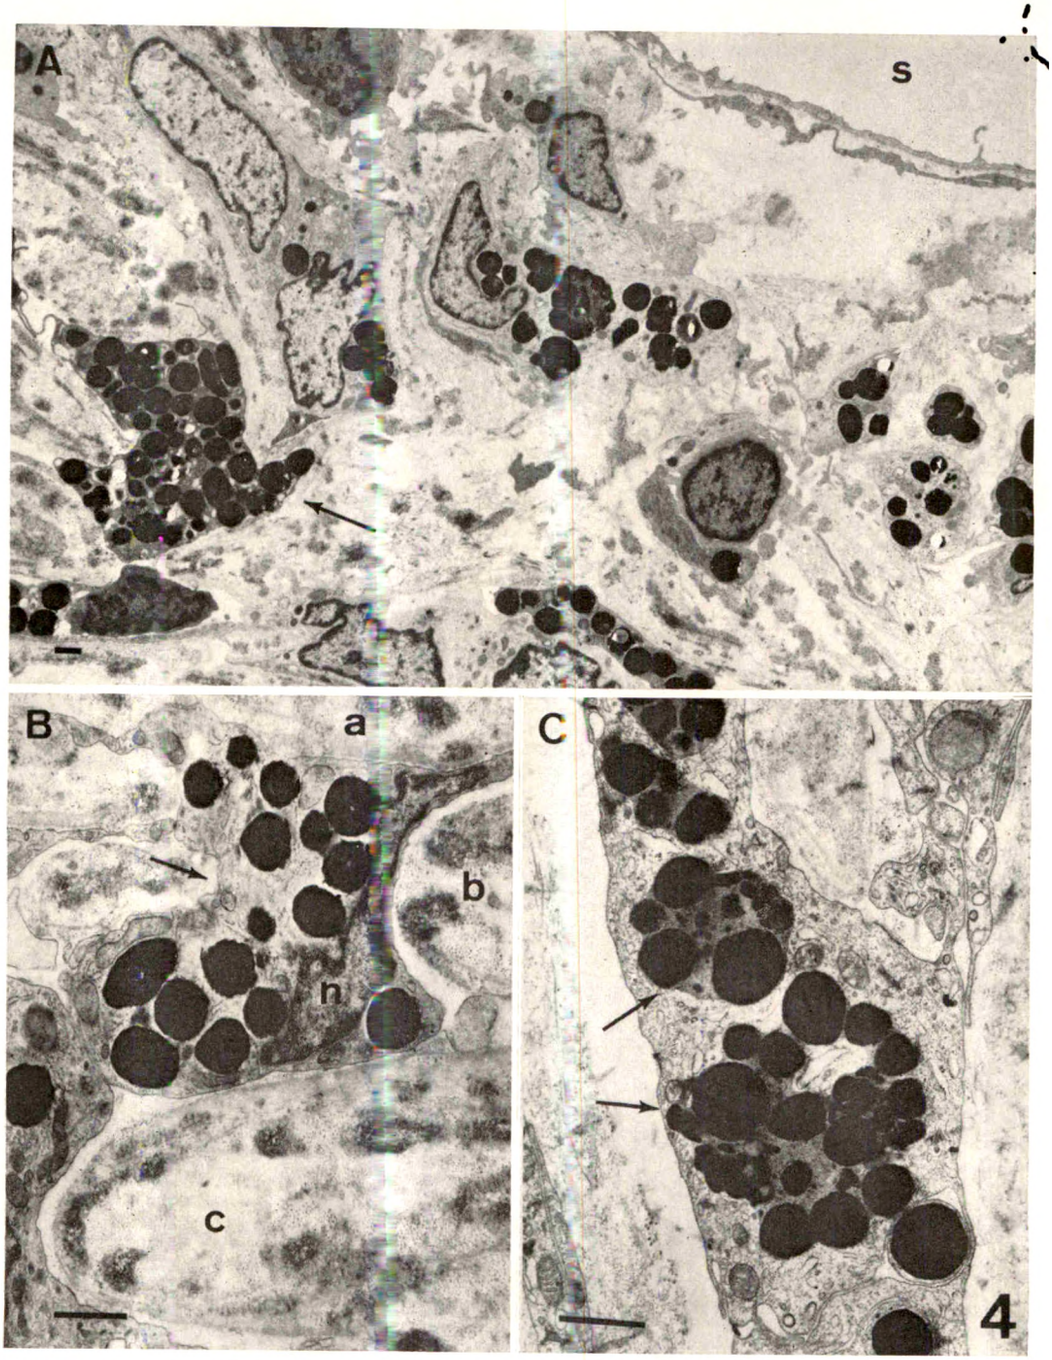

Fig. 4 (Iwamoto, Witmer, and Landolt). (A) A thickened area of the endothelial meshwork or juxtacanalicular connective tissue. Many pigment-containing cells are scattered in this region; one (arrow) assumes a structure similar to the clump cell seen in the iris. Majority of the pigment granules are of large, pigment-epithelial type, (s) Schlemm's canal (×3750). (B) A pigment-containing cell (arrow) in the corneoscleral meshwork. Pigment granules of large epithelial type are distributed throughout the cytoplasm. This cell covers parts of three different trabecular beams (a,b,c), (n) nucleus. (×9300). (C) A macrophage in the trabecular meshwork, containing several groups of pigment granules. Each group is clearly delimited from the surrounding cytoplasm, and composed of pigment granules embedded within a less dense granular matrix (arrow); most pigment granules are of large epithelial type, but some are smaller (×11,700).

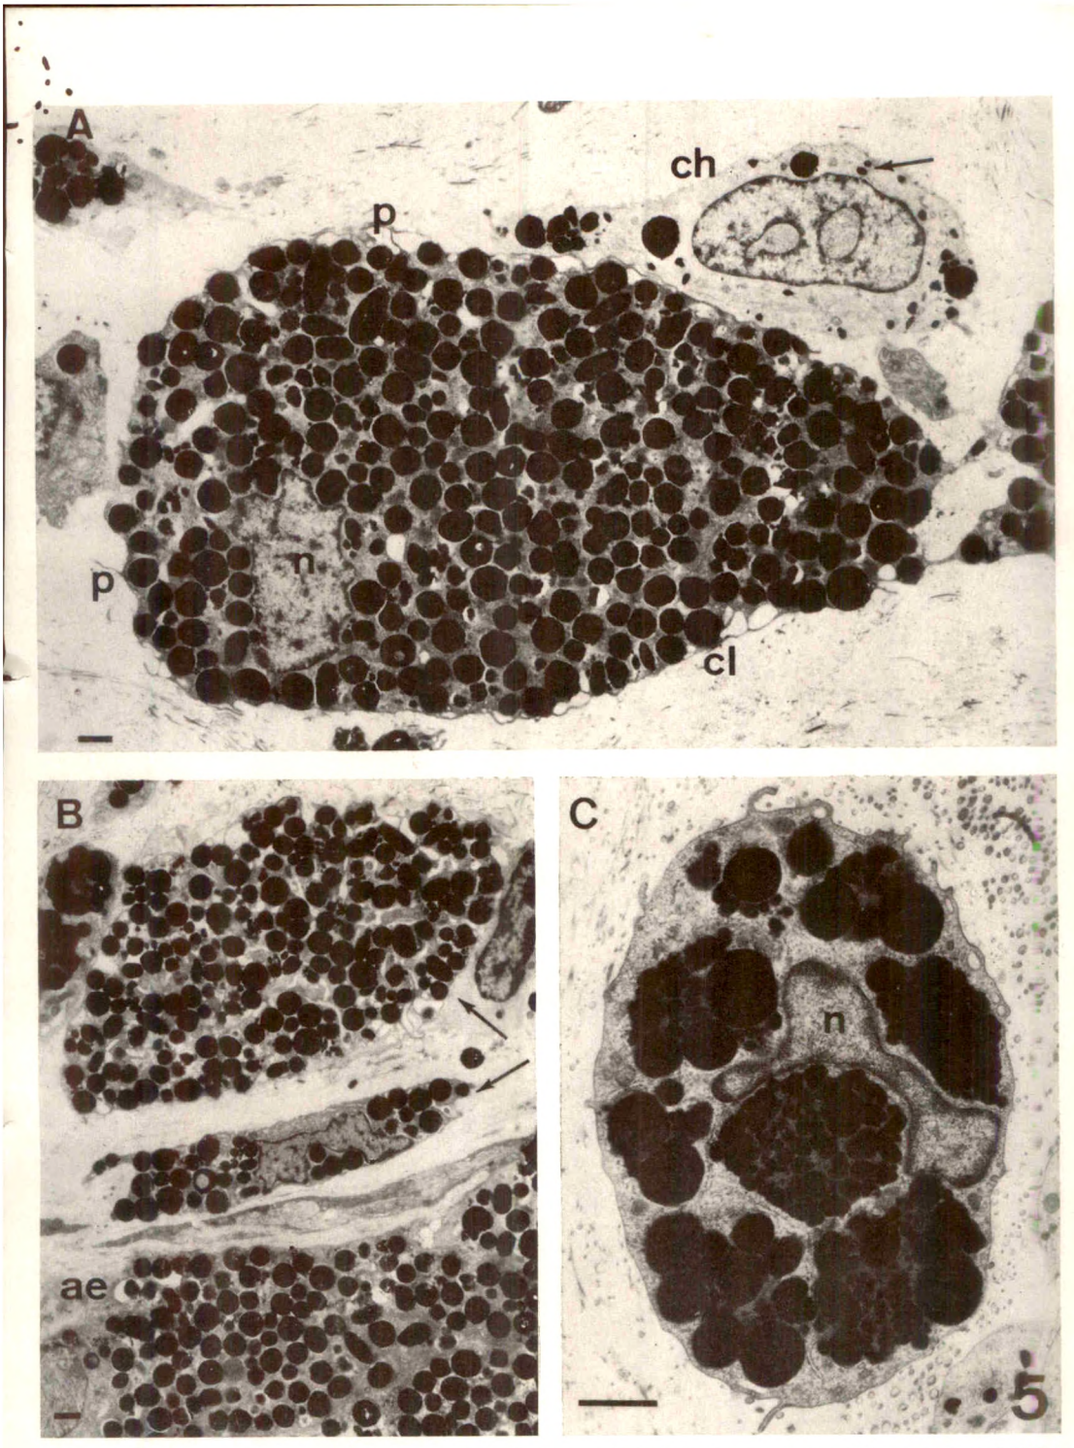

Fig. 5 (Iwamoto, Witmer, and Landolt). (A) A clump cell (cl) in the iris stroma. The cytoplasm is filled with pigment granules mainly of large epithelial type. Thin cytoplasmic processes (p) are on the cell surface; (n) nucleus. This type of clump cell had been classified as the first phase. On the upper right a chromatophore (ch) which has smaller pigment granules (arrow) is seen. This contains some larger granules which may have been phagocytosed. Similar chromatophores with a few large granules have sometimes been seen in this iris (×4600). (B) Two clump cells (arrows) of the same type as in A can be seen in the iris stroma near the anterior epithelial layer (ae) suggesting their derivation from the pigmented epithelial cells (×3230). (C) A pigment-containing cell in the iris stroma. It is filled with aggregates of pigment granules of various sizes, and may belong to the clump cell in the second or third phase. This cell is, however, difficult to distinguish from macrophage; (n) nucleus (×10,500).

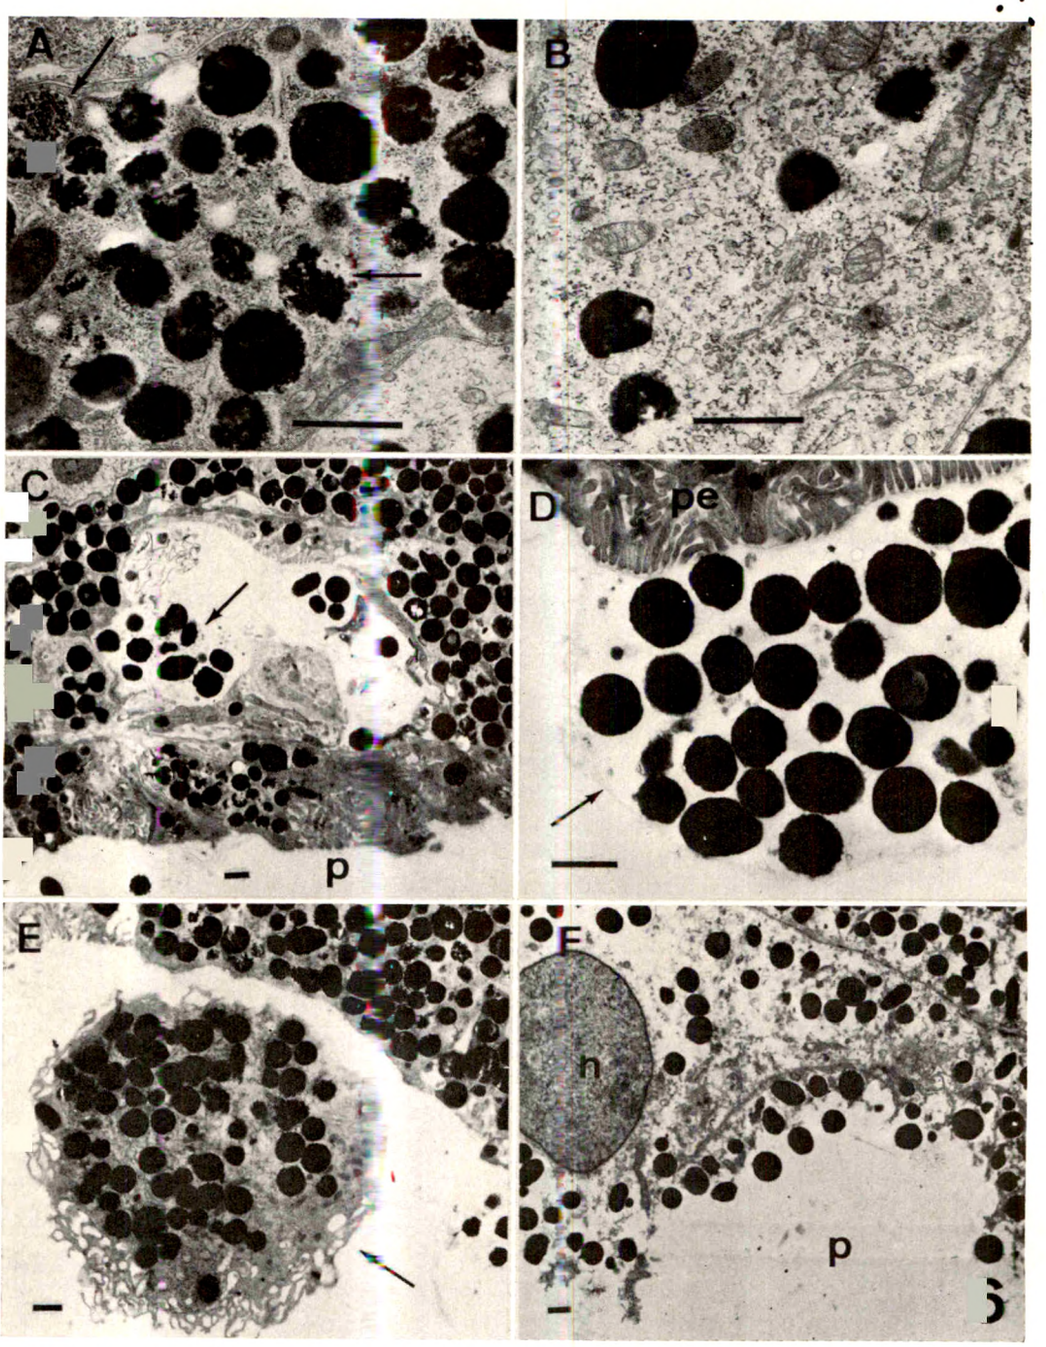

Fig. 6 (Iwamoto, Witmer, and Lambert). Various changes observed in the iris pigment epithelium. (A) Apparently degenerated pigment granules, many of which have lost their round shape, showing rugged surface. Some appear to be disrupted into irregular aggregates of smaller particles (arrows) (×14,700). (B) An area with sparsely distributed pigment granules (×14,700). (C) The cell in the center appears to have been completely degenerated, leaving cell debris and freed pigment granules (arrow). A few granules are in the posterior chamber (p) (×3500). (D) A group of freed pigment granules is surrounded by a membranous structure (arrow), and attached to the posterior surface of the iris pigment epithelium (pe) (×8700). (E) A cell (arrow) resembling the clump cell in the iris stroma is located in the posterior chamber near the iris pigment epithelium (upper portion). This cell may be a pigment epithelial cell released from the epithelial layer (×3750). (F) Most portions of the pigment epithelial cells facing the posterior chamber (p) appear to have been lost. Remaining epithelial cells have degenerative cytoplasms (×3,060).

# PATHOPHYSIOLOGY OF THE DISTAL PORTION OF THE OPTIC NERVE
## IV. Local Temperature as a Measure of Blood Flow

J. Terry Ernest, M.D., and Albert M. Potts, M.D.
*Chicago, Illinois*

During the past several years there has been a concentrated effort to obtain experimental evidence which would elucidate the pathogenesis of glaucomatous optic nerve disease. It has been shown that there is a decrease in vascularity of the optic disk in glaucomatous eyes.[1-3] This decrease in vascularity of the papilla is believed to result from the elevated intraocular pressure.[4,5] Animal experiments have demonstrated that acute increases in the intraocular pressure result in vascular compromise of the distal portion of the optic nerve.[4,6] The retinal circulation, however, and more specifically the radial peripapillary capillaries of the retina,[7] are not affected by intraocular pressures which compromise the choroidal vasculature and its optic nerve branches.[5,8]

This study was undertaken to further analyze the changes in the vascularity of the distal portion of the optic nerve secondary to variations in the intraocular pressure.

### Materials and Methods

Eighteen adult cats, both male and female of mixed breeds, were used. The animals ranged in weight from 2.3 to 3.6 kg and they were anesthetized with sodium pentobarbital, 30 mg/kg administered intraperitoneally. The anesthesia was maintained by supplements of sodium pentobarbital administered intravenously. A tracheostomy was performed and the animal's breathing was assisted by a respirator (Harvard, model 672). The arterial blood pressure was monitored from a cannulated femoral artery with a pressure transducer (Statham, model P23AC) and recorded on one channel of a polygraph (Grass, model 5D).

A lateral canthotomy was done and the eye was stabilized and cannulated by the method we have previously described.[9] Briefly, it consisted of attaching a Flieringa ring to the globe and then using rods to support the ring. The intraocular pressure was regulated through an anterior chamber cannula connected to a saline reservoir by polyethylene tubing. A second pressure transducer whose output was recorded by another channel of the polygraph was inserted in the system to monitor the intraocular pressure levels.

A micromanipulator (Brinkmann, model RP-IV/L) was used to pass a 22-gauge thin-wall needle containing a trocar through the cornea and lens into the vitrous cavity. The trocar was then removed and a copper-constantan thermocouple inserted in its place. The experiment was in two parts. In Part I, actual temperature measurements were made inside the eye. In Part II, relative temperature measurements were made with both the sensor and its reference junction within the eye.

A 30-gauge thermocouple probe (Ultra-miniature Thermocouple Needle, High Temperature Instruments Corp.) was used for the actual temperature measurements in Part I of the study and for half of the relative measurements in Part II of the study. The cooper and constantan wires from the fused junction at the tip of the needle passed through a double-bore quartz tube. The quartz tube was housed within a 30-gauge needle. In Part I, actual temperature measurements were obtained by directing the needle through the eye and into the optic

disk. The reference junction was placed in refluxing dichloromethane. The boiling point of dichloromethane, dependent on the atmospheric pressure, is approximately 40°C. The temperature was measured to the nearest 0.1°C with a liquid-in-glass thermometer.

In Part II, the reference junction was placed inside the eye and relative temperature measurements were obtained. The cannula through the cornea and lens into the vitreous was increased in diameter to 19-gauge and two techniques of relative temperature measurement were employed. In the first technique, two of the needle probes described above were inserted into the eye. The two junctions were connected in series so that the probes referenced each other. A series of measurements were obtained with one probe in the vitreous cavity and the second probe on the optic disk. Another series of measurements were made with one junction on the optic disk and the other pushed into the nerve substance posterior to the lamina cribrosa.

In the second technique of relative temperature measurement a specially designed twin junction probe was used (Differential Temperature Probe, High Temperature Instruments Corp.). The copper and constantan wires of each fused junction passed through double-bore quartz tubes as described above for the single probes. However, there were two such double-bore tubes placed within an outer quartz envelope (Fig. 1). This quartz envelope was then cemented inside a 23-gauge stainless steel needle. The assembled probe is illustrated at the bottom of Figure 1. The first junction was placed at the tip of the probe and connected in series with the second junction which was fixed 2 mm behind it.

The EMFs produced by temperature differences between junctions were amplified in each case by a microvoltmeter (Keithley, model 150B) and recorded by the polygraph.

In conducting the research described in this report, the investigators adhered to the "Guide for Laboratory Animal Facilities and Care," as promulgated by the Committee on Revision of the Guide for Laboratory Animal Facilities and Care of the Institute of Laboratory Animal Resources, National Academy of Sciences—National Research Council.

## Results

*Part I, temperature measurements*—The reference junction for the 30-gauge thermocouple probe was placed in boiling dichloromethane. EMF measurements were then made for air 1 cm in front of the eye, on the cornea, in mid-vitreous, on the optic disk, and in the nerve substance posterior to the lamina cribrosa. In Table 1 measurements from three animals are recorded. The EMF-temperature conversion was made on the basis of the slope of a standard curve at 40°C.[9] This approximation is 42 microvolts per degree centigrade. It is important to note that in all three experiments there is a 0.1°C temperature increase across the lamina cribrosa.

Following the temperature determinations across the eye, the thermocouple was placed on the optic disk and the intraocular pressure elevated and maintained above the systemic systolic blood pressure. Figure 2 is a

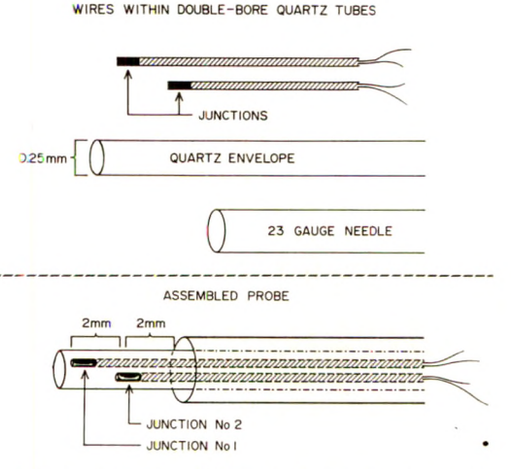

Fig. 1 (Ernest and Potts). Drawing of the differential temperature probe showing the positions of the two copper-constantan thermo-elements (U.S. Army photograph).

TABLE 1

TEMPERATURE MEASUREMENTS
(degrees centigrade)

| Cat No. | Body | Air | Cornea | Vitreous Cavity | Optic Disk | Optic Nerve |
|---|---|---|---|---|---|---|
| 610 | 38.3 | 21.0 | 29.9 | 36.7 | 37.6 | 37.7 |
| 616 | 38.9 | 21.4 | 29.7 | 36.0 | 37.6 | 37.7 |
| 619 | 40.0 | 21.2 | 30.0 | 36.1 | 37.7 | 37.8 |

photograph of the polygraph record obtained from one such experiment. The temperature decreased from approximately 37.7 to 36.4°C over a period of approximately two minutes.

*Part II, differential temperature measurements*—Differential temperature measurements were obtained by two methods. In the first method, two 30-gauge thermocouple probes were inserted into the eye. One needle junction was placed on the optic disk and the second needle junction pulled back 2 mm into the vitreous cavity. The intraocular pressure was then acutely elevated to approximately the level of the systemic diastolic blood

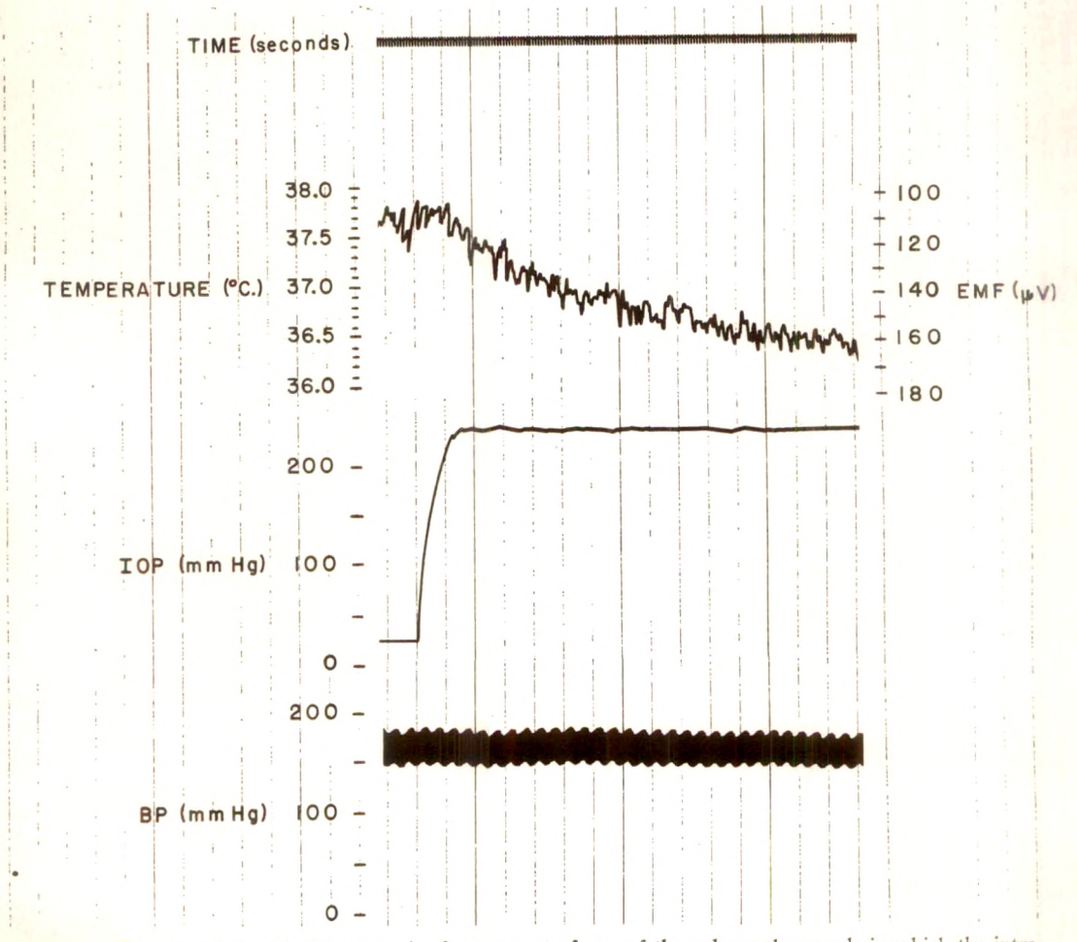

Fig. 2 (Ernest and Potts). Photograph of a segment of one of the polygraph records in which the intraocular pressure was raised above the level of the systemic systolic blood pressure (U.S. Army photograph).

pressure. This resulted in a relative decrease in the temperature of the sensor on the optic disk relative to the sensor in the vitreous cavity (Fig. 3-a). The position of the probe was then changed. The first sensor which had been on the optic disk was pushed through the lamina cribrosa into the nerve substance. The second sensor which had been in the vitreous cavity was placed on the optic disk. The intraocular pressure was again elevated resulting in a relative cooling of the second sensor which was now on the optic disk (Fig. 3-b).

In the second method used to make differential temperature measurements, the specially constructed two-junction probe was inserted into the eye. Junction No. 1 of the probe was placed on the optic disk and the intraocular pressure elevated to approximately 90 mm Hg. This level is considerably below the systemic diastolic blood pressure. Figure 4 is a photograph of one of the polygraph records from this series of experiments. The temperature of junction No. 1 on the optic disk decreased 0.08°C and then started a slow recovery. When the intraocular pressure was normalized, there was an overshoot followed by a slow return to initial levels. The overshoot means that for approximately 15 seconds the optic disk was warmer than control levels.

In the final series of experiments the differential probe was used but a bias voltage was added to the circuit so that the microvoltmeter could be set to a high gain of 3 microvolts, full scale. During brief periods of both temperature and electrical stabilization, it was possible to measure the effect of minimal variations in the intraocular pressure. Figure 5 is a photograph of a segment of one of the polygraph records from this series of experiments. The intraocular pressure was leveled at 17.5 mm Hg and when the temperature became stable, the intraocular pressure was raised 10 mm Hg. It is evident from the record that there was a simultane-

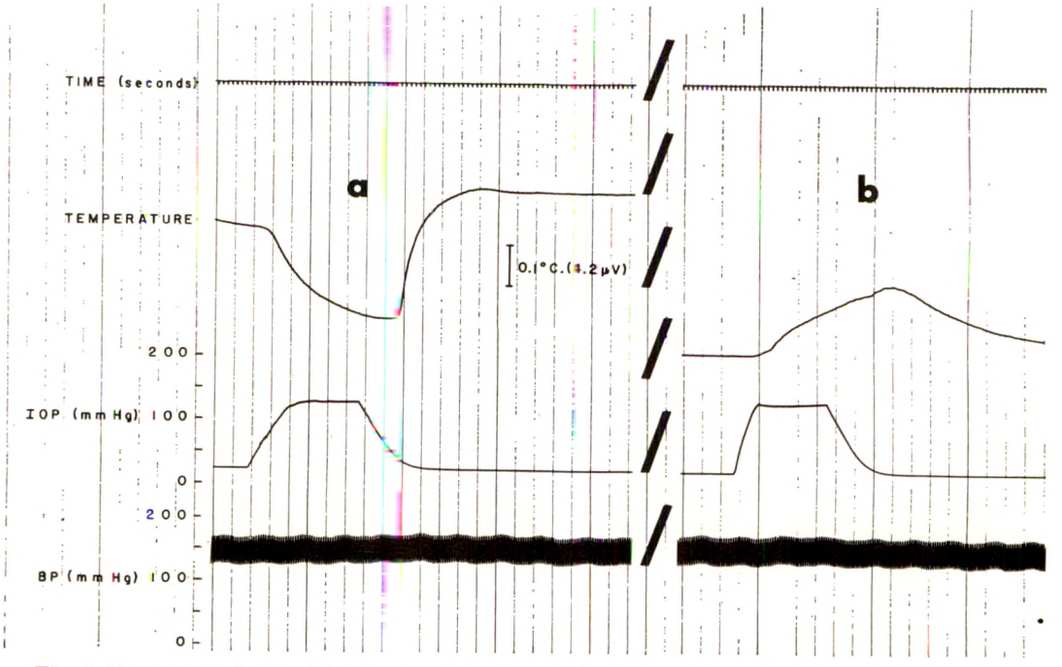

Fig. 3 (Ernest and Potts). Photograph of two segments of one of the polygraph records in which the intraocular pressure was elevated. In the first segment (a) one junction was on the optic disk and the reference was in the vitreous. In the second segment (b) the reference junction was on the optic disk and the other junction 2 mm posterior to the lamina cribrosa (U.S. Army photograph).

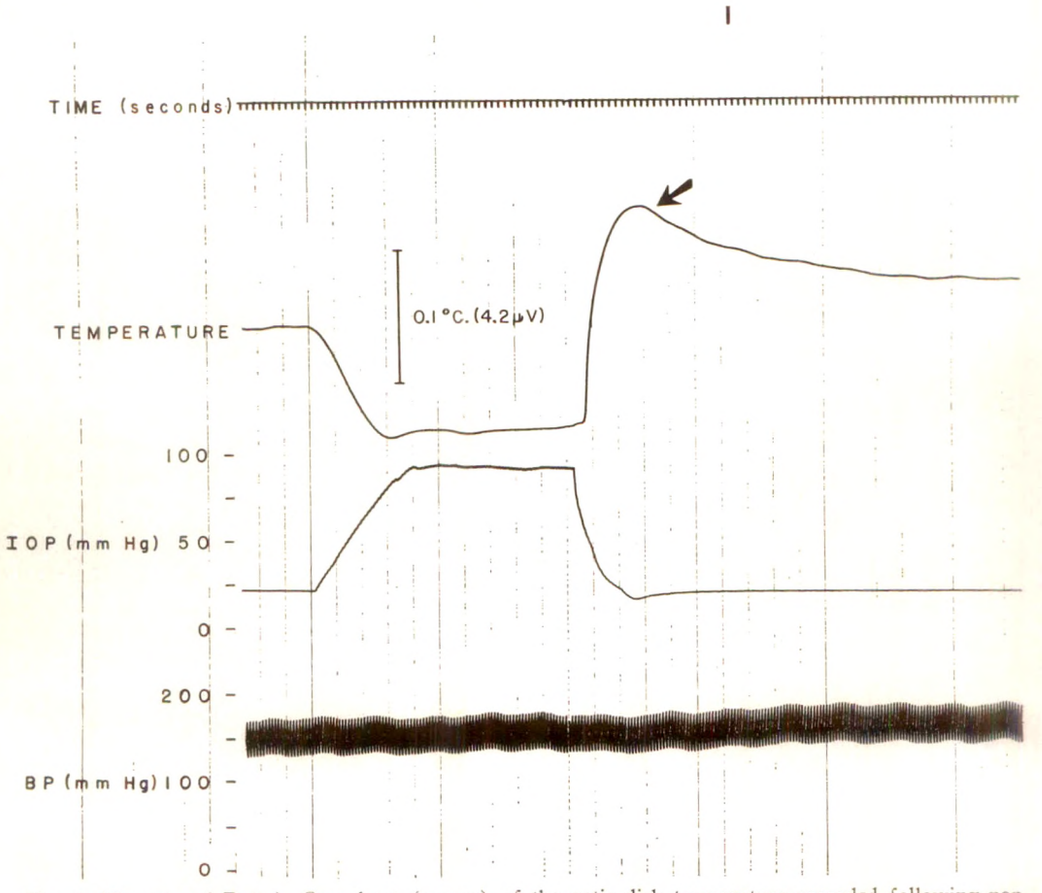

Fig. 4 (Ernest and Potts). Overshoot (arrow) of the optic disk temperature recorded following normalization of an elevated intraocular pressure (U.S. Army photograph).

ous decrease in the temperature of the optic disk. At the end of approximately one minute the pressure was returned to its original level and the optic disk temperature returned to slightly higher than its base line level. Experiments were also carried out in the opposite direction. Following several minutes with the intraocular pressure leveled at 17.5 mm Hg, it was decreased 5 mm Hg. This resulted in a transient increase in the temperature of the optic disk.

## Discussion

With the cornea exposed to the air the globe constantly lost heat. The methods of heat loss from the various eye tissues and the resulting heat gradient are illustrated in Figure 6. Since the blood, heated by the metabolic processes of the entire body, is the source of heat, the highly vascularized posterior segment has the highest temperature. Schwartz and Feller[11] have shown that the optic disk is at a higher temperature than the vitreous. The highest temperature we recorded was in the nerve substance 2 mm posterior to the lamina cribrosa. The amount of heat produced by the tissue of the disk itself is negligible in comparison with the heat conveyed to the disk by the arterial blood. The heat is transferred by conduction through the vitreous, lens, and aqueous to the cornea. The small amount of heat radiated by the optic disk due to its temperature of approximately 310° Kelvin is in the infrared region of the electromagnetic spectrum. It is thus absorbed by the high water

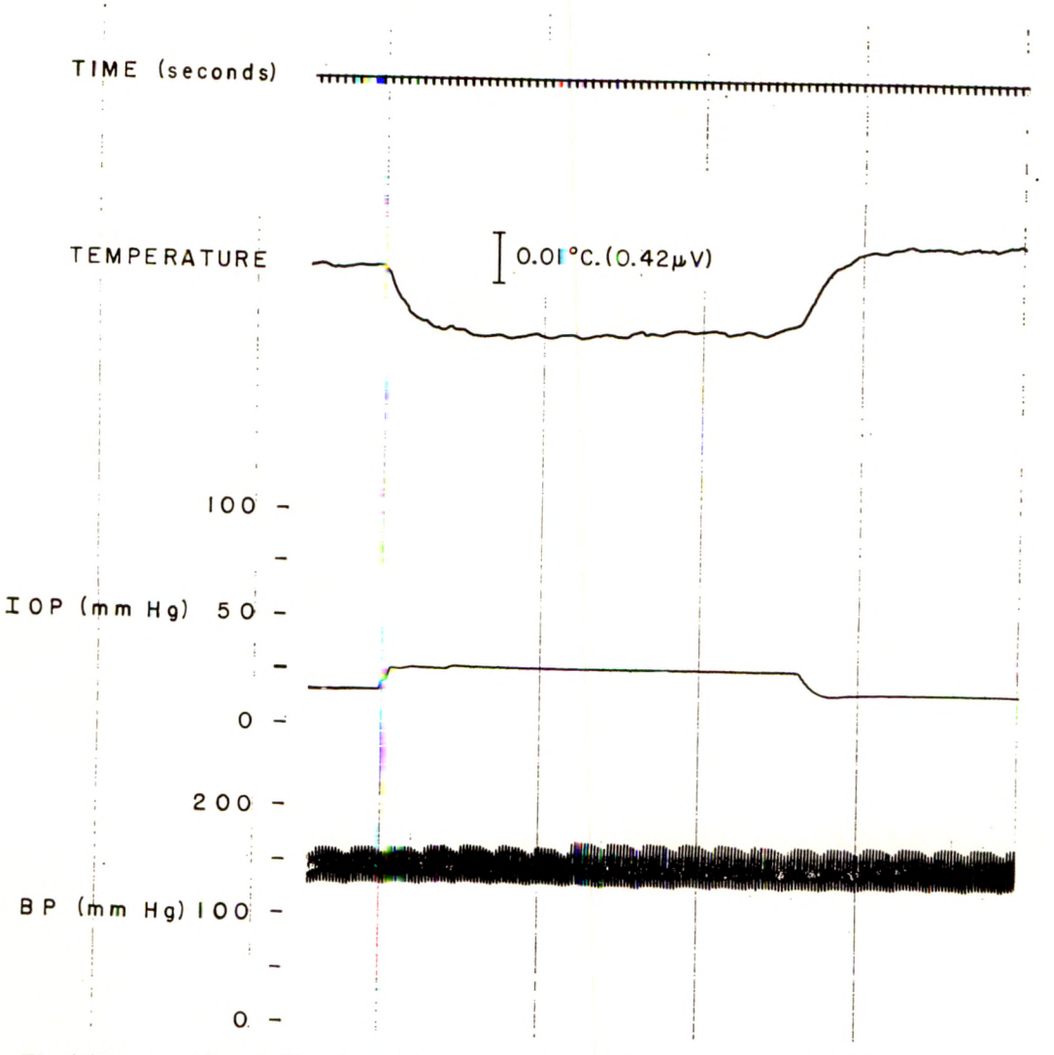

Fig. 5 (Ernest and Potts). The microvoltmeter was adjusted for the maximum amplification possible while still maintaining an acceptable signal-to-noise ratio. This made it possible to record the optic disk temperature decrease which accompanied a 10 mm Hg increase in the intraocular pressure (U.S. Army photograph).

content of the ocular media. The transfer of heat through the aqueous is due to convection as well as conduction. The heat transfer by convection is due partly to aqueous flow in an anterior direction and partly to thermal circulation within the aqueous.

The cornea's heat loss to the atmosphere is the reason for the heat gradient within the eye. When the eyelids are closed so that heat is not transfered from the cornea, there is no longer a heat gradient within the eye.[12] The cornea, like all bodies at a higher temperature than their environment, loses heat by radiation, conduction and convection. Further, because of tear film evaporation, the cornea is also cooled by vaporization. Mishima[13] and Iwata and associates[14] have shown that there is an evaporation of between 2.2 and 3.7 μl/hour/cm$^2$ of cornea. The heat of vaporization of water is 0.54 calories/mg or μl. Thus the cornea loses approximately 1.5 calories/hour by vaporization. If we assume that the

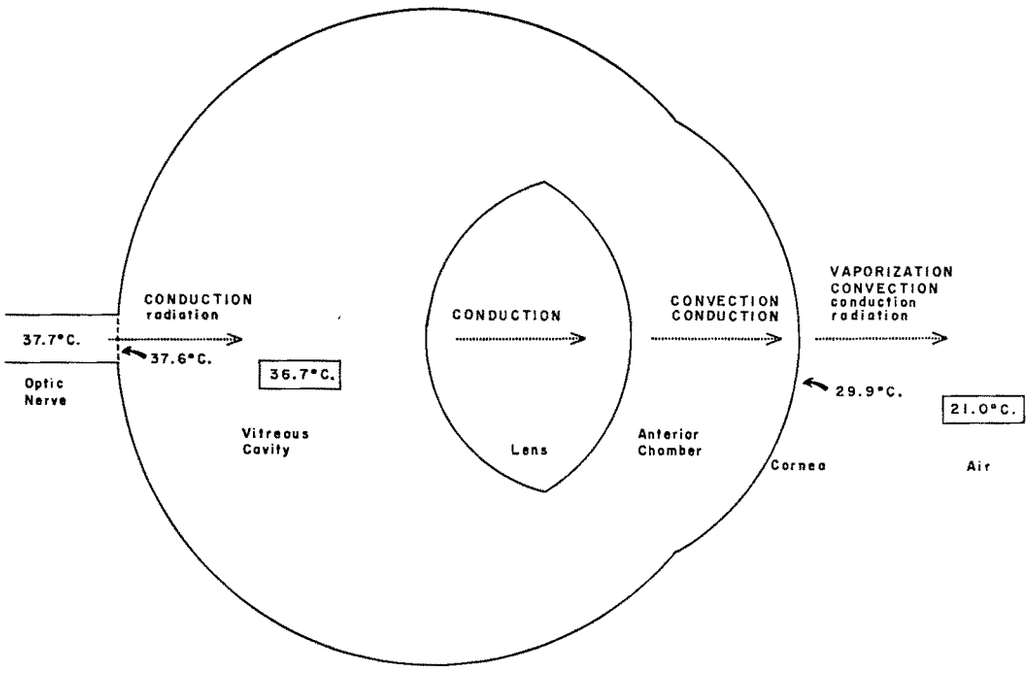

Fig. 6 (Ernest and Potts). Illustration of the temperature gradient within the eye (U.S. Army photograph).

cornea is a blackbody, then the rate of heat loss by radiation is proportional to the area and the fourth power of the absolute temperature (Stefan-Boltzmann law). For the case of small temperature differences, however, the rate of cooling is proportional to the difference in temperature between the cornea and its surroundings. Further, the net rate at which the cornea loses heat by radiation depends on the difference between the rate it receives radiant energy and the rate at which it loses radiant energy, and thus the resultant is variable and of an insignificant magnitude. The transfer functions for convection losses are complicated since they depend on both the conduction of heat into the air in contact with the tear film and the motion of this air. The loss of heat from the cornea to the air by conduction is of small magnitude since the thermal conductivity of air is negligible. The movement of the air in contact with the tear film is obviously variable. In our experiment we tried to minimize air movement so that the only convection currents were natural ones. During normal awake activity with continual blinking, however, heat exchange by forced convection may become a major source of corneal heat loss.

The optic disk temperature depends on two factors. First, the rate of heat brought to it by the blood and second, its rate of heat loss into the eye. If either of these factors is altered, the temperature of the optic disk will change. In our experiment the rate of heat loss was held constant. Thus the changes observed in the optic disk temperature were due to changes in the amount of heat brought to the disk by the blood. The temperature of the blood was constant during the experiment. Therefore, changes in the temperature of the optic disk were due to alterations in blood flow (volume/unit time). There were either changes in the blood volume of the vasculature of the optic disk, changes in the rate of blood flow or a combination of both. It was not possible to determine if only one or both of these parameters was changing.

Further, although the EMF of the thermocouple we used was linear over the range of temperatures measured, it does not mean that there was a linear relationship between the temperature of the optic disk and changes in its blood flow. Nonetheless it was possible to make a qualitative assessment of the blood flow of the optic disk. The records (Figs. 2 through 5) show that the systemic arterial blood pressure remained constant. If it is assumed that the systemic venous blood pressure remained constant, then the decrease in temperature caused by an increase in intraocular pressure must have been due to a mechanical interference with the optic disk circulation. The fall in the temperature of the optic disk when the intraocular pressure was elevated to a level above the systemic systolic blood pressure (Fig. 2) was fitted well by an exponential curve of the form ($y = e^{-ax}$). The $a$, which reflects the rate of temperature decay, was 0.02. This exponential decrease in optic disk temperature from 37.7 to 36.4°C represents the maximum driving force available for our probe temperature measurements over the time periods studied.

A possible source of error in the optic disk temperature measurements was the relative movement of the probe when the intraocular pressure was elevated. With an increase in the intraocular pressure, the internal diameter of the globe enlarged due to compression of the uveal tissue. The probe, however, was not fixed to the globe and so moved slightly with respect to the optic disk. To determine the effect of this change in position of the probe with respect to the disk tissue, the following experiment was performed. The intraocular pressure was maintained at a constant level and the probe was moved up mechanically an amount approximating its relative movement when the intraocular pressure was maximally elevated. The result was a rise of approximately 1% in the recorded temperature. Since this temperature change was small and in a direction opposite to that observed when the intraocular pressure was increased, the movement of the probe relative to the optic disk was considered negligible.

The primary problem was to measure the small changes in temperature associated with minimal alterations in the intraocular pressure. For this purpose, we placed the reference junction physically close to the measuring junction of the probe. The advantage of this technique was that the sensitivity to temperature change was greatly increased. With the junctions at approximately the same temperature, both the EMF generated and the bias required to balance it, were low. Consequently, the electrical noise was minimal and the relative "gain" of the amplifier could be markedly increased. It is important to note however, that when the reference junction was placed within the eye, only transient changes in the intraocular pressure could be studied. Following an increase in the intraocular pressure and the resultant fall in optic disk temperature, the new lower temperature level gradually cooled the reference junction. Thus the original temperature gradient was restored and the EMF returned to the initial level even though the intraocular pressure elevation was maintained.

The probes were placed in contact with the center of the optic disk. The diameter of the cat's optic disk is approximately 1 mm. Nonetheless, the thermocouples could have been monitoring peripapillary temperature changes as well as changes occurring in the distal segment of the optic nerve. To make certain this was not the case, the temperature sensor was placed in several locations on the peripapillary retina and the intraocular pressure elevated. The resulting temperature changes differed in three ways from those occurring when the probe was in contact with the center of the optic disk. First, for the same increment increase in the intraocular pressure, the percentage temperature decrease was less when the probe was in contact with the peripapillary retina than when it was in contact with the optic disk. If the optic disk was acting as a heat sink for the

peripapillary retina and choroid, the percentage changes would be approximately equal. Second, the latencies between the time the intraocular pressure was increased and the temperature decreased were exactly the same whether the probe was on the optic disk or the retina. If the optic disk was only reflecting temperature changes of the retina and choroid, there would be a relative delay in its temperature change with an increase in the intraocular pressure. Third, there was only a small overshoot of the peripapillary retinal temperature when the intraocular pressure was normalized while the overshoot of the optic disk temperature was a minimum of three times greater.

The use of the two separate thermocouple probes made it possible to compare changes in blood flow in the optic disk across the lamina cribrosa. Elevation of the intraocular pressure caused a decrease in blood flow of the optic disk (Fig. 3-a). When the probe was pushed through the lamina cribrosa and the reference junction moved on to the disk, the decrease in blood flow with an elevation in the intraocular pressure again occurred at the disk resulting in a reversal of the temperature curve (Fig. 3-b). The junction which had been in the vitreous and consequently unaffected by a change in optic disk blood flow the first time was now on the optic disk. It was thus cooled by a decrease in blood flow with the elevation in the intraocular pressure. The junction which had been on the optic disk was now in the distal segment of the optic nerve posterior to the lamina cribrosa surrounded by vessels which were not directly affected by the elevation in the intraocular pressure. We have previously shown that the intraocular pressure is not transmitted posterior to the lamina cribrosa.[9] When the reference junction is posterior to the lamina cribrosa, however, temperature changes with alterations in the intraocular pressure were slower and of a smaller amplitude than those measured with the reference junction in the vitreous. This means that there was a slight decrease in temperature of the region posterior to the lamina cribrosa during the periods of intraocular pressure elevation. There are two possible explanations for this. First, the intraocular pressure has an effect posterior to the lamina cribrosa. We have previously shown that this is not the case even when a 30-gauge cannula is in place through the lamina cribrosa.[9] Second, the source of blood for the nerve substance immediately posterior to the lamina cribrosa is the intraocular vasculature which is subjected to the intraocular pressure. Thus, when the intraocular pressure was elevated and the blood flow of the optic disk was compromised there was also a relative decrease in the blood flow and thus the temperature of the nerve substance posterior to the lamina cribrosa. This would also account for earlier findings obtained by contrast material injection experiments.[4,6] When the intraocular pressure was elevated and contrast material was injected into the ocular vasculature, both the optic disk vessels and a variable segment of the optic nerve immediately posterior to the lamina cribrosa showed a filling defect.

To obtain the maximum sensitivity possible, the differential thermocouple with its fixed probe and reference junctions was used. When the intraocular pressure was returned to base line levels following elevations of approximately 90 mm Hg, there was a transient overshoot of the blood flow in the optic disk above control levels (Fig. 4 arrow). Bill[15] has shown that there is a reactive hyperemia of the uveal blood flow following periods of increased intraocular pressure. Why there should be a reactive hyperemia following normalization of the intraocular pressure is not clear. Whether there is a depletion of oxygen in the optic disk tissue with a resultant effect on the vasculature is under study at this time.

In the final series of experiments we demonstrated that an increase in the intraocular pressure of as little as 10 mm Hg caused a decrease in the optic disk blood flow (Fig. 5). For the reasons discussed above, it could not be determined if the optic disk

blood flow eventually compensated for small increases in the intraocular pressure. It is significant, however, that intraocular pressures which are definitely in the physiological range, decrease the optic disk blood flow. Further, this is the first demonstration that changes in the intraocular pressure of the order of magnitude of those seen in chronic open angle glaucoma in man, do indeed decrease the blood flow in the optic disk.

## Summary

Thermocouple probes with maximum diameters of 0.3 mm have been used to measure the temperature changes in the distal segment of the optic nerve of the cat secondary to changes in the intraocular pressure. With all thermal factors (ambient temperature, body temperature, evaporation rate from eye) held constant, small changes in blood flow are detectable as changes in temperature at the thermocouple tip.

Using this system, small elevations in intraocular pressure—well within the range of the elevations found in open angle glaucoma—cause measureable decrease in blood flow as reflected by decrease in temperature.

Conversely, in our experimental system, normalization of the intraocular pressure after relatively large elevations of pressure results in hyperemia of the nerve head and a corresponding temperature increase.

# RESISTANCE TO AQUEOUS OUTFLOW IN THE RHESUS MONKEY EYE

W. S. PETERSON, B.A., V. L. JOCSON, M.D., AND M. L. SEARS, M.D.
*New Haven, Connecticut*

On the basis of current evidence, it is generally held that in human eyes the primary site of resistance to aqueous outflow lies in the trabecular meshwork. In monkey eyes, however, results of investigations attempting to localize the site of maximal resistance have prompted varied conclusions. The present work, utilizing Grant's experimental approach in enucleated human eyes,[1,2] was therefore undertaken to gain further information on the resistance offered by the various portions of the aqueous outflow pathway in enucleated rhesus monkey eyes, information which would be closely comparable with that previously obtained in human eyes.

## MATERIALS AND METHODS

Experiments were done on 50 ostensibly normal adult rhesus monkey eyes which were enucleated at sacrifice, stored in a cool, moist chamber, and used within two days postmortem. Determinations of facility and resistance were made using the constant pressure perfusion method of Grant.[1,2] A 5.0 mm trephine hole was made in the cornea and, after a radial iridotomy was made to prevent artificial deepening of the anterior chamber, the eye was connected to the perfusion-recording system by means of a stainless steel fitting. Perfusion was done at room temperature using 0.9% saline.

In order to assess the degree of resistance offered by different portions of the aqueous outflow pathway, perfusion was carried out before and after certain dissections done under the Zeiss operating microscope:

A. To study the resistance offered by the outermost portions of the outflow channels, 10 eyes were initially perfused with 5-6 mm of perilimbal conjunctiva remaining, with 10-12 mm of recti muscles attached, and with subconjunctival and episcleral tissues present (baseline). After steady state was attained, the conjunctiva was cut away close to the limbus, the muscles cut at their scleral insertions, and the subconjunctival and excess episcleral tissues removed in 360 degrees leaving only a very thin layer of episclera containing blood vessels. The eyes were then reperfused and changes in facility and resistance determined.

B. To assess the resistance offered by the portions of the aqueous outflow pathway in the outer sclera, 10 eyes were initially perfused as described above and then reperfused after the outer one-half to two-thirds of the perilimbal sclera over Schlemm's canal had been shaved away in 360 degrees.

C. To determine the resistance to aqueous outflow presented by the trabecular meshwork, 28 eyes were perfused before and after trabeculotomy was done over 5% (four eyes), 25% (eight eyes), 50% (six eyes), and 100% (10 eyes) of the total circumference. Two of the 5% trabeculotomies were done in the superior quadrant and two in the lateral quadrant, whereas four of the 25% trabeculotomies were done in the superior quadrant and four in the medial quadrant. All six of the 50% trabeculotomies were over both superior and medial quadrants. Trabeculotomy was accomplished directly through the corneal trephine opening using a Sato corneal knife.

At the conclusion of each experiment, perfusion with fluorescein-tinted fluid was carried out under black light in order to study the patterns of aqueous outflow from the

eye. Specimens were then fixed in formaldehyde, embedded in paraffin, sectioned anteroposteriorly at regular intervals, stained, and examined microscopically. Where trabeculotomy was done in only a part of the circumference, sections were cut to include both operated and nonoperated angle on the same slide.

Analysis of the data and plotting of the graphs by standard statistical techniques were carried out using an IBM 7094/7040 direct coupled computer system.

## Results

Control perfusions were carried out in six eyes to evaluate the effects of cold storage, artificial manipulation, and removal and reinsertion of the corneal adapter. In one eye the measured facility value increased by 0.02 μl/minute/mm Hg, in two eyes it decreased by 0.01 μl/minute/mm Hg, and in three eyes the facility did not change.

The results of the experiments of series A are presented in part A of Table 1. The portions of the outflow channels in the conjunctiva, episclera, and proximal extraocular muscles accounted for very little, if any, of the outflow resistance under the experimental conditions.

In the experiments of series B, the operative procedure resulted in a moderately deep circumferential perilimbal scleral defect, in the depths of which could be seen some of the exiting aqueous channels in cut cross-section. Fluorescein perfusion showed colored fluid to exit only from about 20 such cut vessels, and there was no evidence that Schlemm's canal had accidentally been exteriorized. Histologic study of these eyes revealed that the operation had removed the outer one-half to two-thirds of the sclera over Schlemm's canal. The results of facility and resistance determinations in these experiments, tabulated in part B of Table 1, show that approximately 10-15% of the outflow resistance can be localized to the outer sclera removed.

For the trabeculotomies of series C, a surgically satisfactory view of the angle was obtained without abnormal depression of the iris (Fig. 1). The knife tip, which presented no scleral cutting edge, was positioned without difficulty and incision into the trabecular wall of Schlemm's canal was done with relative ease. Different eyes showed variations in their resistance to the actual cutting of the meshwork, however. Where trabeculotomy was done, the glisten-

* Student's t-test performed on paired differences between baseline and postoperative facility values or resistance values.

ing white scleral wall of the canal, bordered by trabecular fragments superiorly and inferiorly, became clearly visible (Fig. 2). This was particularly evident when the edges of the incision were spread slightly apart during the operative procedure. Even in a completely relaxed state, however, the lips of the incision generally did not appear to close. Grossly, no cyclodialysis resulted from these operations.

The results of this third series of experiments are summarized in part C of Table 1. In every case trabeculotomy was followed by a significant decrease in resistance (increase in facility), and the data suggest that the trabecular meshwork as a whole accounts for about 60-65% of the total resistance to aqueous outflow. A great similarity between the two eyes of any given animal was found, both in the initial facility and in the percent of decrease in resistance following the same degree of trabeculotomy. When either 5% or 25% trabeculotomy was done in different quadrants, no significant differences were observed in the mean decrease in resistance following the same percentage of trabeculotomy.

Observations of fluorescein perfusion of trabeculotomized eyes were rather variable, and clear-cut patterns were difficult to identify. Earliest and greatest outflow of colored fluid, however, was not always observed to be through aqueous veins draining the quadrants in which trabeculotomy had been done, although such a pattern was encountered about half of the time. Moreover, outflow was most often earliest and greatest in the superior, inferior, and (to a somewhat lesser extent) medial quadrants, irrespective of the site or extent of trabeculotomy. Flow through aqueous veins in the lateral quadrant was invariably slight. From 30-45 minutes after the start of fluorescein perfusion, by which time aqueous veins of all quadrants were draining fluorescein, examination through several equatorial scleral windows revealed no fluorescence in the suprachoroid to indicate the presence of a cyclodialysis. Also, no colored fluid was seen to exit from any of the vortex veins.

Microscopic examination of sections of the angle (Fig. 3) revealed that the trabecular meshwork had been successfully opened or removed in those areas operated upon. No histologic evidence of damage to the scleral wall of Schlemm's canal was found, the endothelial lining appearing to be intact, and

no microscopic evidence of cyclodialysis was seen.

## Comment

The findings that very little resistance to aqueous outflow can be localized to the aqueous channels in the conjunctiva, subconjunctiva, episclera, and recti muscles, and that only 10-15% of the outflow resistance can be accounted for by the outer one-half to two-thirds of the perilimbal sclera, point out that the site of maximal resistance to outflow in the normal enucleated rhesus monkey eye must reside either in the deeper intrascleral portions of the aqueous outflow vessels or in the region of the trabecular meshwork. That the trabecular meshwork is in fact responsible for the principal resistance is indicated by the consistent results of the trabeculotomy experiments, which showed that 60-65% of the total resistance to outflow is accounted for by this structure. As regards the remaining 25% of the resistance, this must reside within the inner one-third to one-half of the sclera, either principally at the ostia of the collector channels directly draining Schlemm's canal or distributed along the many intrascleral vessels of the collecting system. Which possibility is more nearly correct is impossible to state, though the finding of a small but significant resistance in the outer sclera suggests the latter.

Gross and microscopic observations supporting the actual accomplishment of trabeculotomy without damage to the scleral wall of Schlemm's canal and without cyclodialysis have been presented. While it is probably impossible absolutely to exclude microscopic trauma to the outer wall of the canal, as serial sectioning was not done, it is just as dif-

ficult to conceive how such minute damage, not evident in any of the representative sections, could lead to the extensive increases in facility observed. It would also seem that such damage would be of variable nature and extent from eye to eye and hence unlikely to produce the consistent results in paired fellow eyes such as we have observed.

As seen in part C of Table 1, there is a distinctly nonlinear relationship between the percent of trabeculotomy and the percent of resistance removed, the mean percent of decrease in resistance after trabeculotomy in only a fraction of the circumference being greater than that which would be expected if the relationship were linear. Thus it is apparent that a relatively small initial opening into Schlemm's canal increases the facility of outflow proportionally much more than does subsequent extension of the incision. This observation could mean that there is circumferential flow in Schlemm's canal, but other interpretations cannot be excluded.

The results of the fluorescein perfusions in the present study lend some support to this conclusion, for if no circumferential flow occurred then the fluorescein outflow would have been consistently greatest from the trabeculotomized quadrants where resistance was least. On the contrary, earlier and augmented flow of fluorescein most often came from superior and inferior quadrants, regardless of the site or extent of trabeculotomy. This observation is consistent with anatomical findings that in monkeys the collector channels draining Schlemm's canal in the superior and inferior quadrants are larger, are less intricately disposed, and exit more directly to the episclera than those in the medial and (especially) lateral quadrants (unpublished observations, V.L.J.).

The results of our experiments in rhesus monkey eyes, localizing the site of maximal resistance to aqueous outflow to the trabecular meshwork, are generally consistent with the previous studies in human eyes by Grant.[1,2] One may speculate that our slightly lower estimate of the total trabecular resistance (60-65% vs Grant's 75-80%), and our correspondingly higher estimate of the distal resistance, might be due in part to the differences in the anatomy of the intrascleral outflow vessels in the two species.[3,4] Species differences in the trabecular meshwork might also be an important consideration in this regard. Grant, however, observed greater outflow of perfusion fluid from the aqueous vessels draining the trabeculotomized quadrants more consistently than we did. This, plus his finding that "experimental opening into Schlemm's canal in only a fraction of the circumference does not increase facility of outflow as much as opening into the canal in the whole circumference," led Grant to the interpretation that "perfusion fluid . . . does not readily flow circumferentially in Schlemm's canal." Re-examination of Grant's original published data, however, reveals that in these experiments as in ours, trabeculotomy over a small portion of the circumference resulted in a greater decrease in resistance than would have been expected if the percent of decrease in resistance varied directly with the extent of trabeculotomy.

Our results are also compatible with the observation recently reported by Dannheim and Bárány[5] that trabeculotomy ab externo in four living rhesus monkeys, though generally not in cynomolgus monkeys, significantly lowered the resistence to aqueous outflow. Data from similar experiments reported by Edwards and associates[6] were quite variable and thus not conclusive.

The conclusions based upon the present experiments appear not to agree with those drawn by Perkins[7] and by one of us (M.L.S.)[8] from previous experiments in living monkey eyes. In these studies attempts were made to measure simultaneously, by direct manometry, the pressures in the anterior chamber and in the canal of Schlemm. The close similarity of these pressures was taken as evidence that the major resistance to outflow was located distal to the trabecular meshwork. It must be considered that exposure and cannulation of Schlemm's canal

from the outside are very difficult procedures and are likely to be complicated by injury to the very fragile trabecular meshwork, especially its lining endothelium. The large decreases in resistance which accompanied even small degrees of trabeculotomy in the present experiments suggest that such injury, however minute, might significantly reduce the resistance to aqueous outflow. Donnheim and Bárány[9] in fact found generally larger pressure differentials between the canal and the anterior chamber of monkey eyes than did these previously cited experimenters.

On the other hand, Schlemm's canal might normally be collapsed; in which case an otherwise poorly resistant trabecular wall, by virtue of its apposition to the scleral wall, would present an apparent high resistance to aqueous outflow.[8-10] It should be noted that Perkins[7] observed a marked increase in the rate of flow of saline into the anterior chamber after exteriorizing Schlemm's canal not only in one living and in one enucleated monkey eye but also in one enucleated human eye, observations suggesting that trabecular meshwork-scleral wall apposition might indeed be responsible for the primary resistance in both species. Our present data are not entirely inconsistent with this hypothesis, and experiments are in progress to test this speculation further.

The mean value for baseline facility of outflow in the rhesus eyes of this series is $0.52 \pm 0.02$ (50) µl/minute/mm Hg (mean $\pm$ s.e.m.) at room temperature of 24° C and at a mean experimental intraocular pressure of 8.0 mm Hg. Adjusting for the change in viscosity of the perfusion fluid with temperature, this becomes 0.73 µl/minute/mm Hg at rhesus body temperature of 38° C. The scatter of the values is typical of that observed in facility determinations in many species.[11]

An interesting finding was a rough but definite inverse variation, over the range of intraocular pressures observed (5.5-12.0 mm Hg), between facility of aqueous outflow and anterior chamber pressure at steady state (Fig. 4). Our value for rhesus monkey facility of outflow in vitro, when adjusted to a mean intraocular pressure of 12.5 mm Hg, thus becomes 0.40 µl/minute/mm Hg, a value comparable to the value of 0.41 µl/minute/mm Hg previously obtained in our laboratories[8] in eyes of living green monkeys under intravenous thiopental sodium anesthesia when mean intraocular pressure was 12.3 mm Hg. Examination of the data from this previous study also reveals an inverse relationship between facility of outflow and intraocular pressure as in the present study.

## Summary

Perfusion studies carried out in 50 enucleated normal rhesus monkey eyes suggested that the trabecular meshwork is responsible for 60-65% of the resistance to aqueous outflow, that aqueous outflow pathways in the inner one-third to one-half of the sclera are responsible for about 25%, that pathways in the outer one-half to two-thirds of the sclera account for 10-15%, and that more distal pathways account for very little, if any, resistance. An initial opening into Schlemm's canal increased the facility of outflow proportionally much more than did subsequent extension of the incision. Mean facility of aqueous outflow was found to be $0.52 \pm 0.02$

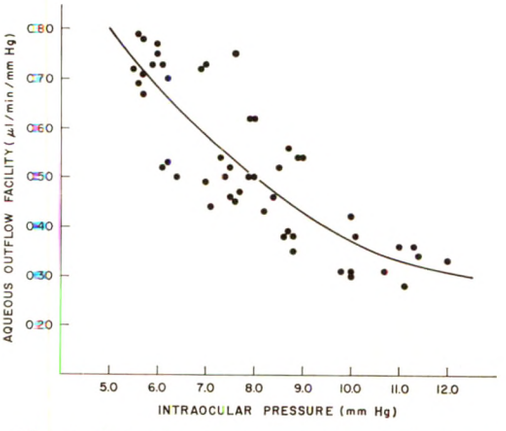

Fig. 4 (Peterson, Jocson, and Sears). Variation of aqueous outflow facility (µl/minute/mm Hg) with intraocular pressure (mm Hg) in 50 enucleated rhesus monkey eyes. Experimental values were determined at steady state, at room temperature, and in the baseline state described in the text.

(s.e.m.) μl/minute/mm Hg at body temperature and at a mean experimental intraocular pressure of 8.0 mm Hg. A rough but definite inverse variation of outflow facility with intraocular pressure was observed over the range of experimental intraocular pressures (5.5-12.0 mm Hg).

## Ophthalmic miniature

At the lonely island of Salvagem Grande, Didi and I went down for our first dive. . . . We pushed off the ladder and immersed our masks. Simultaneously, with desperate reflex motions, we grabbed the ladder. We had glimpsed something which aroused a fear we had never experienced before. It was pure vertigo.

We exchanged glances and cautiously put our eyes under again, holding on to the ship. We saw the bottom 100 feet down in naked detail. There seemed no water below us. There were no motes of animals, plants, or minerals in the space. It was distilled water, not the benign speck-crammed element we call clear water, in which exceptional visibility embraced a space no bigger than a concert hall. We saw a horrible bright landscape. If we let go our handholds we thought we would plummet through empty space and crash on the malign rocks which ranged far across the floor.

At last we submerged and, suprisingly, the sea supported us. We swam down, seeing each other as gross, unfamiliar animals in that surgical water.

# INTRASCLERAL SMOOTH MUSCLE IN COLOBOMA OF THE OPTIC DISK

## Electron Microscopic Verification

Ramon L. Font, M.D., and Lorenz E. Zimmerman, M.D.
*Washington, D.C.*

During the past several years, a group of congenitally malformed eyes has been the object of special interest and study because they have had in common the presence of bundles of elongated, spindle-shaped cells in the sclera and choroid along the edges of a colobomatous optic disk. Also, the optic nerves of these eyes are dysplastic, and their meningeal sheaths are incompletely formed or absent. In a number of them, masses of adipose tissue and bundles of plump, spindle-shaped cells are present within and about the optic nerve. Microscopic examination of sections stained by various methods for connective tissues and nerve fibers give the firm impression that the spindle-shaped elements found in the sclera, choroid, and optic nerve in these eyes are smooth muscle, but some pathologists who studied some of these cases in consultation were of the opinion that the cells in question might be schwannian. This paper reports electron microscopic studies that were carried out in one case to demonstrate more conclusively the nature of these cells.

### Case report*

A 13-year-old white girl was first examined in October, 1957, at the age of two to three months because of esotropia of her left eye. Examination revealed the right eye to be normal. The left eye was interpreted as highly myopic. A more thorough examination of the left fundus under general anesthesia with a well-dilated pupil revealed changes associated with high myopia, a posterior staphyloma, and a probable coloboma of the optic nerve. No definite mass was seen. In September, 1958, recession of the medial rectus and resection of the lateral rectus were performed for cosmetic improvement. At that time, examination of the left fundus under anesthesia showed a posterior staphyloma of some 25 to 30 diopters, with a "shot-silk" retina, underlying choroidal pigmentary changes, and some pallor of the superior nasal sector peripherally. No tumor was visualized. The right fundus was normal. The patient was re-examined in 1963, 1965, and 1967. She had no light perception with her left eye, and the appearance of her fundus remained unchanged. In April, 1969, uncorrected visual acuity in her right eye was 20/200, and she had no light perception in her left eye. In May, 1970, she had an "appendicitis attack," which cleared spontaneously and was followed by an infection of the urinary tract. Shortly thereafter, her left eye became red and painful, and she had tearing and swelling of both eyelids. Ophthalmologic examination two days later revealed corrected visual acuity in her right eye to be 20/20, with no light perception in her left eye, which was congested, with a steamy cornea and an irregular pupil. The iris was heavily vascularized, and hyphema was present. The intraocular pressure was RE: 14.6 mm Hg (5.5 g, Schiøtz) and LE: 43.4 mm Hg (10 g, Schiøtz). The left fundus was impossible to visualize. She was treated with acetazolamide (Diamox), bed rest, and binocular eye pads. Two days later the anterior chamber cleared, and an orange mass was seen in the upper half of the fundus. The intraocular pressure was 30 mm Hg. Re-examination one day later, with glycerin to clear the cornea, revealed a round, smooth, solid detachment of the retina with prominent vessels. No fungating mass was seen. The possibility of a malignant tumor in a congenitally defective eye was suspected, and the eye was enucleated on May 22, 1970.

### Microscopic studies

Microscopic examination of the enucleated left eye revealed dilatation of the limbal vessels and perivascular infiltration of neutrophils. A fibrovascular membrane extended between the intact Bowman's membrane and the corneal epithelium, peripherally. The cornea was otherwise not remarkable. Pe-

ripheral anterior synechias occluded the chamber angle. A thin fibrovascular membrane and collections of erythrocytes covered the surface of the iris. Scattered infiltrates of lymphocytes and plasma cells were seen in the iris and ciliary body. Early ectropion uveae was present. The lens was not included in the sections examined. The retina was totally detached, and there were extensive areas of necrosis and infiltration by neutrophils and pigment-laden macrophages, mainly in the outer retinal layers. Several retinal vessels were thrombosed. Blood and proteinaceous exudate filled the subretinal space. Accumulations of lymphocytes and plasma cells were scattered throughout the choroid. Many drusen were seen on Bruch's membrane. A large colobomatous defect involving the optic disk and peripapillary retina was present (Fig. 1). Strands of gliosed retina and islands of proliferated retinal pigment epithelium were present within the sclera at the edges of the colobomatous area (Fig. 2). Large bundles of spindle-shaped cells believed to be smooth muscle extended within the collagenous tissue of the sclera (Fig. 3), reaching between the inner scleral lamellae and the choroid (Fig. 4). These cells, which were arranged in interlacing bundles, showed small round to oval nuclei and abundant acidophilic cytoplasm. The Masson trichrome procedure stained these cells reddish brown, while the phosphotungstic acid-hematoxylin stain revealed numerous dark-blue filaments in their cytoplasm. Cross-sections of the optic nerve demonstrated a complete failure of formation of the meningeal sheaths, severe atrophy of nerve bundles, and astrocytic gliosis. The dysplastic remnants of optic nerve were surrounded by adipose tissue containing strands of smooth muscle and scattered blood vessels (Fig. 5).

*Histopathologic diagnoses*—Our diagnoses were as follows: congenital coloboma of optic disk and peripapillary retina containing large intrascleral bundles of smooth muscle; dysplasia of optic nerve with lipomatosis and failure of formation of leptomeningeal sheaths; rubeosis iridis and periph-

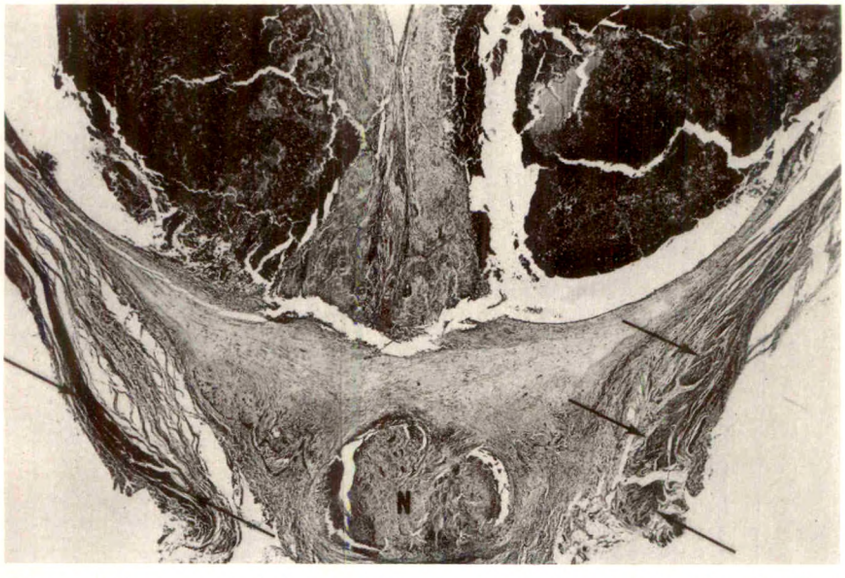

Fig. 1 (Font and Zimmerman). A large colobomatous defect of optic disk and peripapillary retina is present. Fascicles of smooth muscle (arrows) are embedded within the sclera on both sides of the dysplastic optic nerve (N). The retina is totally detached, and blood fills the subretinal space (Masson stain, ×9, AFIP Neg. 70-7276).

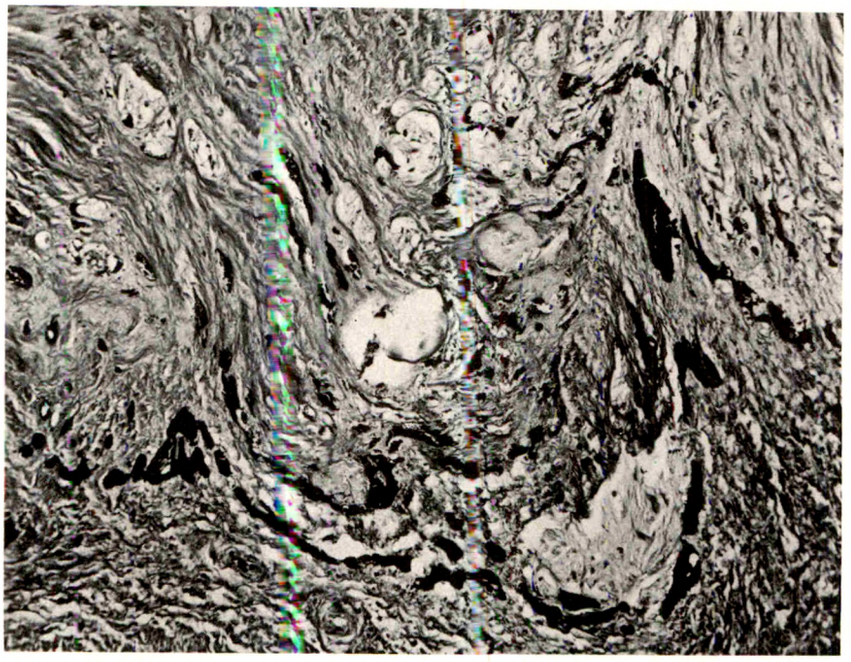

Fig. 2 (Font and Zimmerman). Marked pseudoadenomatous proliferation of the retinal pigment epithelium and strands of glial tissue are seen at the edge of the coloboma (hematoxylin-eosin, ×90, AFIP Neg. 70-7761).

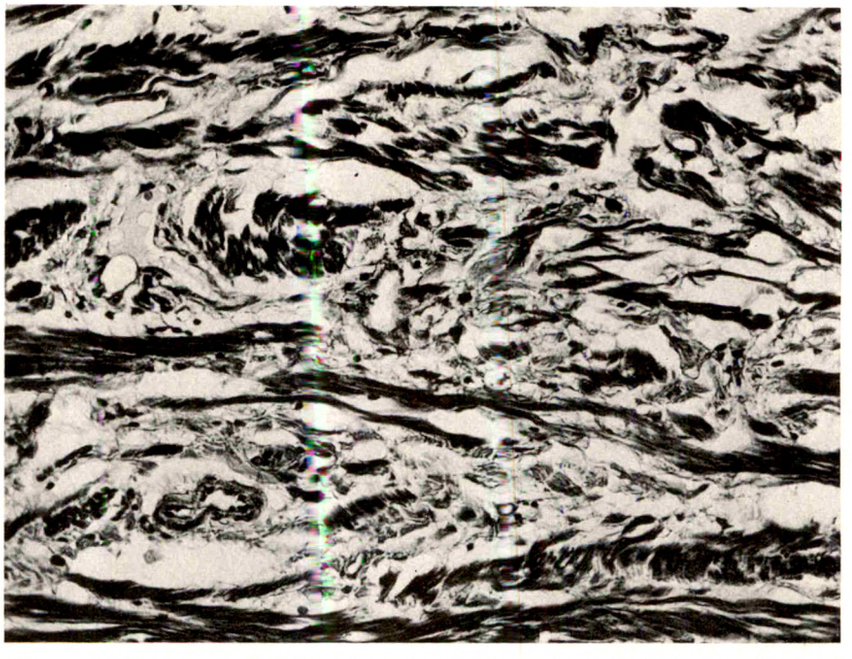

Fig. 3 (Font and Zimmerman). Bundles of smooth muscle are located within the collagenous tissue of the sclera (Masson stain, ×195, AFIP Neg. 70-7281).

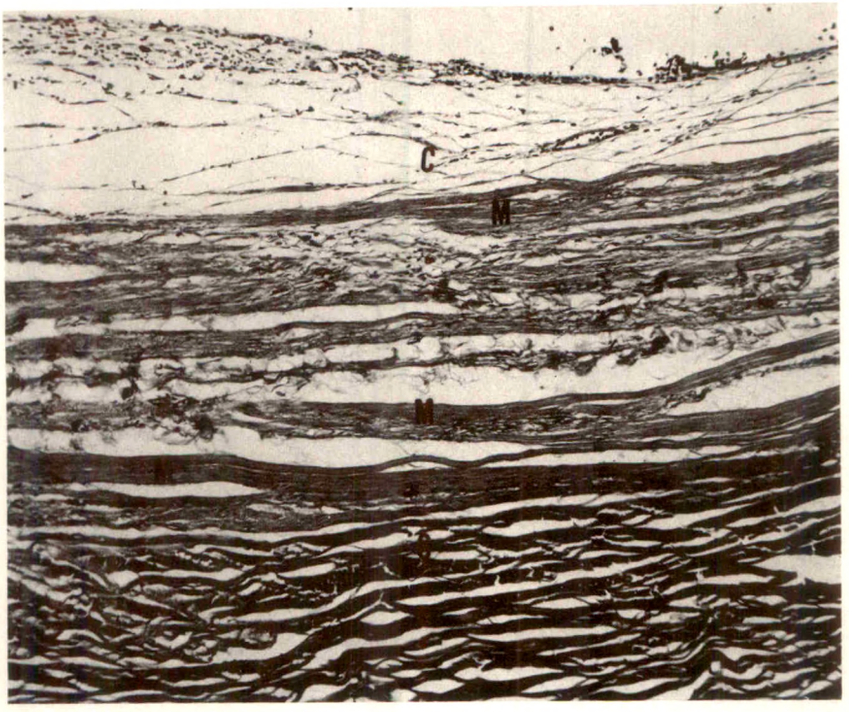

Fig. 4 (Font and Zimmerman). Parallel bundles of smooth muscle (M) are interspersed between the choroid (C) and sclera (S) (hematoxylin-eosin, ×80, AFIP Neg. 70-7283).

eral anterior synechias; chronic nongranulomatous uveitis; total retinal detachment, with areas of retinal necrosis; large subretinal hemorrhage.

Electron microscopic studies of the formalin-fixed, paraffin-embedded tissue were undertaken, after specially stained sections had been prepared from the re-cut paraffin blocks. The method employed to process the specimen for electron microscopy has been previously described from our laboratory.[1] The sections were stained with uranyl acetate and lead citrate and examined in the RCA model 3G electron microscope. We found remarkably good preservation of cytologic details that permitted us to identify the intrascleral bundles of spindle-shaped cells unequivocally as smooth muscle cells.

All the ultrastructural criteria that are used for identification of smooth muscle cells were satisfied (Figs. 6 and 7).[2] These include: (1) myriad intracytoplasmic filaments, often arranged parallel to the main axis of the cells; (2) scattered oval or fusiform areas of density lying within the masses of intracytoplasmic filaments; (3) similar cytoplasmic densities in continuity with the limiting plasma membranes; (4) almost complete investment of each cell by a basement membrane; and (5) numerous pinocytotic vesicles (or "caveolae") connected to the plasmalemma.

## Summary

The congenitally malformed blind left eye of a 13-year-old girl was enucleated because of the possibility that it contained an intraocular neoplasm. Microscopic examination revealed an unusual colobomatous malformation of the optic disk and nerve. Bundles of smooth muscle were conspicuously present on both sides of the nerve within the sclera

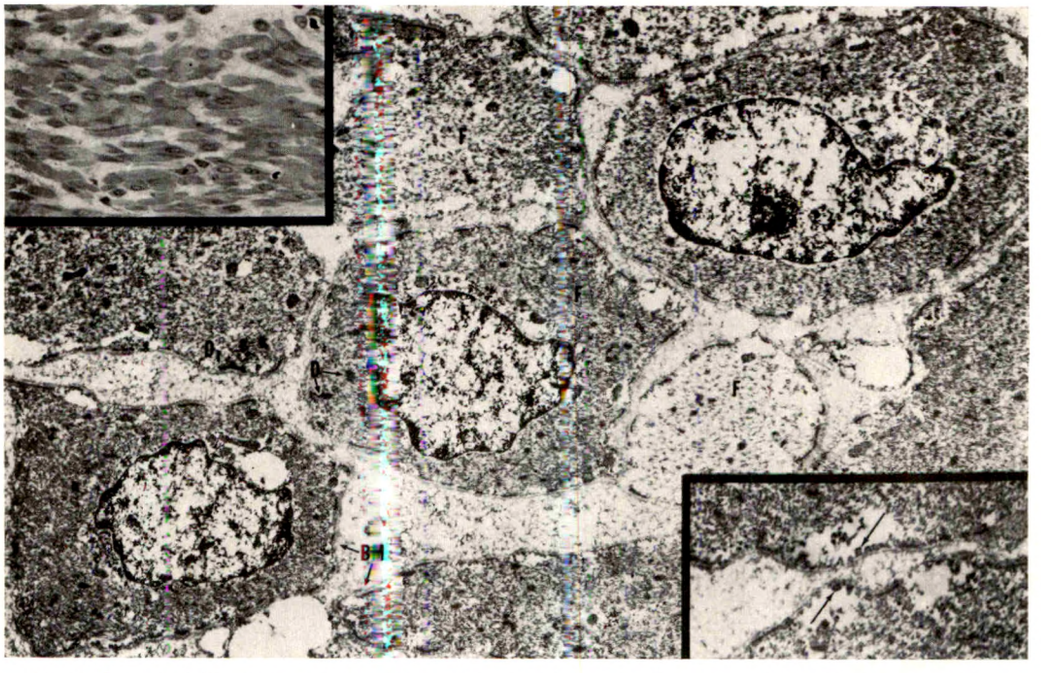

Fig. 6 (Font and Zimmerman). Smooth muscle cells almost totally surrounded by basement membranes (BM) and containing myriad intracytoplasmic filaments (F) with associated dense patches (D), some of which are connected to the plasma membrane ($D_1$) (large micrograph, ×11,000, AFIP Neg. 70-9896-2). The inset in the upper left corner shows the parallel bundles of smooth muscle cells (toluidine blue, ×440, AFIP Neg. 70-7277). The inset in the right lower corner reveals the numerous micropinocytotic vesicles or "caveolae" (arrows) that are attached to the plasmalemma (×21,000).

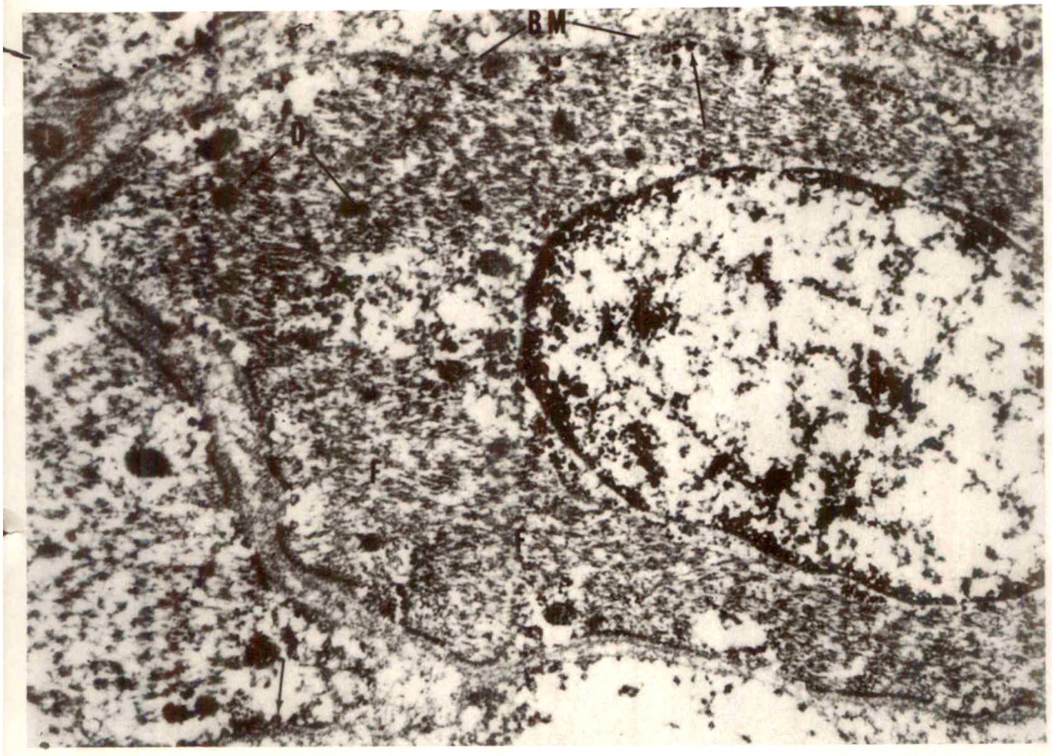

Fig. 7 (Font and Zimmerman). Higher magnification of a smooth muscle cell that is surrounded by basement membrane (BM) and shows intracytoplasmic filaments (F), focal densities (D), and micropinocytotic vesicles or "caveolae" (arrows) (×21,000, AFIP Neg. 70-9896-1).

and between the sclera and choroid. Electron microscopic examination of the formalin-fixed, paraffin-embedded tissue provided unequivocal evidence in support of the interpretation that smooth muscle was present in the sclera.

# DELAYED SPONTANEOUS HYPHEMA FOLLOWING SUCCESSFUL SCLEROTOMY WITH CAUTERY IN THREE PATIENTS

LAURENCE S. HARRIS, M.D., AND MILES A. GALIN, M.D.
*New York, New York*

Complications after successful external filtering operations for open-angle glaucoma have been extensively catalogued in the ocular literature. Cataracts have been noted in approximately 30 to 40% of such patients.[1-3] Postoperative uveitis is another frequent finding, whereas persistent hypotony is noted much less commonly.[4] Ruptured blebs have been ascribed both to trauma and to infection, or may predispose to the latter.

This paper presents a report of three cases in which hyphema was a late complication of external filtering procedures which, to our knowledge, has not been previously described.

## CASE REPORTS

*Case* 1—A sclerotomy with cautery and peripheral iridectomy was performed on the right eye of a 74-year-old white woman in 1965 because of continued visual field loss despite maximal medical therapy. A similar procedure was performed on the left eye two years later. Thereafter, intraocular pressures and outflow facilities remained well within the normal range in the absence of therapy.

Almost five years after the right eye surgery, the patient was seen complaining of sudden onset of blurred vision on the right with a mild feeling of ocular discomfort and irritation. Examination disclosed the anterior chamber to be approximately half filled with bright red, unclotted blood. An area of subconjunctival hemorrhage was noted superonasal to the filtration site. The remainder of the ocular examination, including intraocular pressure, was within normal limits.

The patient was put to bed with her head elevated to 30°, bilaterally patched, and total resorbtion of the hyphema occurred within 48 hours. She denied any antecedent trauma and was found to be normotensive and without disturbances in her clotting mechanism. Gonioscopy performed immediately after resorbtion of the hyphema disclosed no aberrant vessels in the angle or fistulous tract.

Subsequent follow-up has vevealed no permanent alteration in the patient's aqueous dynamics or in the appearance of the filtration bleb.

*Case* 2—A sclerotomy with cautery and peripheral iridectomy was carried out on the right eye of a 33-year-old white man with advanced juvenile glaucoma in 1963. Two weeks postoperatively, his visual acuity in the operated eye was 20/20 with correction.

Five weeks postoperatively, the patient noted right eye blurring and a miniscule hyphema was seen on examination. This cleared within 24 hours without therapy and the patient remained asymptomatic. Nine months later, the patient had a recurrence of hyphema and, during the ensuing three years, he had at least 20 episodes of intraluminal bleeding. Clearing was always prompt and the patient learned to recognize the hyphema grossly in the pathognomonic manner. At no time were aberrant vessels seen by gonioscopy. At no time did intraocular pressure rise, nor was any abnormality ever noted in the patient's filtering bleb, sclerotomy site, or angle.

No bleeding has occurred for the past two years, the patient's intraocular pressure is 10 mm Hg and his outflow facility is 0.32 $mm^3$ $min.^{-1}$ $Hg^{-1}$ without medications.

*Case* 3—A 58-year-old white woman underwent a left sclerotomy with cautery and peripheral iridectomy for uncontrollable open-angle glaucoma in 1967. Her postoperative course was uneventful and eight weeks after surgery the patient's visual acuity returned to its preoperative level. Two years after the procedure, the patient had blood filling a quarter of the anterior chamber in the operated eye, which cleared within 48 hours without therapy. Four months later, a second, smaller hyphema occurred which also cleared spontaneously. No alteration in the patient's glaucoma control resulted and, at present, her intraocular pressure is 16 mm Hg and her outflow facility 0.20 $mm^3$ $min.^{-1}$ $Hg^{-1}$. In each instance, gonioscopy failed to disclose any source for the recurrent hemorrhage.

## DISCUSSION

Three patients with spontaneous hyphema occurring or recurring more than two years after successful external filtration procedures are presented. In no case was there an antecedent history or the physical findings of trauma, infection, hypertension, or abnormal clotting mechanisms. In each instance, the

From the Department of Ophthalmology of the New York Medical College. This study was supported in part by Public Health Service Grant NB-07162-04, Grant 69-869 from the American Heart Association, and by Grant T-517 from the American Cancer Society, Inc.

Reprint requests to Laurence S. Harris, M.D., Department of Ophthalmology, New York Medical College, 1249 Fifth Avenue, New York, New York 10029.

presenting complaints were of the sudden onset of decreased visual acuity. Usually, this was associated with some ocular irritation, but pronounced pain and discomfort were not noted.

Two of the three patients had repeated episodes of hyphema, and only one required therapy with bilateral, occlusive eye patches and bed rest. In all instances, prompt resorbtion of blood from the anterior chamber occurred. Elevation in the intraocular pressure did not occur at any time when blood was present in the anterior chamber, nor did it interfere in any way with the long-term success of the surgical result.

The collagenolytic effect of aqueous has been used to explain the progressive polycystic nature of bleb formation.[5] Small vessels which might bridge a scleral area that is progressively "digested" might rupture as support is lost. It is, however, interesting to note that most successful blebs are ischemic and that aqueous appears to retard episcleral blood vessel growth.[5] The exact mechanism of the hyphema phenomenon, however, remains obscure.

## Summary

Vision became blurred in a 74-year-old woman with open-angle glaucoma five years following sclerotomy with cautery and peripheral iridectomy. The anterior chamber was one-half filled with bright red, clotted blood and a subconjunctival hemorrhage was noted above and nasal to the filtration site. No cause was found and the blood resorbed in 48 hours with bed rest. Sclerotomy and cautery with peripheral iridectomy in a 33-year-old white man was followed five weeks later by a minute hyphema and blurring of vision. Bleeding recurred at least 20 times in the subsequent three years, but there was none in the subsequent two years. A 58-year-old white woman with similar surgery had hyphema on two occasions during the four months following surgery.

In all three patients, the hyphema cleared spontaneously, did not impair aqueous humor dynamics, and was not associated with visible blood vessels in the angle examined by gonioscopy.

# CHOLINESTERASE ISOENZYMES IN HUMAN OCULAR TISSUE HOMOGENATES

I. H. Leopold, M.D., and M. Furman, M.S.
*New York, New York*

The enzyme cholinesterase has been described in animal and human ocular tissues.[1-3] Its function, other than its role in autonomic nervous system, has not been clarified. Rabbit plasma contains principally true cholinesterase.[4] The rabbit eye has mostly true cholinesterase isoenzymes in the sclera, cornea, iris, ciliary body, lens capsule, retina-choroid, optic nerve, aqueous and vitreous humors.[5] Pseudocholinesterase was found in small amounts in these tissues except in the aqueous, vitreous, and lens capsule.[5] The cholinesterase in normal human plasma was shown to consist of pseudocholinesterase isoenzymes.[6] It seemed important to determine the nature of the cholinesterase isoenzymes in human ocular tissues.

## Materials

Eighty fresh human eyes, obtained from the eye bank, were partitioned into sclera, cornea, iris, ciliary body, retina, choroid, optic nerve, and vitreous. Aqueous and lens capsules were obtained from patients undergoing cataract surgery. The tissues were homogenized (10-20% w/v) in 0.1 M phosphate buffer, pH 8.0. The homogenates were centrifuged at 13,000 × g for 20 minutes in a refrigerated centrifuge. The supernatants were divided into aliquots, quick frozen, and stored at −20° C until used.

## Methods

Disk electrophoretic separation of the proteins in the ocular tissue homogenates was performed according to the technique of Ornstein[7] and Davis[8] in glass tubes, 10 cm long and 0.5 cm internal diameter, containing 1.4 ml of separation gel, and 0.4 ml spacer gel. Protein determinations in the homogenates was performed according to Lowry,[9] using lyophilized crystallized bovine serum albumen (BSA), as a standard.

In each determination, we used sets of four identical columns—i.e., the gels were prepared at the same time, layered with equal amounts of a particular homogenate, and resolved in the same operation. One column was incubated with AcSCh, as substrate. The second column was incubated with AcSCh and $10^{-4}$M BW. The third contained AcSCh and $5 \times 10^{-5}$M iso-OMPA. The fourth had BuSCh as substrate. In addition, a set of 10 columns each containing a specific tissue homogenate was incubated using AcSCh as substrate and $10^{-5}$M eserine.

The cholinesterase isoenzyme analysis is based on the thiocholine method of Koelle and Friedenwald,[10] by which the thiocholine formed from the AcSCh or BuSCh hydrolysis is precipitated as copper thiocholine and appears as a white band at the enzyme site on the gel column. The copper thiocholine is subsequently stained with dithioxamide. The method for the preparation of the gels and

buffers and the procedure for the staining of the bands has been fully described by Juul.[6]

## Results

The columns incubated with AcSCh as substrate and $10^{-5}$M eserine showed no enzyme activity, that is no bands formed on the gel columns. The columns incubated with AcSCh only, gave varying numbers of bands depending on tissue used. The columns incubated withBuSCh as substrate failed to develop any bands. The columns incubated with AcSCh plus $5 \times 10^{-5}$M iso-OMPA were completely identical with the columns incubated with AcSCh only. The columns incubated with AcSCh plus $10^{-4}$BW showed complete inhibition of enzyme activity—i.e., no bands appeared. The results are summarized in Table 1.

TABLE 1

NUMBER OF BANDS OBTAINED BY INCUBATION WITH SUBSTRATE (AcSCh) AND SUBSTRATE PLUS INHIBITORS USING DISK ELECTROPHORESIS

| Tissue | Substrate Alone | Substrate Plus BW $10^{-4}$ or $10^{-5}$ Eserine | Substrate Plus iso-OMPA $10^{-5}$ |
|---|---|---|---|
| Sclera | 2 | 0 | 2 |
| Cornea | 1 | 0 | 1 |
| Iris | 3 | 0 | 3 |
| Ciliary body | 5 | 0 | 5 |
| Aqueous | 1 | 0 | 1 |
| Lens capsule | 1 | 0 | 1 |
| Retina | 3 | 0 | 3 |
| Choroid | 4 | 0 | 4 |
| Vitreous | 1 | 0 | 1 |
| Optic nerve | 2 | 0 | 2 |

## Discussion

A characteristic of cholinesterases is their pronounced sensitivity to low concentrations of eserine, and this fact may be used to distinguish cholinesterases from other tissue esterases.[11] It has been shown that a $10^{-5}$M concentration of eserine causes complete inhibition of cholinesterases while being without effect on other tissue esterases.[12] In our experiments, when the preincubation and incubation mixtures contained $10^{-5}$M eserine, a complete inhibition of AcSCh hydrolysis was effected; that is, no bands appeared on the gel column. This indicates that, under the conditions of the experiment, only cholinesterases are being analyzed. Of the three widely used methods, namely, substrate inhibition, substrate specificity, and selective inhibition, to distinguish between the cholinesterases, the latter two methods are suitable for disk electrophoresis.

*Substrate specificity*—True cholinesterase (AChE) hydrolyses AcSCh more rapidly than PrSCh and PrSCh more rapidly than BuSCh. Pseudocholinesterase (ns-ChE), on the other hand, hydrolyses PrSCh or BuSCh more rapidly than AcSCh[13]. In our experiment, the gel columns incubated with BuSCh as substrate did not show any bands (Figs. 1 and 2).

*Selective inhibition*—Certain inhibitors, at a given concentration, selectively inhibit one type of cholinesterase while having practically no effect on the other type. It has been shown that $10^{-6}$M iso-OMPA inhibits selectively ns-ChE while $10^{-5}$M BW inhibits AChE only.[14] For the method used, it was found that a concentration of $5 \times 10^{-5}$M iso-OMPA and $10^{-4}$M BW was best suited for differentiation between true and pseudocholinesterase.[5]

In our experiment, $10^{-4}$M BW completely inhibited the enzyme activity, while $5 \times 10^{-5}$M iso-OMPA had no inhibiting effect at all. The results of these experiments indicate the human ocular tissue enzyme to be true cholinesterase. Purified enzymes (Sigma Chemical Company), used in amounts to give the same total activity as in the ocular tissues, when taken through the same regimen gave similar results; that is, the purified enzymes were selectively inhibited by the inhibitors used in the given concentrations. Also, the purified true cholinesterase did not hydrolyse BuSCh—i.e., no bands were obtained.

Disk electrophoretic separation of the isoenzymes was used because of its superiority

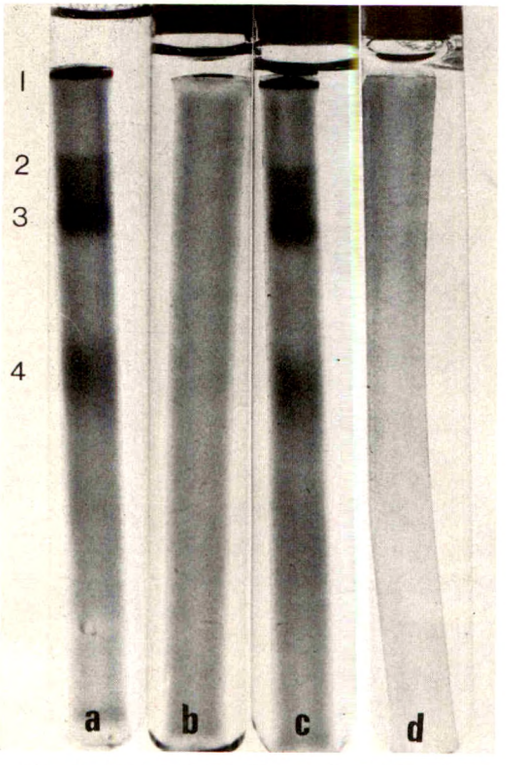

Fig. 1 (Leopold and Furman). Cholinesterase isoenzymes in human choroid. (a) With acetylthiocholine as substrate, four bands can be identified: 1 = thin, intense band, 2 = wide, diffused band, 3 = medium, intense band, and 4 = wide, diffused band. (b) With acetylthiocholine plus BW $10^{-4}$M, there is inhibition of all activity; column is completely clear. (c) With acetylthiocholine plus iso-OMPA $5 \times 10^{-5}$M, there is no inhibition of acidity. Bands are the same as in (a). In (d), with butyrylthiocholine as substrate, there is no activity.

over other electrophoretic methods. Juul[6] for example, was able to demonstrate twelve ChE isoenzymes in human plasma by disk electrophoresis, as compared to seven isoenzymes obtained by other investigators.[15] Additionally, this method appeared best suited for the experiment. The separation of ChE-isoenzymes proved to be extremely difficult. This may be due to their similar molecular properties and to the unequal distribution of activity between the individual bands. To effect a meaningful separation, the amount of acrylamide in the separation gel, the time allowed for electrophoresis, the time allowed for the development of the bands, the quantity of protein used per column had to be determined empirically. The data are presented in Table 2. Because of the restrictive nature of this study the results may be in variance with results obtained by other investigators using other techniques.[3]

## Summary

Proteins of human ocular tissue homogenates were separated by disk electrophoresis. By the use of specific substrates and selective inhibitors, it is shown that only true cholinesterase is present in the ocular tissues

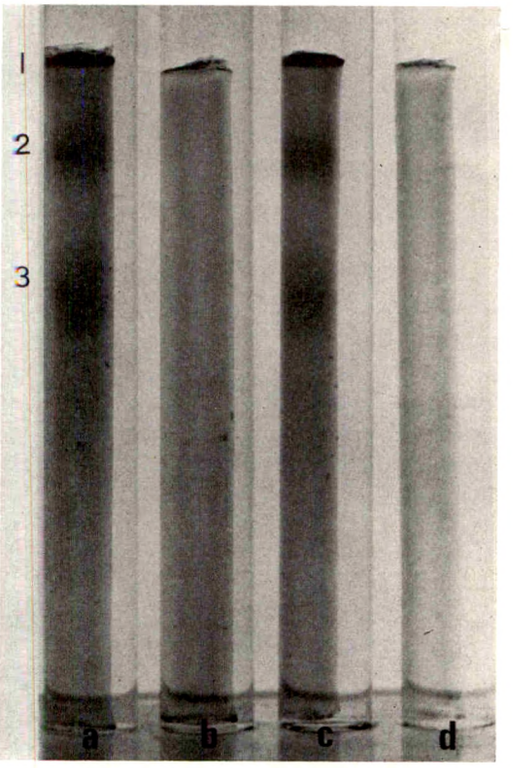

Fig. 2 (Leopold and Furman). Cholinesterase isoenzymes in human iris. (a) With acetylthiocholine as substrate, three bands can be identified: 1 = thin, intense band, 2 = medium, diffused band, 3 = wide, diffused band. (b) With acetylthiocholine plus BW $10^{-4}$M, there is complete inhibition of activity. (c) With acetylthiocholine plus iso-OMPA $5 \times 10^{-5}$M, there is no inhibition of activity, as in column (a). (d) With butyrylthiocholine as substrate, there is no activity.

TABLE 2

CONDITIONS FOR SEPARATION OF ISOENZYMES*

| Tissue | Acrylamide in Separation Gel (in %) | Amount of Protein per Column (in μg) | Time for Electro-phoresis (in hours) | Incubation Time |
|---|---|---|---|---|
| Sclera | 9.5 | 200 | 7 | Overnight at 4° C |
| Cornea | 9.5 | 200 | 7 | Overnight at 4° C |
| Iris | 8.0 | 100 | 6 | Six hours at room temperature |
| Ciliary body | 8.0 | 120 | 6 | Six hours at room temperature |
| Aqueous | 7.5 | 150 | 7 | Seven hours at room temperature |
| Lens capsule | 7.5 | 200 | 7 | Overnight at 4° C |
| Retina | 7.5 | 200 | 8 | Overnight at 4° C |

# LINCOMYCIN LEVELS IN RABBIT OCULAR FLUIDS AND SERUM

ROBERT S. COLES, M.D., GERARD L. BOYLE, F.I.M.L.T., IRVING H. LEOPOLD, M.D. AND S. STANLEY SCHNEIERSON, M.D.

*New York, New York*

Lincomycin hydrochloride monohydrate is derived from the actinomycete, Streptomyces lincolensis, var. lincolnensis (Mason, Dietz, and DeBoer[1]). The mechanism of its antibacterial activity is probably through inhibition of bacterial protein synthesis. The antibiotic is active in vitro primarily against Gram-positive coccal microorganisms with the exception of the enterococci. Kohn, Hewitt, and Fraser,[2] as well as Saunders, Foster, and Scott,[3] report that lincomycin-resistant strains of Group A streptococci have been isolated in some patients undergoing treatment with this antibiotic.

Lincomycin does penetrate the blood–brain barrier, producing significant detectable cerebrospinal levels in the presence of inflamed meninges, according to Kaplan, Chew, and Weinstein.[4] These authors also report that, in the presence of meningeal infection, the level of the drug in the cerebrospinal fluid is about 40% of that in the blood. Becker[5] reports that in 14 patients given lincomycin before routine eye surgery, significant levels were observed in all samples except one taken from a patient in whom the drug had been administered orally. The other 13 patients were given the drug parenterally; 11 received 2.4 g intramuscularly in multiple doses, and two patients received the drug intravenously, all in the same dosage. Following the last injection in patients with noninflamed eyes, the average lincomycin level of the aqueous humor was 1.3 μg/ml after one and one-half to two hours. After intramuscular injection, the aqueous humor level in the affected eye (glaucoma, staphyloma) was 21 μg/ml, and in the same time period the serum levels ranged from 10.2 to 23 μg/ml. Boyle, Lichtig, and Leopold[6] report that significant concentrations appeared in the aqueous humor as early as two minutes after lincomycin was injected subconjunctivally (0.25 ml of a solution containing 300 mg/ml) in 20 patients with noninflamed eyes who were hospitalized for elective ocular surgery (usually cataract extraction). Peak levels of the antibiotic in the aqueous humor occurred between one and three hours, while minimal levels persist in the serum and aqueous humor for 12 hours after injection.

In the study reported here, we measured the concentration of lincomycin in the aqueous humor, vitreous humor, and serum of normal rabbits after administration by various routes—intramuscular, intravenous, and subconjunctival—and the results were compared.

## MATERIALS AND METHODS

All rabbits used in this study weigh 1.5 to 4.0 kg. The average dose per animal was 15 to 20 mg/kg. Lincomycin HCl monohydrate, 300 mg/ml, was diluted to 50 mg/ml with sterile sodium chloride and then administered intramuscularly or intravenously; another series of rabbits received 0.1 ml of a 300 mg/ml solution of lincomycin subconjunctivally to each eye. Samples of aqueous humor, vitreous humor, and serum were obtained at one-half, two-, four-, and six-hour intervals, following the intramuscular and intravenous administrations, and one- and four-hour intervals after subconjunctival injection.

The ocular fluids and serum were assayed for lincomycin by the tube dilution method.

This method consists of an arithmetic progression of aliquots of standard antibiotic with the addition of media in inverse amounts to achieve a constant total volume of 1.0 ml per tube in all tubes.

The inoculum of the test organism, Sarcina lutea (FDA No. 1001), was prepared by inoculating glucose broth from a stock agar slant maintained at 4 to 6°C. After incubation at room temperature for 24 hours, extent of growth was determined and adjusted on a Lumetron colorimeter with a number 650 mμ filter until an optical density reading of 0.15 was obtained. This suspension was then diluted $10^{-3}$. Fresh 1.5% trypticase soy broth, pH 7.0, was employed as the medium and diluent.

The minimum inhibitory concentration of the lincomycin standard was determined. The standardized Sarcina lutea test inoculum was found to be consistently inhibited by 0.15 μg/ml of the lincomycin standard solution.

The volume of test sample and volume of standard inoculum employed in all assays was 0.5 ml of each per tube to obtain a total volume in each tube of 1.0 ml. Appropriate controls were also prepared to verify the sterility of samples and medium, and also the viability of the test organism. The minimum concentration of lincomycin that could be detected by this procedure was 0.3 μg/ml.

## Results

The levels of lincomycin in the aqueous humor, vitreous humor, and serum of normal rabbits following intramuscular, intravenous and subconjunctival administration are indicated in Table 1.

*Intramuscular administration*—Lincomycin was present in detectable concentration in the aqueous humor of all of the test rabbits but was not detectable in the vitreous humor of most of the animals. At one-half hour the highest concentration in the aqueous humor was 1.0 μg/ml and in the serum 10.3 μg/ml. Aqueous humor levels tapered off gradually with no marked decline up to six hours. As opposed to this situation, the serum levels declined rapidly between one-half and two hours; between two and six hours the decline was more gradual.

*Intravenous administration*—Lincomycin was detected in the aqueous humor, serum, and in the vitreous humor only after the one-half and the two-hour aspiration. At one-half hour, the highest concentration found in the aqueous humor was 1.19 μg/ml and in serum 6.44 μg/ml. Decline in the aqueous humor and serum levels followed the same

TABLE 1

LINCOMYCIN LEVELS IN THE SERUM, AQUEOUS HUMOR, AND VITREOUS HUMOR OF NORMAL RABBITS AT VARYING INTERVALS AFTER INTRAMUSCULAR (IM), INTRAVENOUS (IV), AND SUBCONJUNCTIVAL (SC) INJECTIONS

| Time (in hours) | Route of Administration | Serum Levels (μg/ml) | | Aqueous Levels (μg/ml) | | Vitreous Levels (μg/ml) | |
|---|---|---|---|---|---|---|---|
| | | Average | Range | Average | Range | Average | Range |
| 1/2 | IM | 10.3(10)* | 3.2 –15 | 1.0(7) | 0.75–1.5 | | |
| | IV | 6.44(7) | 3.3 –15 | 1.19(9) | 0.75–1.5 | 0.39(3) | 0.33–0.5 |
| 1 | SC | Not detectable | | >15(2) | | | |
| 2 | IM | 4.16(13) | 2.25–7.5 | 0.92(9) | 0.5 –1.5 | | |
| | IV | 1.96(7) | 0.5 –3 | 0.87(5) | 0.6 –1.5 | 0.47(4) | 0.37–0.5 |
| | IM | 1.78(8) | 0.75–2.25 | 0.75(5) | 0.5 –1.25 | | |
| 4 | IV | 1.25(6) | 0.5 –2.25 | 0.83(3) | 0.5 –1.0 | | |
| | SC | Not detectable | | >0.75(2) | | | |
| 6 | IM | 1.64(8) | 0.5 –2.25 | 0.64(6) | 0.5 –0.83 | | |
| | IV | 0.62(11) | 0.37–0.75 | 0.44(2) | 0.37–0.5 | | |

* Figure in parenthesis represents the number of rabbits in each group.

pattern of decline observed after intramuscular injection. The aqueous level tapered off gradually, whereas the serum level rapidly declined between one-half and two hours, and then tapered down slowly between two and six hours. The concentration of lincomycin in the vitreous humor was slightly greater at two hours than at one-half hour, but the antibiotic could not be detected at the four- and six-hour assays.

*Subconjunctival administration*—Lincomycin penetrated the aqueous humor of the test rabbits, but no perceptible level of lincomycin was found in the serum or vitreous humor. The aqueous humor lincomycin concentration after subconjunctival injection exceeded 15 μg/ml after one hour but at four hours the level was found to be greater than 0.75 μg/ml.

## Comment

The design of the assay was planned to accommodate the small volume of each sample that could be aspirated from the eye of a rabbit—approximately 0.2 ml of aqueous humor and 0.75 ml vitreous humor. It was necessary to pool the aqueous from both eyes of each animal, at each time interval, in order to have enough sample to perform the assay. The vitreous humor from each eye was assayed individually.

Comparison of the serum levels, following intramuscular and intravenous administration, revealed similar curves. The serum levels after intramuscular administration were found to be higher than the serum levels after intravenous administration at all time intervals tested. It is possible that the intravenous concentration peaked prior to the 30-minute specimen. Kaplan and associates[4] reported finding no significant differences in serum levels in humans when intramuscular and intravenous injections are compared. The aqueous humor level after intravenous administration was found to be somewhat higher than after intramuscular injection at one-half hour but, after one and one-half hours, it was slightly lower than the intramuscular injection. With both intramuscular and intravenous injections a gradual straight line decline was noted. Lincomycin did penetrate the vitreous humor after intravenous administration up to at least two hours, but beyond two hours no lincomycin could be detected by the assay method employed. Subconjunctival administration produced the highest intraocular concentrations obtained in this study. Kaplan and associates[4] showed that concentrations of lincomycin required to inhibit 60 strains of Staphylococcus aureus ranged from 6.2 to 0.75 μg/ml, against eight strains of Streptococcus pyogenes from 1.5 to 0.09 μg/ml, against six strains of Streptococcus viridans from 0.75 to 0.19 μg/ml, and against five strains of Diplococcus pneumoniae from 1.5 to 0.19 μg/ml.

It is evident that the required antibacterial concentration for the above bacteria is readily achievable in the serum after both intramuscular and intravenous injection after one-half hour, and for some strains up to six hours (Fig. 1). Concentration of lincomycin obtained in the aqueous humor is adequate

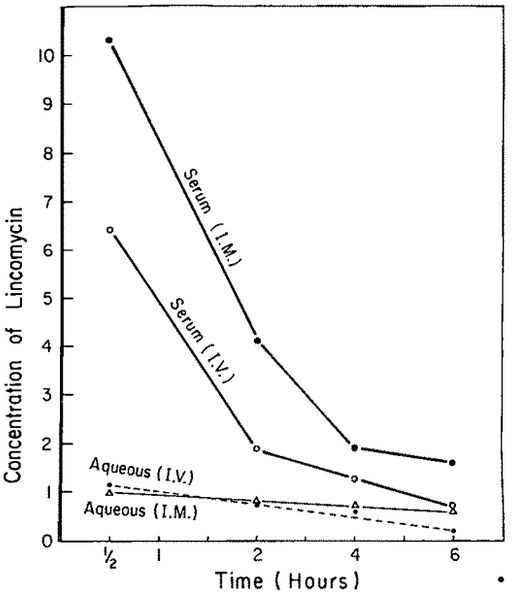

Fig. 1 (Coles, Boyle, Leopold, and Schneierson). Average lincomycin levels (in μg/ml) in aqueous humor and serum at varying time intervals following intramuscular and intravenous injections.

against all strains with a minimal inhibitory concentration below 1.19 μg/ml after intravenous and 1.0 μg/ml after intramuscular injection at one-half hour. Some but not all of the above bacterial strains will be inhibited by the aqueous humor concentrations. Intravenous injection of lincomycin will achieve antibacterial concentration in the vitreous at one-half and two hours against some strains of Streptococcus pyogenes, viridans streptococci, and Diplococcus pneumoniae.

The concentration of lincomycin in the aqueous humor one hour following subconjunctival administration is theoretically adequate to inhibit all strains with minimal inhibitory concentrations below 15 μg/ml, and most strains will still be inhibited by the concentrations observed up to four hours after administration.

## Summary

A series of experiments were performed to determine the level of lincomycin in the aqueous and vitreous humor of noninflamed eyes and in the serum of rabbits at varying periods following intramuscular, intravenous, or subconjunctival injection. Detectable levels were achieved by all routes of administration within one-half hour and up to six hours after injection. The concentrations found in the serum and aqueous humor were sufficient to be effective against a number of Gram-positive coccal pathogens. Absorption into the vitreous humor was irregular and was of questionable significance in the noninflamed eye.

## Acknowledgment

The lincomycin used in this study was supplied as Lincocin by the Upjohn Company.

# PRILOCAINE AS A LOCAL ANESTHETIC USEFUL IN OPHTHALMIC SURGERY

LEMUEL T. MOORMAN, M.D., AND GEVES S. KENNY, M.D.
*Denver, Colorado*

Prilocaine (Citanest), an anesthetic agent structurally very similar to lidocaine (Xylocaine), provides excellent local anesthesia for ophthalmic surgical procedures. Since the initial synthesis of prilocaine in 1960, many detailed clinical and laboratory studies have been performed with an emphasis on comparison with lidocaine, considered to be the standard of local anesthetics on the basis of popular ussage. The latency of onset of anesthesia is the same or only slightly longer. The specificity of the anesthesia is the same,[1] the toxicity is 50% that of lidocaine,[1-5] the diffusion of the agent is greater,[5,6] and only minimal irritation is noted locally[1] (Table 1). A cross allergenicity exists with local anesthetics of the amide type such as lidocaine. One of us (LTM) has been using prilocaine routinely as the anesthetic agent for retrobulbar and seventh-nerve infiltrate blocks in private practice. The adequacy and advantages of this agent are reported here.

## METHODS AND RESULTS

A total of 508 surgical cases were performed in a private hospital utilizing prilocaine without epinephrine as the sole anesthetic agent (Table 2). All surgery was performed at an altitude of 5280 feet (Denver, Colorado), with a large number of patients not acclimated to this high altitude. A cardiac monitor was attached in all cases except photocoagulations and non-surgical cryocoagulations. Approximately 3 to 5 ml of 2% prilocaine without epinephrine was used for the retrobulbar anesthesia and 10 ml for the seventh nerve akinesia. Hyaluronidase (Wydase) was mixed with prilocaine for the cataract procedures. This agent has been used also on patients judged not suitable candidates for general anesthesia, including those with borderline compensated heart failure, hypertensive cardiovascular disease, previous coronary occlusions, heart blocks, and pulmonary emphysema. Fifty-one primary retinal detachment cases were successfully treated, with the shortest case lasting 33 minutes and the longest case lasting two hours and 22 minutes (average duration, one hour and two minutes). Fifty-two intracapsular lens extractions were performed, with the shortest case lasting 25 minutes and the longest one hour and 37 minutes (average duration, 51 minutes). Twenty-nine cases of lens aspiration, external filtration, and peripheral iridectomy were performed, with the shortest case taking five minutes and the longest one hour and 13 minutes. (average duration, 37 minutes). The duration of surgical anesthesia persisting after the procedures were completed was not determined. In addition, 376 photocoagulation and surgical and non-surgical cryocoagulation procedures were performed utilizing the above anesthetic routine. Surgically adequate block was obtained in each case, but three cases complained of some discomfort during the procedure. Repetition of anesthetic block to extend the duration of anesthesia was not necessary. No complications due to central nervous system stimulation or seizures, cardiovascular decompensation, respiratory insufficiency, or cyanosis were noted.

TABLE 1

ADVANTAGES OF PRILOCAINE OVER LIDOCAINE

1. Duration of anesthesia is greater
2. Epinephrine not needed
3. Tissue diffusion greater, systemic adsorption slower
4. Toxicity is 50% less
5. Less local irritation

Reprint requests to Lemuel T. Moorman, M.D., 2045 Franklin Street, Denver, Colorado 80205.

## Discussion

Prilocaine is a derivative of aniline and is chemically closely related to lidocaine, phenacetin, acetanilide, and sulfonamide. Prilocaine is marketed as a 1 or 2% solution of 2-propylamino-O-propionotolulidide HCl with sufficient sodium chloride to render the solution isotonic and the pH 6 to 7. Methylpareben is added in multiple-dose vials. Stability in both prilocaine and lidocaine is of indefinite duration. Prilocaine differs in chemical structure from lidocaine mainly by a substitution in the end radical of the side chain (Fig. 1).

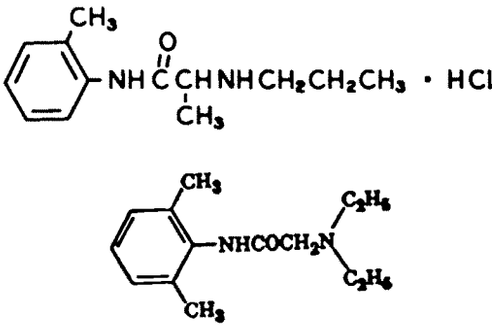

Fig. 1 (Moorman and Kenny). Chemical structure of prilocaine (top) and lidocaine (bottom).

Prilocaine without epinephrine has been used successfully for a variety of ophthalmic surgical procedures. The anesthetic has been adequate for primary retinal detachment circling band and buckling procedures, intracapsular lens extraction, anterior segment procedures, and photocoagulations and cryocoagulations.

Of greatest interest to the opthalmologist is the extended duration of anesthesia obtained with prilocaine. Various authors[6-8] have demonstrated that the duration of anesthesis produced by 2% prilocaine is of 25% longer duration than that produced by lidocaine. This 30-minute extension of anesthesia (from 115 to 146 minutes) is highly significant. It enables the performance of complicated ophthalmic procedures without the addition of epinephrine to the agent. Sudove[5] has noted that regional blocks with 2% prilocaine will last approximately two hours and 40 minutes without epinephrine. We have found that such duration of anesthesia is adequate for the performance of extended retinal detachment procedures in clinical practice. The increased duration of anesthesia seems to be related to a 50% decrease in vasodilating effect as compared with lidocaine.[2]

TABLE 2

PRILOCAINE IN OPHTHALMIC SURGERY

| Procedure | No. Cases |
|---|---|
| Retinal detachment | 51 |
| Anterior segment procedures | 29 |
| Intracapsular lens extractions | 52 |
| Photocoagulations and cryocoagulations | 376 |
| Total | 508 |

A greater margin of safety is evidenced with prilocaine, as it has a toxicity factor which is only 50% that of lidocaine.[1,2,5,9,10] Toxicity effects noted with lidocaine range from mild drowsiness, tinnitus, vertigo, apprehension and muscle twitching, to convulsions and coma, respiratory depression, and bradycardia.[11-13] Cardiac depression due to involvement of the heart conduction system has been reported with lidocaine,[11,12] but no such effects have been reported with prilocaine. In separate studies by Astrom and Person,[2] Englesson, Paymaster, and Hill,[3] and Eriksson,[4] it has been demonstrated that prilocaine's toxic effects on the central nervous system are approximately half that of lidocaine using comparable volumes and concentrations of both drugs. A lower central nervous system and cardiovascular effect was noted by Englesson[14] with a 400 mg dosage of prilocaine as compared with a 200 mg dosage of lidocaine. Astrom and Person[2] attributed the lower toxicity of prilocaine to its lower plasma levels which are a result of the decreased vasodilation and absorption rate from the injected area and a higher rate of renal excretion. Englesson, Paymaster, and Hill[3] demonstrated the same seizure pattern in electroencephalograms (EEGs) in dogs,

but twice the dosage was necessary with prilocaine to elicit the same effect as with lidocaine. Eriksson[4] found essentially the same results in experiments using EEGs with simultaneous automatic frequency analysis. This effect seemed to be mediated by a lower blood level and a lower lipid solubility of prilocaine which decreased the degree of brain penetration from the vascular system. In consideration of the decreased central nervous system excitation pattern, prilocaine may be significantly safer in patients with epilepsy.

### Complications and contraindications

A complication reported with prilocaine which does not occur with lidocaine is the production of methemoglobin. Methemoglobin is a form of hemoglobin in which the iron of the heme complex has been oxidized to the ferric form by electron transfer to oxygen. It cannot be disassociated by changes in the oxygen tension. Normally, methemoglobin is continually being formed in the body, is reduced by enzyme reductase, and has a blood concentration rarely exceeding 1% in the normal patient. A rise of methemoglobin in a patient to 5 or 6% of the circulating hemoglobin (0.8 to 1 g%) produces clinical cyanosis. Prilocaine causes the formation of methemoglobin through a breakdown metabolite either of the aromatic chain or the side chain. Clinical studies by Lund[15] showed that with a maximum dose of 600 mg (30 ml of a 2% solution), an average methemoglobinemia of 0.1 g% was found, with a maximum of 0.9 g% occurring in only one person out of the 74 examined. Even with a dosage level of 900 mg and a maximum level of 2.7 g% methemoglobin, no symptoms of hypoxia were noted. Clinically, with doses of 400 mg or less, Lund was unable to note clinical signs of methemoglobinemia. At a 600 mg dosage, some patients developed signs of cyanosis in the nail beds and lips, but no symptoms of cardiovascular or central nervous system involvement were noted. In 9000 cases, only one case of lightheadedness and dizziness was noted. The clinical symptoms of cyanosis in this case were rapidly eradicated by the injection of methylene blue, the specific antidote for methemoglobinemia. Von Bohr and Eriksson[16] failed to demonstrate any instances of cyanosis in 6000 cases using prilocaine in the same doses, concentration, and volume as they had previously used in lidocaine-anesthetized cases. Eriksson[4] states that with doses of 600 mg or less clinical signs of methemoglobinemia are so slight that patients easily compensate for this minor reduction in oxygen-carrying capacity of the blood by slightly increased cardiac output. The methemoglobinemia does not seem to be a factor except in severely anemic patients with severe cardiac decompensation, but is contraindicated in patients with idiopathic or congenital methemoglobinemia. Bonica and associates[7] judged that at the dosage level of 600 mg, methemoglobin is a minor drawback to utilizing the drug in regional blocks and that, in the face of the extended duration of the anesthesia, it is a very useful agent and perhaps in many cases the drug of choice.

In the cases we have referred to here, the maximum dosage of prilocaine used was 400 mg (20 ml of 2% solution). At this dosage level, the duration and degree of anesthesia obtained is judged to be more than satisfactory for retinal detachment, anterior chamber, and photocoagulation cases.

### Summary

Prilocaine has enabled the performance of surgical procedures lasting as long as two hours and 20 minutes without the adjunctive use of epinephrine and without reinjection. In clinical practice, this agent has proven an excellent anesthetic for local blocks required in retinal, cataract, and anterior chamber procedures. The reduced toxicity, increased local diffusion, and greater duration of anesthesia allows the ophthalmic surgeon to select local anesthesia in patients with severe cardiovascular and respiratory problems. No instances of central nervous system toxicity,

cardiovascular decompensation, respiratory depression, or hypoxia have been noted. The reported surgical procedures were performed at an altitude 5000 feet above sea level (Denver, Colorado), and in many cases in this series, patients were not acclimated to this altitude. This is perhaps additional evidence of the inherent safety of this drug.

# ADRENERGIC MYDRIASIS IN HORNER'S SYNDROME

## HYDROXYAMPHETAMINE TEST FOR DIAGNOSIS OF POSTGANGLIONIC DEFECTS

H. STANLEY THOMPSON, M.D., AND JOHN H. MENSHER, M.D.
*Iowa City, Iowa*

In Horner's syndrome, the pupil often fails to respond normally to adrenergic mydriatic drops. Cocaine, for example, dilates the Horner's pupil poorly and epinephrine dilates it unusually well. The mydriatic response varies with the location of the lesion in the sympathetic pathway. In 1932, Foerster and Gagel[1] proposed the schema shown in Table 1 to localize the lesion in Horner's syndrome, and later a number of modifications were proposed.[2-5] In such tables the term "central neuron" denotes the sympathetic efferent pathway that originates in the hypothalamus and passes through the lateral part of the brainstem and cervical cord down to the $C_8$, $T_1$ level. It is not certain, however, whether this path actually is composed of a single neuron, or of a chain of neurons. The preganglionic neuron emerges from the spinal cord, passes over the apex of the lung and through the stellate ganglion, and ascends in the cervical sympathetic chain to synapse in the superior cervical ganglion. The postganglionic neuron to the iris follows the carotid plexus into the skull and is carried into the orbit with the ophthalmic division of the trigeminal nerve. The sweat fibers to the lower face follow the external carotid artery.

The cocaine and epinephrine tests are still used, but in practice they often fail to be sufficiently clear-cut to allow localization of the defect causing a Horner's syndrome.

In order to understand these tests it is necessary to have the mode of action of various adrenergic mydriatics clearly in mind.

*Cocaine*—When nerve impulses arrive at sympathetic nerve endings norepinephrine is released. Normally, some of this norepinephrine is taken up again by the axon and this terminates the adrenergic action. Cocaine blocks this re-uptake of norepinephrine into the axon and consequently the transmitter substance accumulates at the receptors of the effector cell. If the sympathetic pathway is interrupted, no norepinephrine is released at the neuro-effector junction and cocaine will have no mydriatic effect.

*Epinephrine and phenylephrine*—These are directly acting sympathomimetics. By virtue of their structural similarity to the natural transmitter substance (norepinephrine) they have a direct stimulating action on sympathetically innervated effector cells. When the sympathetic innervation is impaired, these cells become supersensitive to directly acting sympathomimetics and will then respond to weak and ordinarily ineffective concentrations of these drugs.

*Indirect-action adrenergic mydriatics*—There is a third class of adrenergic mydriat-

ics: those which act indirectly by causing endogenous norepinephrine to be released from the sympathetic nerve endings. Such indirectly acting sympathomimetics do not, by themselves, stimulate the effector cell. They act on the presynaptic side of the neuroeffector junction to release norepinephrine from the stores in the nerve terminal. Hydroxyamphetamine 1% (Paredrine) belongs to this group of drugs and we chose to work with it (rather than with tyramine, amphetamine, or ephedrine) because it is already a widely used mydriatic and readily available. Using guanethidine, which depletes the axon's stores of norepinephrine,[6,7] we were able to show in the human eye that hydroxyamphetamine has, for practical purposes, an exclusively indirect mode of action (Fig. 1).

If the lesion causing a Horner's syndrome is central (brainstem or cord) or preganglionic (chest or neck), hydroxyamphetamine should cause normal mydriasis because the nerve endings of the postganglionic neuron are unimpaired. If, on the other hand, the lesion is postganglionic, some or all of the adrenergic nerve terminals will have degenerated, depending upon the extent of the damage. Consequently the stores of norepinephrine normally contained in them will be reduced or absent. When hydroxyamphetamine is instilled into the eye the pupil will therefore dilate incompletely or not at all.

According to our understanding of the action of these drugs, then, the cocaine dilation should be reduced or absent in any Horner's pupil, regardless of the site of the impairment. In contrast, hydroxyamphetamine should dilate the pupil normally in cases with central or preganglionic Horner's syndrome, but the reaction should be reduced or absent in cases with postganglionic Horner's syndrome. The following cases demonstrate that, with these drugs, a clear distinction between pre- and postganglionic lesions can indeed be made.

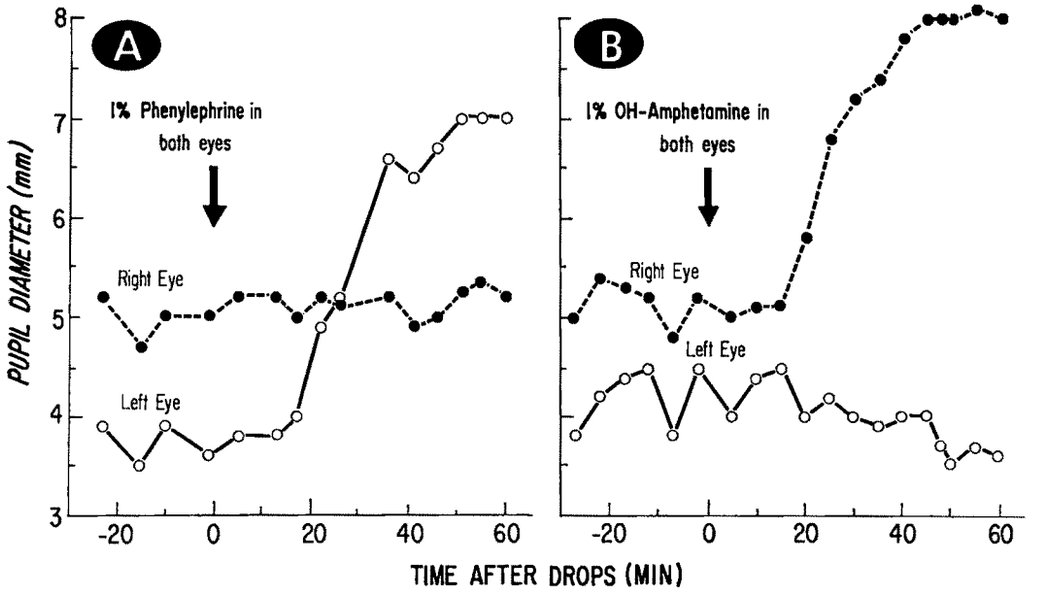

Fig. 1 (Thompson and Mensher). Experimental Horner's syndrome in the human eye, induced by the sympatholytic drug, guanethidine (5%), applied once daily to the left eye. (A) On the 10th day of treatment, this subject showed a dramatic supersensitivity of the pharmacologically sympathectomized pupil to 1% phenylephrine. No guanethidine drops had been placed in the eye since the day before; the eye was not irritated; the corneal epithelium did not stain with fluorescein. (B) After 16 days of guanethidine, OH-amphetamine 1% had no mydriatic effect upon the left pupil.

## METHODS

Thirteen patients with unilateral Horner's syndrome were seen in this series (Table 2). All were white; 10 were men and three, women; Their ages ranged from 32 to 74 years. Most were referred to the Ophthalmology Department at the University of Iowa Hospitals from the Neurology or Neurosurgery Departments, but six patients with surgical preganglionic lesions were sent from the Des Moines Veterans Administration Hospital Surgery Department through the courtesy of Louis Palumbo, M.D., Chief of Service. Pupillography was done using the Lowenstein-Loewenfeld electronic pupillograph. In addition, photographs of the pupils were taken with the Polaroid close-up camera (CU-5) with a three-inch lens. To

TABLE 2

DESCRIPTION OF CASES STUDIED

| Case, Years of Age, and Sex | History | Findings | Diagnosis | OH-amphetamine Response |
|---|---|---|---|---|
| 1. 32—F | Taking oral contraceptives; sudden onset of ataxia, vertigo, numbness of left face and right side of body | Blepharoptosis, miosis, and corneal hypesthesia on the left; sensory deficits | Lateral medullary syndrome (Wallenberg) | Dilation |
| 2. 54—M | Chronic hypertension; sudden onset of diplopia and vertigo | Left facial hypesthesia; right body hypesthesia; vocal cord paralysis; left blepharoptosis and miosis | Lateral medullary syndrome (Wallenberg) | Dilation |
| 3. 41—M | History of migraine; sudden onset of vertigo diplopia and ataxia and sensory deficit | Hypesthesia right side of face and body; Horner's syndrome and anhidrosis on the left | Superior cerebellar artery thrombosis | Dilation |
| 4. 49—M | Apical lung disease; bilateral progressive weakness and loss of sensation | Left Horner's syndrome | Suspected syringomyelia; apical lung disease, etiology unknown | Dilation |
| 5. 65—M | Intermittent claudication, acrocyanosis; bilateral, dorsal and lumbar sympathectomy; postoperative left blepharoptosis and miosis | Left Horner's syndrome; anhidrosis above nipples and below knees; later skin biopsy showed scleroderma | Surgical Horner's syndrome | Dilation |
| 6. 44—M | Intolerance to cold in arms and hands, vascular insufficiency; postoperative right blepharoptosis and miosis | Right Horner's syndrome with facial anhidrosis on right | Surgical Horner's syndrome | Dilation |
| 7. 70—M | Ten-year history of angina pectoris; left dorsal sympathectomy brought relief of precordial pain | Postoperative left blepharoptosis, miosis and anhidrosis of face, chest, and arm | Surgical Horner's syndrome | Dilation |
| 8. 38—M | Acrocyanosis; bilateral dorsal sympathectomy ($T_1$–$T_5$); postoperative right blepharoptosis and miosis | Right Horner's syndrome with anhidrosis above nipples | Surgical Horner's syndrome | No dilation |
| 9. 52—M | Numbness and cramps in right hand on exposure to cold; right dorsal sympathectomy ($T_1$–$T_5$) | Postoperative right blepharoptosis, miosis, and anhidrosis of right side of face, arm, and right upper chest | Surgical Horner's syndrome | Dilation |
| 10. 74—M | Five-year history of angina pectoris; atrial fibrillation; left dorsal sympathectomy for oppressive left precordial pain | Postoperative left Horner's syndrome | Surgical Horner's syndrome | Dilation |
| 11. 51—F | Left-sided headaches; diplopia for one year | Left abducens palsy; left Horner's syndrome; left corneal hypesthesia | Infraclinoid aneurysm of left internal carotid artery | No dilation |
| 12. 74—F | Intermittent right facial pain for seven years, accompanied by ipsilateral blepharoptosis, miosis, and nasal congestion | Persistent right Horner's syndrome | Cluster headaches with Horner's syndrome | No dilation |
| 13. 51—M | Trigeminal neuralgia and Horner's syndrome on left side treated with alcohol injection of gasserian ganglion | Hypalgesia and hyperesthesia of left face; left corneal hypesthesia; left Horner's syndrome | Trigeminal neuralgia with Horner's syndrome | No dilation |
| 14. 18—M | Auto injury at 13 months; crush injury to head and chest with over-riding occipital bones and pneumothorax; anisocoria noted postrecovery | Persistent right Horner's syndrome | Traumatic Horner's syndrome | No dilation |
| 15. 59—F | Auto injury at eight years of age with skull fracture; hospitalized at age 59 for cardiac surgery | Persistent Horner's syndrome | Traumatic Horner's syndrome | No dilation |
| 16. 8—M | Tractor crush injury to head and pelvis with basal skull fracture | Blind right eye, right abducens palsy and right Horner's syndrome; facial hypesthesia in first and second division of fifth nerve | Traumatic Horner's syndrome | No dilation |

reduce corneal reflections, 80% of the built-in ring flash was blocked out. The film used was Polacolor 75, type 108. Drugs used were: cocaine 5%, epinephrine HCl 0.1%, OH-amphetamine 1%, and phenylephrine HCl 10% viscous solution (Neo-Synephrine). One drop was placed in each conjunctival sac from standard plastic ophthalmic drop bottles. The pictures were taken in room light at 10-minute intervals with the patient focusing in the distance. Pupillary diameters were measured directly from these life-sized photographs to the nearest 0.1 mm, using a magnified scale (Mirroptic Comparator, National Tools). At least two days, sometimes four, were allowed to elapse between drug tests.

## Results

On the basis of the clinical picture, patients were separated into three categories according to the neuron presumably damaged (Table 3): central (Cases 1-3), preganglionic (Cases 4-10), or postganglionic (Cases 11-13). In Cases 14-16, Horner's syndrome was associated with head trauma.

All the patients demonstrated the characteristic pupillary features of Horner's syndrome: some tardiness of dilation in darkness after light reflexes and an increase of anisocoria after sudden noise. Otherwise, no pupillary motor defects were found in the pupillograms, even in the "central" cases.

Case 4 was classed with the preganglionic group on the basis of clinical judgment, even though the Horner's syndrome could have been due to a high cervical spinal cord defect. This patient was kept in the study because there was nothing to suggest that the postganglionic pathway was involved. Case 8 was observed to have a blepharoptosis and miosis after his thoracic sympathectomy and he may well have acquired a preganglionic Horner's syndrome at that time, yet in his drug tests he behaved in every way like the patients with postganglionic Horner's syndrome, failing to dilate to cocaine or to (OH-amphetamine, yet showing supersensitivity to phenylephrine. This patient may have had a pre-existing postganglionic sym-

* Tests in which the Horner's pupil "crossed over" and became the larger pupil.

pathetic defect, since there was an extensive sector heterochromia of the affected iris, or he may have developed a postganglionic lesion on top of the surgical preganglionic Horner's.

The mydriatic responses of the three patient groups are shown in Figures 3 through 5: cocaine (Fig. 2), hydroxyamphetamine (Figs. 3 and 5) and phenylephrine (Fig. 4). The individual responses, and the reactions to 1:1000 epinephrine, are given in Table 3. These values are all shown in millimeters of pupil diameter before and after the application of the drug, rather than as percentage increase of pupil size, because of the marked influence of mechanical factors upon pupillary movements.[8]

## Discussion

### Chief limitations of the cocaine test

If the sympathetic outflow pathway is interrupted at any level—that is, central, pre- or postganglionic—cocaine should have no mydriatic effect because in each case the flow of nerve impulses has been halted, and no norepinephrine is released.

Foerster and Gagel[1] reported a series of patients with anterior lateral cervical cordotomies whose Horner's pupils dilated normally to cocaine, yet our patients with medullary interruptions of the sympathetic path had Horner's pupils which dilated very poorly to cocaine. Similarly, Carmel[9] found reduced cocaine reactions in patients with lesions involving the ocular sympathetic pathways as rostral as the subthalamic area. These are not new observations; as early as 1906, Müller[10] reported a patient with Horner's syndrome associated with a brainstem stroke. The Horner's pupil dilated poorly to cocaine.

When the lesion is in the brainstem or spinal cord, cocaine mydriasis is usually impaired but not entirely abolished. This may be due to incomplete interruption of the descending sympathetic pathway. The cocaine test is a useful screening test to confirm the presence of a sympathetic pupillary deficit, but it will not indicate the location of the impairment.

### Chief limitation of tests for adrenergic supersensitivity

One drop of 1:1000 epinephrine had little or no mydriatic effect, even in cases with

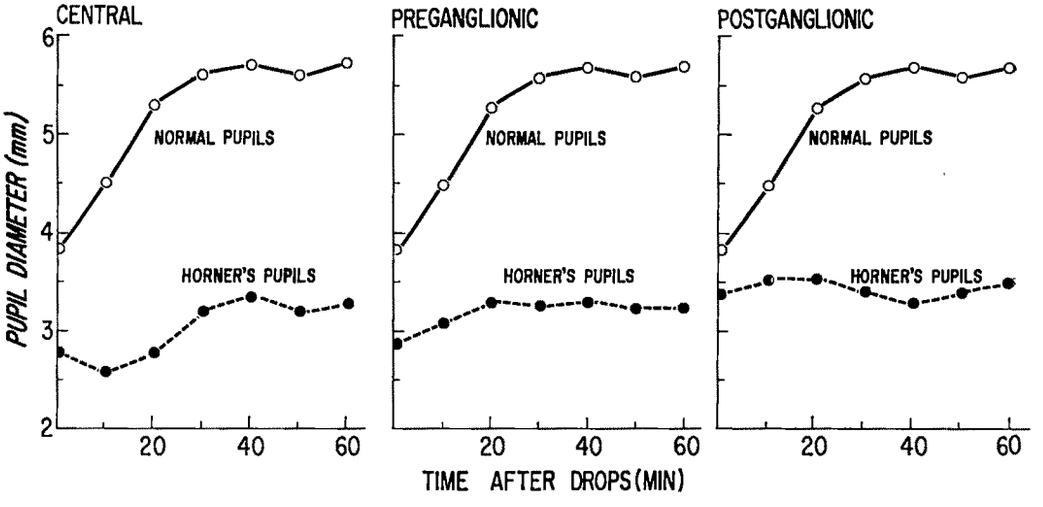

Fig. 2 (Thompson and Mensher). Summary of pupillary responses to cocaine in 12 patients with unilateral Horner's syndrome. The mean dilation curves are shown for each group. The unaffected pupils (12 patients, open circles) dilated normally. All of the Horner's pupils (three central, six preganglionic, three postganglionic) showed impaired dilation. There was a tendency for the most peripheral lesions to be associated with the least mydriasis.

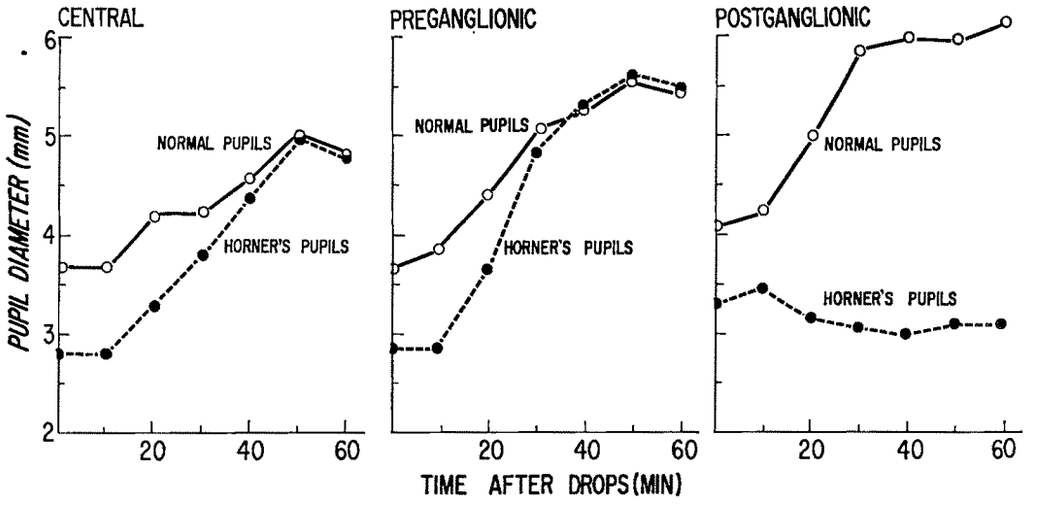

Fig. 3 (Thompson and Mensher). Summary of pupillary responses to OH-amphetamine in 12 patients with unilateral Horner's syndrome (three central, six preganglionic, three postganglionic; mean dilation curve was calculated for each group). The postganglionic group of Horner's pupils not only failed to dilate but actually became smaller during the test, partly because the patient sat in a chair for 90 minutes and became progressively more bored and sleepy, and partly because more light was entering the pupil of the other eye, which was dilating normally.

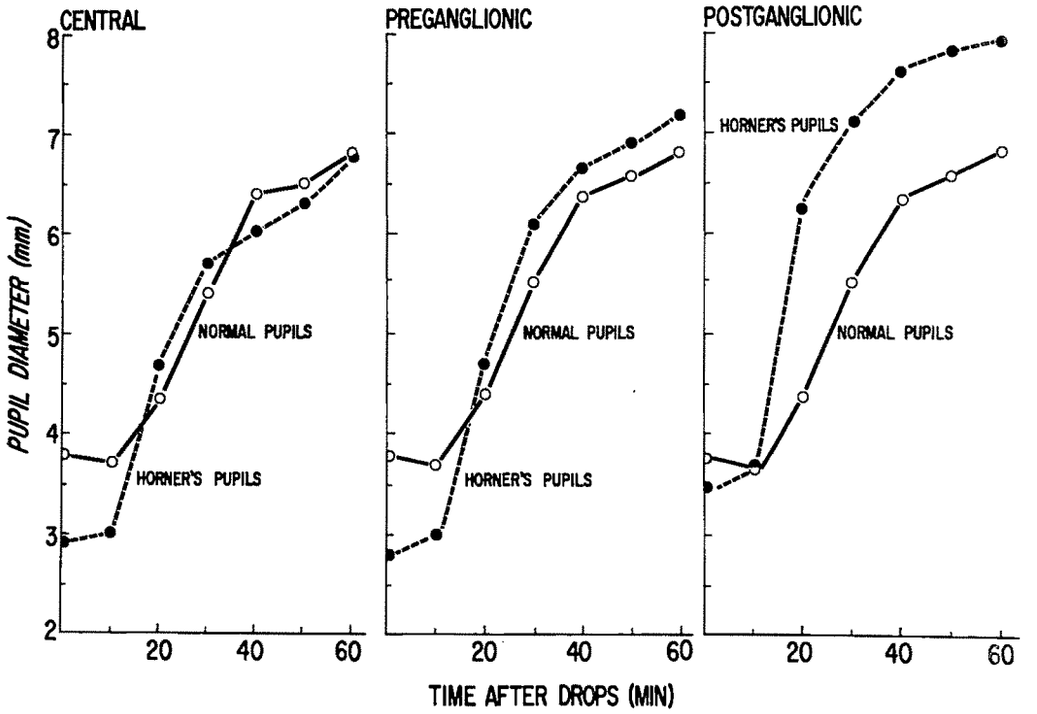

Fig. 4 (Thompson and Mensher). Summary of mydriatic responses to 10% phenylephrine in 12 patients with unilateral Horner's syndrome. The data were plotted as in Figure 2. Although all pupils showed a good dilation, the Horner's pupil always dilated sooner than the normal pupil. This supersensitivity of the Horner's pupil was most evident in the postganglionic cases.

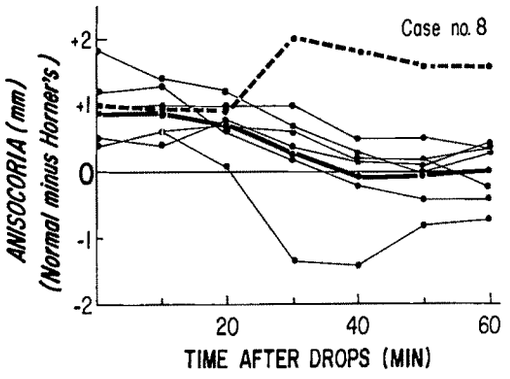

Fig. 5 (Thompson and Mensher). Case 8. Responses of the preganglionic group to OH-amphetamine in both eyes. The anisocoria due to the Horner's syndrome tended to disappear as the drug took effect. Some of the Horner's pupils in this group (heavy line is the mean) "crossed over" to become the larger pupils. Only Case 8 showed an increasing anisocoria due to failure of the Horner's pupil to dilate to OH-amphetamine.

postganglionic sympathetic lesions with demonstrable supersensitivity of the iris dilator. In many cases in the literature "maximal dilation" of the pupil in response to 0.1% epinephrine has been described.[5] But because it penetrates the cornea poorly and because there are great individual differences in sensitivity to epinephrine, even repeated instillations of this drug may give inconclusive results. Phenylephrine was, in our hands, a more dependable clinical tool than epinephrine for the demonstration of supersensitivity of the iris dilator to adrenergic drugs. The phenylephrine tests in this study were done with a very strong solution (10%, viscous), strong enough to cause extensive mydriasis in the normal pupil. Yet, in spite of this, a clear supersensitivity of the Horner's pupil was demonstrated in all the postganglionic cases. A weaker solution of phenylephrine, for example 1%, which has only a mild mydriatic affect on the normal pupil, provided a more dramatic demonstration of supersensitivity (Fig. 1).

When epinephrine or phenylephrine is used to distinguish a preganglionic from a postganglionic defect, a judgment must be made of the degree of supersensitivity of the iris dilator. In general, a denervated muscle (postganglionic lesion) is considerably more sensitive to these drugs than a decentralized muscle (preganglionic or central lesions),[11,12] and in the presence of marked supersensitivity a postganglionic lesion can thus be recognized.[13] However, a partial postganglionic lesion cannot be distinguished from a preganglionic lesion on the basis of supersensitivity to adrenergic drug tests; in both conditions the iris will show a slight supersensitivity. Similarly the effect of partial regeneration cannot be judged.

Tests for supersensitivity are also subject to false positive errors due to variations in penetration of the drug through an intact or damaged corneal epithelium.[14] The right iris must receive the same dose of the drug as the left iris or else erroneous conclusions about supersensitivity will be reached. This kind of mistake has been made in the past, for example in Löwy's test for facial nerve involvement.[15] In these cases, the mydriasis to 1:1000 epinephrine was mistaken for adrenergic supersensitivity. The mydriasis was, in reality, due to the penetration of the drug through a cornea which had been damaged by exposure.

### Advantages of the OH-amphetamine test

In contrast, the response to hydroxyamphetamine is not subject to errors due to interpersonal variations in drug sensitivity, or to somewhat uneven administration of the drops. The reaction depends upon the amount of norephinephrine available in the iris for release, and, provided that at least a dose sufficient to dilate the normal pupil is used, one eye may get a great deal more of the drug than the other without causing a difference in mydriatic response. Furthermore, if one pupil dilates poorly, this deficit cannot be due to a central or preganglionic lesion, because even complete excision of the preganglionic neuron does not impair OH-amphetamine mydriasis (Fig. 5). The poor

dilation indicates that there was insufficient norepinephrine available for release in that eye; and less than normal dilation therefore suggests a loss of postganglionic nerve fibers. This test thus provides a clearer distinction between pre- and postganglionic defects than is available with any other mydriatic test.

### Precautions

In all these tests, the drops should be instilled in both eyes, so that the reaction of the Horner's pupil can be compared with that of the normal eye. False results due to extremes of drug sensitivity can thus be avoided. Tests for supersensitivity can be done only when the corneal epithelium is intact in both eyes, so there should be no tonometry and no testing of corneal sensitivity before the drops are given.

For the cocaine test, it is important to remember that in some patients, especially those with dark irises, the response may be extremely slow. It is possible for cocaine mydriasis to take as long as two or three hours to become fully established, after which the mydriasis tends to be long-lasting. If, therefore, no dilation is observed in either eye after about 45 minutes, it is advisable to add more cocaine and to allow additional time.

Pretreatment with cocaine interferes with the action of hydroxyamphetamine (Fig. 6). For this reason, at least two days should elapse after cocaine administration before the OH-amphetamine reaction is tested.

### Summary

Adrenergic mydriasis was studied in a group of patients with unilateral Horner's syndrome. Cocaine dilated the central Horner's pupil poorly and the pre- and postganglionic pupils not at all. Phenylephrine (Neo-Synephrine) was used to demonstrate the supersensitivity of the denervated dilator muscles to adrenergic substances. OH-amphetamine (Paredrine) had a mydriatic action only when the postganglionic neuron was intact. OH-Amphetamine was shown to have an exclusively indirect mode of action. The cocaine test and the OH-amphetamine test cannot be done on the same day. The lat-

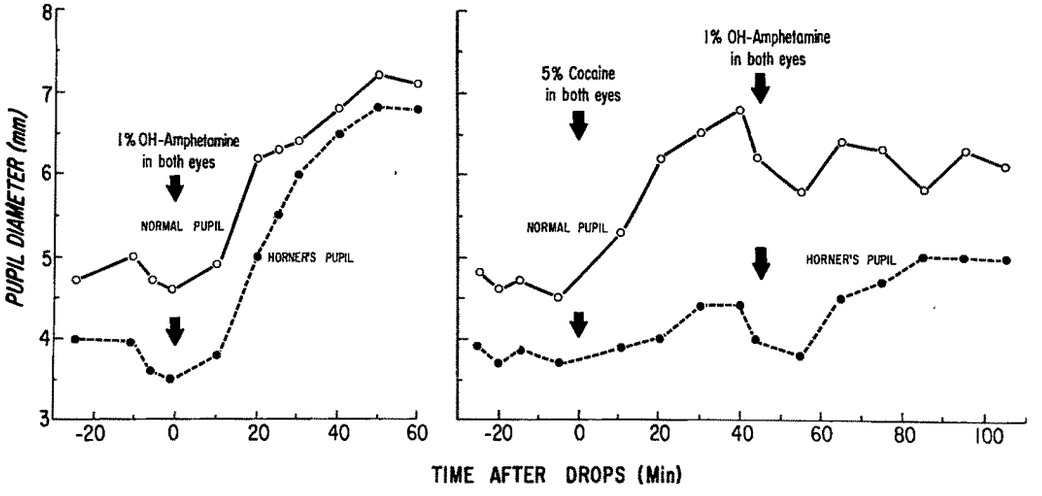

Fig. 6 (Thompson and Mensher). Case 8. This patient had had a blepharoptosis and miosis on the left side for 20 years dating from surgery for goiter on the left side of the neck. Both pupils dilated well to OH-amphetamine. Ten days later, cocaine dilated the Horner's pupil poorly. OH-amphetamine added on top of the cocaine failed to produce as much mydriasis as OH-amphetamine alone. This suggests that the cocaine and OH-amphetamine tests should be done on separate days so that they do not interfere with each other. Cocaine may block the uptake of amphetamine into the nerve endings.

ter test is offered as a new and better way to distinguish pre- from postganglionic sympathetic defects.

ACKNOWLEDGMENTS

We thank Mr. E. E. Brown for his skilled and patient technical assistance throughout this investigation and during the many preliminary experiments leading up to it.

# GIANT CYST OF THE PARS PLANA

RICHARD STRANAHAN RUIZ, M.D.

*Houston, Texas*

Grignolo, Schepens, and Heath,[1] Okun,[2] and Allen, Miller, and Straatsma[3] state that pars plana cysts are formed by separation of the nonpigmented from the pigmented ciliary epithelium. They are usually confined to the temporal side of the globe, and usually conform to the individual ora bay, but may become confluent. These cysts are associcated with peripheral cystoid degeneration of the retina and can be considered a benign degenerative process increasing in incidence with age. There is often evidence of vitreal or zonular traction on the surface of the cysts, but holes in the walls of the cysts are unusual.

Possible causes for pars plana cysts include traction by the vitreous and zonules, secretory phenomena, vascular sclerosis, faulty embryologic development, and inflammation. This report describes a case of a giant pars plana cyst associated with other pars plana cysts of exceptionally large size.

## CASE REPORT

A 57-year-old white woman was seen for routine ophthalmic examination. Visual acuity was 20/15 in both eyes with correction and positive findings were confined to the posterior segments.

In the left eye, the temporal ora was irregular and unusual in appearance and there were multiple, large, irregular, highly-elevated cysts of the pars plana which overhung the ora region. In the inferior temporal quadrant, the pars plana extended posterior to the equator in a crescent shape and had the appearance of a huge ora bay. Overlying this large bay was a giant round cyst. No attachment was present from the vitreous or zonules to the surface of the cyst. The walls of the cyst were thin, gently undulating, and transparent, allowing easy visualization of the underlying retina and pars plana. The external wall of the cyst was composed of the posterior extension of the pars plana. The posterior extent of the cyst overhung the large ora bay and almost reached the visual axis. The anterior limit was lost from view over the anterior portion of the pars plana. No vessels were present on the surface of the cyst but normal retinal vessels could be seen on the surface of the retina under the cyst and extending up to but not over the large ora bay. Fluorescein did not accumulate in the pars plana cysts within one hour of intravenous injection. There was no visual field defect demonstrable

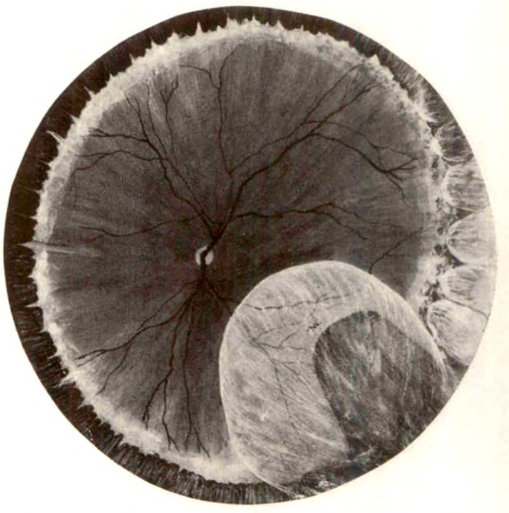

Fig. 1 (Ruiz). Fundus illustration of the left eye, showing giant cyst.

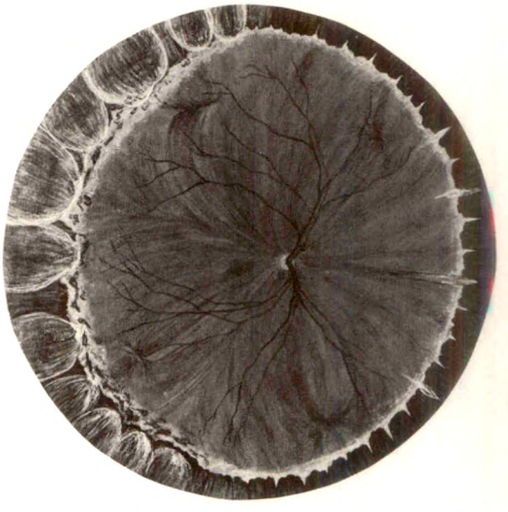

Fig. 2 (Ruiz). Fundus illustration of the right eye, showing large pars plana cyst and large ora serrata.

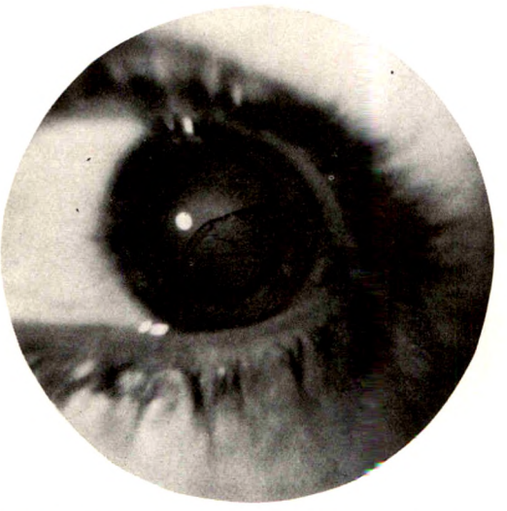

Fig. 3 (Ruiz). Slit-lamp photograph of giant pars plana cyst protruding into pupilliary opening.

with the Goldmann perimeter and no angle anomalies were present.

Examination of the right eye was negative except for multiple large pars plana cysts which overhung an irregular and anomalous ora serrata temporally.

No therapy was recommended. The fundus appearance is unchanged and the patient remains asymptomatic over a two-year period.

## Summary

A giant pars plana cyst was associated with additional unusually large pars plana cysts in a 57-year-old woman without symptoms and with no other abnormal ocular findings. In this case, the unusually large size of the cysts and their association with anomalies of the ora region suggested faulty embryologic development as the cause.

## Acknowledgment

This case was referred by Sylvan Brandon, M.D., fundus illustrations were done by Kay Smith, and photographs were taken by Antonino Deleza, both of Houston Eye Associates.

# NOTES, CASES, INSTRUMENTS

## METALLIC FOREIGN BODY REMOVED FROM TEAR DUCT

MOHAMMAD H. LASHKARI, M.D.
*Tehran, Iran*

A thorough survey of all available literature failed to reveal the report of a single case similar to that of my patient in whose right tear duct roentgenographic examination detected a metallic foreign body.

### CASE REPORT

A 22-year-old white woman complained of tearing from both eyes and of pain in the area of the tear duct of the right eye.

Her history showed that epiphora had developed after she had had smallpox at the age of four years. In 1967, at the age of 20 years, she underwent a dacryocystectomy on the left eye. The tear duct of the right eye was unsuccessfully probed in January, 1969. The pain worsened and a third ophthalmologist treated her for two or three weeks without discovering the cause of the pain.

When I first saw the patient in November, 1969, the right eye showed a scar in the region of the tear duct, caused by pericystitis, and the left eye showed the dacryocystectomy scar.

Laboratory examinations detected no abnormalities. X-ray studies, however, revealed a needle-shaped metallic foreign body (Fig. 1) that appeared to be about 1.0 cm in length. Its somewhat horizontal placement in the medial aspect of the right orbit suggested that it was located in the lacrimal canal.

The patient was admitted to the hospital. A dacryocystorhinostomy under local anesthesia made possible the removal of a slender piece of metal 10 mm in length (Fig. 2) which was identified as the broken-off tip of a probe.

The postoperative course was uneventful. The patient left the hospital in three days (Fig. 3) and, three days later, the suture was removed and the tear duct was irrigated. Recovery continued to be satisfactory. The most recent follow-up examination (Fig. 4) showed the patient to be in good condition. The epiphora had disappeared completely and she had no complaints.

### SUMMARY

Acting on x-ray evidence, the broken-off tip of a metal probe was removed in a dacry-

ocystorhinostomy from the tear duct of the right eye of a 22-year-old woman who had suffered from epiphora since childhood and who had had severe pain in the area of the tear duct following numerous probings of the lacrimal canal. Removal of the metallic foreign body relieved the pain and cured the epiphora.

ACKNOWLEDGMENT

I thank A. Fatemi, M.D., radiologist, and B. Parsa, M.D., for the x-ray studies and the use of laboratory facilities. I also thank Mr. Jahanfar for taking the photographs.

OPHTHALMIC MINIATURE

A child is taken, tied up in a small net, and placed towards the front part of the stage. A Sengalese comes in, bows, and slowly walks toward the place where the child is lying on the floor tied up in the net. He stoops over, looks intently at the child, and as he straightens up, the child's body is actually lifted from the floor and follows him as he walks several steps backward. He again stoops forward and allows the child to sink to the floor. To all appearances he has lifted the child from the floor with power from his eyes.

The child and the net are unprepared, but the Sengalese is prepared with a set of false eyes which he wears over his natural eyes. These are made of silver and are painted to resemble the human eye. These artificial eyes have aperatures which permit a perfect range of vision and are held in place by being inserted underneath the eyelids.

A very strong piece of silk twine (reaching below the knees) is fastened to each artificial eye, and a small strong hook is secured to the lower end of each piece of twine. As the Sengalese bends over and gazes intently at the child, he bends his knees and secretly inserts the hooks into the net entwining the child.

After the hooks are made fast, he slowly straightens up and bends backwards, and so causes the twine to rest upon his chest, thereby taking the actual strain from his eyes, and thus raises the child from the floor.

# MEETINGS, CONFERENCES, SYMPOSIA

EDITED BY THOMAS CHALKLEY, M.D.

## AMERICAN OPHTHALMOLOGICAL SOCIETY MEETING—1971

The 107th annual meeting of the American Ophthalmological Society was held at the Homestead in Hot Springs, Virginia, May 24-26, 1971, under the direction of the president, Dohrmann K. Pischel. The weather was sparkling, the athletics stimulating, the papers interesting, and the ladies charming. The meeting was enjoyed by all.

More than half of the papers were devoted to various aspects of cataract or glaucoma. Lorenz Zimmerman gave the Verhoeff lecture, and described medulloepitheliomas, providing a masterful exposition of clinical observation and pathologic study, utilizing histochemical techniques, light and electron microscopy, and embryologic investigation. Most remarkable was the demonstration of striated muscle arising from the anterior extremity of the optic vesicle in the malignant form of this tumor. The paper will appear in an early issue of the JOURNAL.

Patz and Maumenee obtained good results with argon laser photocoagulation in serous fluid leakage beneath the neural epithelium in the macular region. Burian and Smith found that in many cases intermittent exodeviations became manifest when measurements were carried out 100 feet or more rather than 20 feet. Sharply demarcated destructive areas of chorioretinitis were observed in chronic granulomatous disease of children, a genetically determined disease due to a defect in leukocytes to destroy phagocytized microorganisms (Martyn, Lischner, and Harley, Philadephia).

A sharply defined central corneal opacity sensitive to chelation with EDTA was found in glaucomatous patients (Kennedy, Roca, and Landers, Rochester). Other members described similar opacities, not always associated with glaucoma.

Traumatic, secondary, and acquired cataracts in patients 15 to 40 years of age were easily aspirated, provided the nucleus was not hard (Maumenee and Barlow, Baltimore). Transformation of the mebomian glands into hair follicles to create an additional row of lashes on the posterior eyelid margins (distichiasis) was found in association with congenital lymphedema of the legs in three generations of a single family (Hoover and Kelley, Baltimore).

Injury from broken spectacles is more common in compound myopia than hyperopia and can be largely prevented by specifying heat-tempered glass of 3 mm or more or by using plastic lenses. Modification of the spectacle frame with a lip to prevent backward displacement of the lenses, careful study of the polarization pattern, and freedom from surface defects will additionally reduce damage (Keeney and Estlow, Philadelphia).

Soft contact lenses in keratoconus gave rise to surprising difficulties (McTigue and Townsend, Washington), a finding also described by several discussants.

At the annual business meeting, Trygve Gendersen, vice-president, succeeded Dohrmann K. Pischel as president. A. Gerard DeVoe was named vice-president, and Samuel D. McPherson, Jr., was re-elected secretary-treasurer. Clement McCulloch was re-elected editor of Transactions. William F. Hughes was named to the council, while Joseph A. C. Wadsworth completed his term on the council. During the meeting, seven associate members were named.

Frank Walsh awarded the Howe medal to C. Wilbur Rucker for his many contributions to ophthalmology, and he delighted the members and surprised Dr. Rucker by showing a number of photographs secretly provided by the Rucker children.

The annual business meeting was followed by the AOS picture show, with John Wend-

land showing spectacular motion pictures taken from a helicopter in the ski country of the Canadian Rockies.

The next meeting of the Society is May 29-31, 1972, at the Homestead.

Frank W. Newell

## COMBINED MEETING OF THE EUROPEAN OPHTHALMIC PATHOLOGY SOCIETY AND THE VERHOEFF SOCIETY

On the occasion of the 25th meeting of the Verhoeff Society and 10th meeting of the European Ophthalmic Pathology Society, a combined meeting of the two organizations was held in London, April 25-28, 1971. It was indeed a memorable occasion. Five years ago, an attempt was made to bring the two organizations together for the first time. This was thought to be so successful that an official combined meeting was organized for this jubilee occasion.

The meeting was held in the School of Pharmacy of the University of London. It was organized by Prof. Norman Ashton of London, aided by a most competent staff, and it was probably the best organized meeting I ever attended. It was so efficiently run that it was awe-inspiring! Particularly worthy of note was the spacious meeting room with 60 binocular microscopes, and the flawless projection of slides—everything ran without problems, and on time.

The emblem of this Congress (Fig. 1) was designed by Prof. Ashton and illustrates the two societies united by a semidecussation producing perfect binocular vision.

The meeting was opened by Prof. Casanovas of Barcelona, the chairman of the European Society. From then on each member presented his case and pointed out its unusual features. Usually, a lively discussion followed and thanks to a number of linguists in the audience all the remarks were readily translated into English. A total of 60 cases

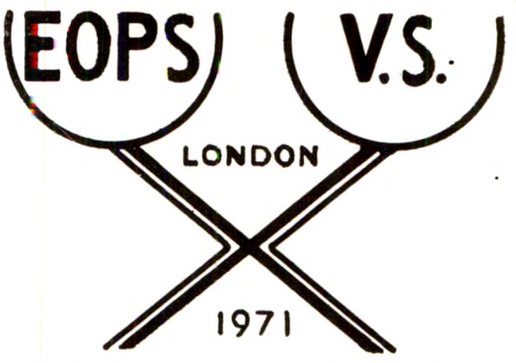

Fig. 1 (Blodi). Emblem of the Combined Congress designed by Prof. Norman Ashton, London.

were presented and discussed during the three days. Many of them will soon appear in print and will contribute to the advancement of our knowledge in ophthalmology in general and in ocular pathology in particular. A few most unusual and interesting cases should be mentioned here: an intraocular rhabdomyosarcoma (Nauman of Hamburg), the electron microscopic picture of asteroid hyalitis (Barry of Birmingham), the metaplasia of lens epithelium into bone (Landolt of Winterthur), and a retinitis pigmentosa with a choroidal hemangioma (Dhermy of Paris). The ocular manifestations of systemic diseases were especially well illustrated and some of them were described for the first time, such as: Kufs' syndrome (Font of Washington), mucopolysacchroidosis type 3 (Jensen of Copenhagen), Paget's disease of the bone (Gass of Miami), and coccidioidomycosis (Spencer of San Francisco). An interesting discussion centered around the proposed new classification of epithelial tumors of the ciliary body. Let's just hope that in the near future the proposal by Ry Anderson (Copenhagen) and the new classification as suggested by Zimmerman (Washington, D.C.) in his Verhoeff lecture can somehow be reconciled and combined.

The strenuous scientific meeting was complemented by a beautiful social program. The ladies had scheduled entertainment during the day, but the evenings were devoted to festive and impressive celebrations. On Sun-

day evening, the Verhoeff Society entertained the European Society at a cocktail party. This was followed by a dinner and then everybody departed by bus to visit Westminster Abbey. The Abbey was opened for the societies that night by special arrangement through the good offices of Prof. Ashton. The Dean and the Canons of the Abbey welcomed the group and guided them through the building. On Tuesday evening, the societies were invited by the Corporation of London to an official reception at Mansion House in the presence of the Lord Mayor. A number of the aldermen and other officials of the city of London were present and again acted as hosts, explaining the ceremony and the rituals. The reception was followed by a dinner given by the Department of Pathology of the Institute of Ophthalmology in London. This dinner was held at one of the old taverns on the Thames. The official banquet was held in the memorable Goldsmith Hall and Sir Stewart Duke-Elder and Derrick Vail were the special guests of the evening. The toast of the Verhoeff Society was given by Ted Sanders of St. Louis as the chairman of the group.

This combined meeting was certainly an unqualified success. It has helped bring together those ophthalmologists and pathologists who are interested in ocular pathology. Such an exchange of ideas and experiences can only be fruitful for the development of this branch of ocular sciences. In addition, it renews old friendships and establishes new ones. The language barrier was minimal and it is only to be hoped that this experience will lead to many more similar combined meetings of related societies.

OPHTHALMIC MINIATURE

"Light is a thing that cannot be reproduced" Cezanne said "but must be represented by something else—by colour. I was pleased with myself when I discovered that." This interchangeability of light and colour is similar to the modern notion of charges of energy. When Cezanne said "The painter is above all else an optic" he meant that the artist vibrates under the energy impulse of colour and translates the charge on to the canvas.

## THE CAUSE OF THE ARGYLL ROBERTSON PUPIL

An erudite and most valuable review summarizing the clinical and experimental bases for the hypothesized pathophysiology of the Argyll Robertson pupil has recently appeared.[1] It was stated that the pupillary light-near dissociation combined with miosis could be explained on the basis of a rostral midbrain lesion. The lesion needs to be located beyond the central hemidecussation of the light reflex path because impairment afferent to this decussation would involve both eyes, and, of course, the pupil of Argyll Robertson may be unilateral. A small lesion just rostral to the Westphal-Edinger nucleus —i.e., in the dorsal part of the midbrain tegmentum—would encounter both crossed and uncrossed pretectal fibers and thus abolish the light reflex. The near vision fibers which approach the nucleus slightly more ventrally would be spared, and the pupillary light-near dissociation would be explained.

It was further stated that the mechanism of the miosis must be sphincter contraction, cholinergically mediated, because (1) the miosis is pronounced, (2) the pupil does enlarge when the third nerve is blocked or

damaged, and (3) atropine, in the absence of iris damage, dilates the pupil.

Paralysis of the sympathetic was dismissed as causal because (1) miosis is more intense than that found in the usual Horner's syndrome, (2) no other signs of sympathetic paralysis are seen, (3) pupillary reflex dilation and dilation to cocaine can be shown to persist, and (4) there is no evidence for a pathway because the descending sympathetic runs quite lateral to the midline.

It was concluded that a destructive lesion of a supranuclear inhibitory pathway to the Westphal-Edinger nucleus must be the mechanism therefore of the Argyll Robertson pupil. But what is the nature of the inhibitory pathway?

I agree with this analysis that the miosis is cholinergically mediated and that the conventional sympathetic path descending in the lateral medulla is not involved. *Other central "sympathetic" fibers may well be, however.* In fact, there is a richly developed group of adrenergic fibers shown in the rat brain, containing the catecholamines norepinephrine and 5, hydroxytryptamine in large amounts, that are supranuclear and that contact specifically with the cells of the Westphal-Edinger group but not with those of the larger cells within the oculomotor complex; these, therefore, fit the requirement of a dorsomedial path (avoiding the ventral area described above).[2] Loss of this central "sympathetic" inhibitory path to produce the Argyll Robertson pupil is compatible with the site required by all the clinical and experimental data reviewed, and fits with the pharmacologic studies cited.[1]

The nature of the pathway interrupted in the production of the Argyll Robertson pupil would thus be a group of supranuclear inhibitory fibers, indeed, but a group of adrenergic fibers. The reproduction of a like miosis by the reserpine-induced depletion of norepinephrine in the central nervous system without peripheral (irridial) catecholamine depletion, as well as the miosis seen during sleep, are phenomena consistent with this concept. A search for these adrenergic fibers in higher animals should now be made so that the final chapter in the story of the Argyll Robertson pupil may be written.

The purpose of this note is to draw the clinician's attention to the new finding[2] of these adrenergic midbrain fibers[2] and to apply the results of the work to our understanding of the Argyll Robertson pupil.

## IN MEMORIAM

### WILLIAM A. MANN
### 1898–1971

William A. Mann, M.D., Secretary-Treasurer of the Ophthalmic Publishing Company, parent company of the AMERICAN JOURNAL OF OPHTHALMOLOGY, and a member of its editorial board since 1946, died May 18, 1971, in Chicago, Illinois. His death was sudden and unexpected; he and Mrs. Mann had planned to leave within the next several days on a leisurely drive to Hot Springs, Virginia, to attend the American Ophthalmological Society meeting and the annual meeting of the board of the Ophthalmic Publishing Company. On the evening of his death, he and Mrs. Mann left for a meeting of the trustees of Hadley School for the Blind, but returned home because of what was thought to be a slight indisposition.

Dr. Mann was Professor Emeritus of Ophthalmology at Northwestern University and Chairman Emeritus of the Department of Ophthalmology at Chicago Wesley Memorial Hospital and the Veterans Hospital at Hines, Illinois. He devoted his entire professional career to these institutions. He began as a clinical assistant at Northwestern

William Alfred Mann, M.D.

University in 1927, and ascended the academic ladder to become professor in 1949. He was acting chairman of the department of ophthalmology following Sanford Gifford's unexpected death in 1943, and managed the department until Derrick Vail became a professor in 1945. He was devoted and loyal to the department and did yeoman service in its organization and activities.

He served on the staffs of both Wesley and Passavant hospitals, and with the opening of the new Wesley Hospital in 1940, he became chairman of its department of ophthalmology and a consultant at Passavant. He began service with the United States Veterans' hospital in Hines in 1933 and became its chairman in 1946. He was responsible for instituting the residency program at both Wesley and Hines hospitals. In addition, he played an active role in the formation of the facility at Hines for training newly blinded soldiers.

The details of Dr. Mann's career are related in the special issue of the JOURNAL published in his honor in October, 1967. He attended the public schools in Chicago and Wilmette. He graduated from the University of Illinois and interned at Evanston hospital. His ophthalmic training was obtained at the University of Illinois and in Vienna.

In his early professional career he was active in the affairs of the Alpha Kappa Kappa medical fraternity. He served as president of the professional interfraternity council from 1933 to 1935 and was chairman of the medical interfraternity conference from 1947 to 1949. He was Grand Primerius of the Alpha Kappa Kappa Fraternity from 1949 to 1953, and again from 1963 to 1965. He also edited the Centaur, their official magazine, and served as president, grand vice-president, and grand historian. He was president of Omega Beta Pi, honorary national fraternity from 1932 to 1935 and served as president of Lambda Chi Alpha while attending the University of Illinois.

His scientific contributions were in two main areas, photography of the eye, and therapy. He was active in the development of color and infrared photography of the fundus and wrote his thesis for the American Ophthalmological Society describing an animal eye as a camera after Scheiner. He was active in the initial development of ACTH and the corticosteroids. For many years he gave a course in the optical correction of aphakia at the American Academy of Ophthalmology and Otolaryngology, from which he received its honor medal, and he wrote extensively concerning hysterical amblyopia.

His major love, however, was history. And at the time of his death he was historian of the Chicago Ophthalmological Society and had written extensively concerning the history of ophthalmology in the Illinois region.

He combined his interests in his final contribution, relating the history of photography in ophthalmology (Surv. Ophth. 1970).

Dr. Mann served as secretary-treasurer of the Ophthalmic Publishing Company from 1948 until his death. When he first took office the circulation of the JOURNAL was 4,000 and he saw it grow to more than 13,000. He also participated in the transition of the JOURNAL from a small enterprise managed principally in the office of its editor to an independent publishing group.

In reviewing Bill Mann's career, one is impressed by the number of successful enterprises with which he was associated: the training of nearly 100 ophthalmologists in residency programs he established at Wesley and Hines; the remarkable growth of the Hadley School for the Blind, where Bill served on the executive committee for many years; the extraordinary work done with rehabilitation of the blind at Hines Veterans Hospital; and the development of ophthalmology at Northwestern University.

He was a member of numerous organizations: American Medical Association, Illinois State Medical Society, Chicago Medical Society, American Ophthalmological Society, American Academy of Ophthalmology and Otolaryngology, Association for Research in Vision and Ophthalmology, American Association of Ophthalmology, Oxford Ophthalmological Congress, and American Society of Ophthalmology and Chicago Ophthalmological Society (President, 1946-47). He served as a member of the revision committee and as chairman of the panel on ophthalmology of the U.S. Pharmacopia from 1950 to 1960, and on the panel of ophthalmology from 1960 to 1965. He was a Congregationalist and a Knight Templar.

No description of Bill Mann's life would be complete without mention of the major role of his wife. They met at Northwestern University in 1928 where she worked in the social service department. In 1931, they were married, and since then she has played an active role in the things in which Bill was interested. Mrs. Mann is active in the Women's Board of Wesley Hospital, Northwestern University, and served as a trustee with him at the Hadley School for the Blind. She entertained his friends, colleagues, and residents at a sumptuous home in suburban Wilmette, and later, in their apartment overlooking Lake Michigan in Chicago. She traveled with him on his professional journeys and they were going to celebrate their 40th wedding anniversary at the Homestead during the meeting of the American Ophthalmological Society.

Chancellor Roscoe J. Miller of Northwestern University, a friend of Bill's since the time both were members of the faculty in medical school, stated in his eulogy, "Greatness is a quality that is measured by the impact a man creates on his family, his peers, his associates. Greatness in a man is found in the quality of his life, whether he be renown or unknown, popular or unsung, rich or poor, and the quality of a man's life is measured by the ways in which he comes to terms with life as that life unfolds itself to him."

The JOURNAL and its staff extend to Mrs. Mann, their three children, and seven grandchildren, their sincerest sympathies. We shall miss him greatly.

Frank W. Newell

---

## HAIL AND FAREWELL

The executive family of the American Journal of Ophthalmology has suffered a grievous blow in the loss of William A. Mann. For 25 years as secretary-treasurer of the Ophthalmic Publishing Company, the parent of the JOURNAL, Bill had always given sound advice in the exercise of his calm judgement and great common sense. He was a good balance wheel, controlling my impulsive nature and quick decisions that might have been harmful. I am grateful for this.

Bill had an unusually sweet nature and this endeared him to a very large number of fast friends. He had great integrity and honesty. I shall miss him and will always cherish his loyal friendship.

Derrick Vail

## CORRESPONDENCE

### Gonioscopic evaluation of the narrow angle

Editor,

American Journal of Ophthalmology:

I found Dr. Gorin's article, Re-evaluation of gonioscopic findings in angle-closure glaucoma: Static versus manipulative gonioscopy (Am. J. Ophth. 71:894, 1971) of particular interest, as the gonioscopic evaluation of the narrow angle has been an area of considerable interest to me. Because many of my observations relate directly to this subject and differ somewhat from his I would like to make a few hopefully clarifying points:

1. Dr. Gorin states that static gonioscopy (applying the prism centrally to the eye without manipulation) elicits the "true state of narrowness of the angle." I do not believe this statement to be correct. Regardless which gonioprism is used (and the view of the angle will differ as it is dependent on which gonioprism one chances to use), the moment the gonioprism is applied to the eye inadvertant distortion—and therefore, inadvertant manipulation—occurs with alteration of the anatomic relationships and appearance of the angle. This has been described previously[1] and has been verified photographically.[2]

2. It has been well established that gross manipulation of the prism with pressure causes alteration in the normal anatomic relationships in the angle.[3] The more subtle and inadvertant distortion that occurs in the angle with manipulation of the prism, as occurs with sliding of the prism, has likewise been elucidated,[4] and it is indeed comforting that other gonioscopists such as Dr. Gorin are now recognizing and confirming these earlier observations.

I am always in favor of coining new terms when they add to our insight and understanding of a subject; however, I believe that all gonioscopy as presently performed results in distortion of the cornea and angle and therefore the words "static versus manipulative" has little meaning.

Stanley C. Becker
*St. Louis, Missouri*

### Reply to Dr. Becker

Editor,

American Journal of Ophthalmology:

Dr. Becker seems to have overlooked the main purpose of my paper.

Teaching gonioscopy for the past 20 years, I have become concerned recently by the practice of undue manipulation of the gonioscopic lens leading to misjudgment of the narrowness of the angle. I was not interested in coining new terms. I used the term "static gonioscopy" as opposed to manipulative gonioscopy merely to emphasize the two different aspects of gonioscopy.

My paper had two main objectives:

1. To warn against undue manipulation in reaching a diagnosis of angle-closure glaucoma

2. To indicate that proper manipulation may assist in estimating the extent of synechial closure.

Experience with the Goldmann lens has shown that in most eyes gentle application of the lens to the center of the cornea causes hardly any change in the angle. The minimal change which occurs in a few eyes is of no clinical significance and does not depreciate the value of Goldmann lens gonioscopy in diagnosis and treatment of angle-closure glaucoma.

George Gorin
*New York, New York*

### TREATMENT OF ANTERIOR CHAMBER OBLITERATION AFTER SURGERY

Editor,

American Journal of Ophthalmology:

Two days after a peripheral iris inclusion procedure for early, chronic, angle-closure glaucoma, a 64-year-old white housewife developed a stony-hard painful eye. The anterior chamber was obliterated. I pressed on the cornea 2 mm from the upper limbus with a Graefe muscle hook. The anterior chamber immediately reformed, pain was dramatically relieved and a small bleb was present. Two days later symptoms recurred and the same treatment was repeated with similar results. After six similar episodes, the apparent ball-valve action of the lens stopped and the chamber remained formed. There was no bleb and tension was 10 mm Hg. Subsequently, the opposite eye did well after a peripheral iridectomy, and in retrospect, that would appear to be the procedure of choice in this eye.

I submit this report in the hope that my colleagues, in a similar unhappy situation, may find similar relief for themselves and their patients by the use of this maneuver.

John A. Fusco
*Whittier, California*

## BOOK REVIEWS

THE WORLD THROUGH BLUNTED SIGHT. By Patrick Trevor-Roper. New York, Bobbs-Merrill, 1970. Clothbound, 191 pages, table of contents, bibliography, list of illustrations, index, 83 black and white figures, 29 color figures. $12.50

This beautiful volume, with its profuse illustrations (29 in color) and its wealth of information, deals with the consequences of visual defects on the work and personality of artists, poets, authors, and composers. Every form of impairment is considered, including refractive errors, color perception deficiency, incipient cataract, strabismus, and aniseikonia. Psychedelic art and the art of the semi-sighted and blind are discussed. Examples and anecdotes are given: Probably because of his myopia, Gordon Craig introduced a new approach to stage design, emphasizing color and form over distracting details. Hitler's documents were prepared for him on a special large-type typewriter. El Greco's style has been attributed to astigmatism (Ahlström) or aniseikonia (Linksz), but x-ray examination of his work revealed that the elongations were secondarily imposed on the original sketches. It is suggested that Constable's color values probably stemmed from defective color discrimination. The amblyopic James Joyce compensated by stressing sound effects, alliteration, and musical words.

Trevor-Roper's encyclopedic erudition is revealed in the surprising incidental data: e.g., Lombroso, in 1883, was the first to note the usual association of right eye dominance with right-handedness; ancient Egyptian art indicated sex by color, males being red and females yellow; Lucretius recorded blindness from sun-gazing.

This unusual book should have a wide appeal, especially to those who would extend their ophthalmic insight beyond diagnostic and therapeutic needs.

James E. Lebensohn

MANUAL OF DISEASES OF THE CORNEA. By Merrill Grayson and Richard H. Keates. Boston, Little, Brown & Company, 1969. Clothbound, 311 pages, index, appendix, 236 figures in black and white, two figures in color.

This book was prepared to assist the resident in correlating information concerning the cornea. In this it wonderfully succeeds, for it presents a concise overview of a large variety of corneal diseases divided into those associated with primary corneal degenerations and those associated with systemic conditions. The text is richly illustrated and the references are current. A number of differential diagnoses are presented in table form. Treatment, which the authors plan to describe in another monograph, is not discussed. The text is highly recommended.

Frank W. Newell

---

Cry-ophtalmologie. By P. J. Moreau, J. Haut, R. Alfieri, M. Brihaye, P. Payrau, Y. Pouliquen, D. Simatos, and P. Sole. Paperback, 746 pages, index of authors, alphabetical index of material, table of contents, 278 black and white figures. 100 francs

At the request of the French Ophthalmological Society, Profs. Moreau, of Dijon, and Haut, of Paris, with collaboration of six Gauls who are especially knowledgeable in cryo-ophthalmology, have prepared a report on all that has been done in this field. The documentation is extensive. More than 400 authors have contributed to the ophthalmic literature since 1918 when Schoeler reported causing an adhesion of internal tissues in the rabbit eye following the application of carbon dioxide snow to the sclera. The 1960s saw a deluge of papers on the subject, and I was surprised to learn that the first report in this decade on producing a chorioretinal adhesion was not by an American, but by a Russian. The book will be indispensable in the future for an author who wants to provide proper references for a cryosurgical paper.

There are six uneven parts to the book. The first is a basic science section on the physics of freezing and the response of cells to cold. This scholarly essay, by Mlle. D. Simatos, of Dijon, is couched in terms agreeable to the clinician. The second part, by Prof. Moreau, describes the instrumentation as well as the basic mechanics of cryosurgical devices. There follows a long section by Profs. Haut, Pouliquen, and Brihaye on biological experiments in the various tissues. Included are Brihaye's exceptional tables on the pathologic changes in sclera, choroid, and retina at every conceivable temperature and time.

The pathologic sections that were selected for reproduction are not as instructive. Nearly all were obtained after applications of degrees of cold in excess of that which causes total destruction of the rabbit retina, demonstrating that sclera survives almost any amount of freezing—for example, −160° C for 40 seconds.

The fourth part of the book is a short one on the treatment of skin lesions by cryosurgery. The fifth is a long report on therapy of the eye and tells about all the things for which cryosurgery is useful and a few for which it is not. Sixty pages are devoted to the management of cataract. The sixth part is about preservation of tissues, particularly cornea, and is 18 pages.

Most of the sections of the book conform to a pattern of presentation, reporting the literature in chronological order and precise form first. This is followed by a commentary from the author which is usually interesting and only occasionally indifferent. At the end of each part there is a brief resume in English. This is the 20th publication by the French Society since 1951. Profs. Moreau, Haut, and the collaborators deserve much credit for producing this handsome volume which continues a tradition of excellence.

Harvey Lincoff

PHYSIOLOGY OF THE RETINA AND VISUAL PATHWAY, 2nd ed. Edited by G. S. Brindley. Baltimore, The Williams and Wilkins Company, 1970. Clothbound, 315 pages, table of contents, bibliography and index of authors, index of subjects, 64 black and white figures. $17.50

Unlike many second editions we see today, this book, first published in 1960, has been extensively rewritten, and it superbly integrates the older and classic lieterature with the exciting progress made in the field over the past 10 years.

The book remains a precise and concise introduction to the field, and it continues to be highly useful both to the serious student and to the expert. The selection of literature cited in the volume has been most carefully chosen, and, as noted in the preface, "most omissions are intentional." Although I (and many others in this field) would have selected additional experiments to mention, and would perhaps have omitted some of those cited, this book is extraordinarily comprehensive in the areas it covers and is probably the most objective work of its type available today.

In eight highly readable chapters (and in only 260 text pages!), the volume covers topics ranging from the photochemistry of the visual pigments to the psychophysics of visual thresholds and color vision. Along the way, the author discusses the electrical activity of the receptors and retinal nerve cells, the electroretinogram, and the structure and function of the higher visual centers.

One of the special charms and values of the book is the occasional section that points out the difficulties with the prevailing point of view on a particular subject; it discusses alternative hypotheses that cannot be dismissed at the moment (although many of us might like to do so). Two examples of such sections are entitled "Objections to the hypothesis of electrical signals" in the chapter on receptor activity, and "Function of centrifugal fibers to the human retina, *if they exist*" (italics mine) in the chapter on central pathways. There is also an excellent short chapter entitled, "Introduction to Sensory Experiments," particularly valuable for students, that assesses the role of various types of sensory experiments and provides a convenient classification of such experiments.

I highly recommend this book to any newcomer in the field of vision, or to anyone who would like to be brought up-to-date in this rapidly moving field. This book will be given a prominent place on my bookshelf, and I am confident it will be used often while we eagerly await the third edition. The price ($17.50) seems unnecessarily high, however, since the volume is only a little over 300 pages (including bibliography and index) and it contains only two half-tone reproductions. I would like to suggest that this book be purchased by every student in the field of vision, whether he is planning a career in the laboratory or in the clinic, but I am afraid that the price may put this splendid book beyond the reach of many.

John E. Dowling

VISUAL PROSTHESIS—THE INTERDISCIPLINARY DIALOGUE. Edited by T. D. Sterling, E. A. Bering, Jr., S. B. Pollack, and H. G. Vaughn, Jr. New York, Academic Press, 1971. Clothbound, 382 pages, table of contents, list of participants, 105 black and white figures. $18.50

If man could replace vision, even in the primitive form, this would represent a significant triumph of his knowledge, scientific technology, and determination over the forces which govern many of his actions as a biological organism. During a two-day period in June, 1969, some 50 investigators in the fields of neurophysiology, neurosurgery, engineering, and computer science met at the University of Chicago and considered ways and means by which a functioning visual prosthesis could be produced. This book is a record of that conference, the second to be held

on this subject under the sponsorship of the Association for Computing Machinery.

Each of the individuals who contributed to the book are knowledgeable in their fields and most of them are presently working on one or more of the many aspects that could make artificial vision a possibility.

There was a free exchange of views, and much was learned from the discussions which took place between the formal presentations. The editors have de-emphasized extraneous material so that the reader can partake of some of the enjoyment and stimulation of the conference. The presentations of this conference have been arranged into a number of sections, each self-explanatory and each with editorial comment to serve as a guideline.

The phenomenon on which the possibility of a visual prosthesis is based has been considered until the present time more of a curiosity than a useful observation by most neurophysiologists. An illusion of a point or a surface of light is created when the cells in the visual cortex are stimulated. These sensations are called phosphenes. By implanting multiple electrodes in the visual cortex, it is possible to create an array of these phosphenes, or "lights." Perhaps, when combined with a clever system that arranges to turn on some and not others, this may be used to present images. Perhaps the phosphene phenomenon may offer a way of creating a practical visual prosthetic device. To bring the information to its present position required interdisciplinary cooperation in order to provide a common language so that dialogue could be pursued in a rewarding fashion.

A summary of the previously confidential first conference is included in this book as an appendix. This first conference served as a valuable sounding board for all good reasons why a useful visual device could not be built up to the time of that meeting, it also allowed a realistic assessment of the prospects of encouraging work that ultimately will lead to direct cortical stimulation. To Giles Brindley goes the credit for cutting through the skepticism and procrastination in order to present an actual demonstration of the feasibility of a direct implant. His work produced the stimulating discovery.

The conference on which this book is based was supported by funds from the NINDB Vocational Rehabilitation Agency and American Foundation for the Blind, as well as by interested friends.

Discussions at the second conference were based on observations of phosphenes in human subjects, and of brain stimulation. Stimulation studies done on the cortex in the geniculate bodies in the primary visual pathway and retina are reviewed. Discussions of ways of preprocessing visual information and potential designs of the system are analyzed in detail. Other possible approaches to aiding the blind are not neglected; some of these are a reading maching with tactile display, tactile visual synthesis, aids to mobility, and computer-aided generation of speech from the printed word.

It is difficult to decide how one should invest money for research to aid the blind. Perhaps much functional legal blindness might be overcome by greater expenditures for known remedies, such as ophthalmic therapy and surgery, better refraction, magnifiers, and counseling on the best use of existing aids. However, attention must be paid to psychological factors—the blind individual's acceptance of certain aids and the training entailed in their use. There does remain a strong case for the wisdom of expenditures for research and development on a broader spectrum.

Much consideration is given in this book to the propriety of prosthetic experiments on humans. There are some blind individuals who have given a great deal of thought to this, and some of them feel that the blind do not need a visual prosthesis as contemplated here. There are several discussions devoted to a thorough analysis of their position.

This text tells of a fascinating venture which will be of great interest to ophthalmologists, neurologists, neurosurgeons, neuro-

physiologists, biophysicists, computer scientists, engineers, and all those concerned with education and rehabilitation of the blind.

FAMOUS HUNGARIAN OPHTHALMOLOGISTS. Edited by Magda Radnót. Budapest, Akadémiai Kiadó, 1970. Paperback, 31 pages, 12 black and white figures.

Hungary is a small country with a population of 10 million. Therefore, it is remarkable that such a small nation should produce as many leading figures in ophthalmology as this short monograph describes. The names of Imre, Hoor, Grosz, and Blaskovics are well known to ophthalmologists throughout the world. Their work and that of others named in this book serves as a stimulus to many young ophthalmologists in central Europe.

It is appropriate that such a volume should be published in preparation for the Fourth Congress of the European Society of Ophthalmology which is to be held in Budapest next spring. It demonstrates the important role Hungarian ophthalmology has played in Europe in the past 150 years and justifies the decision of the Congress to hold the meeting in Budapest. The editor should be congratulated for compiling this collection of biographies and providing us with this handsomely printed book.

Tibor G. Farkas

LEPROSY IN FIVE YOUNG MEN. By George J. Hill, II. Denver, University of Colorado Press, 1971. Clothbound, 204 pages, table of contents, table of illustrations, Legend of Tables, glossary, index, references, 90 black and white figures. $8.00

In 1962 the National Institute of Health began a clinical study of leprosy in five selected patients. The major goal in bringing patients to the NIH clinical center was to stimulate the interest of medical and biological scientists in diverse fields in the hope that new ideas for research in leprosy might by forthcoming. The first objective was to describe in detail all the abnormalities present in the leprous patient. The present volume achieves that objective and concludes that leprosy can be effectively analyzed and treated in a general hospital or research hospital if precautions are followed similar to those for active tuberculosis.

Of specific interest to me were the findings confirming earlier observations that the nervous system, skeletal muscles, heart and lungs are spared in the vast majority of cases. Further, extensive skin lesions, neuropathy, fever and leonine facies may exist in patients with few lepra organisms. On the other hand, extensive involvement of viscera and other tissues may occur with only mild symptoms.

Ocular involvement is common. The five patients studied shed no new light on the occurrence or pathogenesis of ocular symptoms. One patient had a chorioretinitis related to toxoplasmosis. Others showed neural and follicular involvement on a leprous basis. Contrary to most experience, the two patients with lepromatous leprosy did not show anterior segment changes in the iris.

The book is handsomely printed and serves to alert the clinician to the fact that leprosy is a multisystem disease to be suspected in instances when the skin is discolored or hypesthetic, or whenever acid-fast bacilli are recovered which will not grow in culture.

CONGENITAL AND PEDIATRIC GLAUCOMAS. By Robert N. Shaffer and Daniel I. Weiss. St. Louis, Mosby, 1970. Clothbound, 221 pages, 253 illustrations, color plate, subject index. $20.50

The book, in its first edition, is a timely and welcome addition to the libraries of pediatricians and ophthalmologists. The authors, through their vast personal experi-

ence, provide the reader with a thorough comprehensive survey of the field of pediatric glaucomas, emphasizing the clinically significant features and eliminating the clutter of the myriad "special" attributes that characterize each variant. This simplifying feature renders the book of great value to medical students and those in the health-related fields as well.

The book is organized in 12 chapters. The first two deal with general principals including classification of the glaucomas, the role of heredity and methods of diagnosis. The following six chapters discuss the genetically determined pediatric glaucomas: infantile glaucoma, primary glaucoma occurring after infancy, glaucoma associated with the phakomatoses, with mesodermal anomalies, with metabolic diseases, and with iris anomalies.

Nongenetic pediatric glaucomas (secondary glaucomas) are discussed in two chapters: one devoted to glaucoma associated with rubella infection; the last two chapters presenting medical and surgical therapy.

Throughout the entire book the lucid presentation of the authors is reinforced by elegant and effective illustrations that demonstrate clinical conditions, methods of investigation and therapy, light and electron microscopic findings, and photographic records of the optic disk and of fluorescein angiograms.

Mansour Armaly

---

PHYSIOLOGY OF COLOR AND PATTERN VISION. By K. Motokawa. Clothbound, 283 pages, table of contents, list of references, author index, subject index, 137 black and white figures. $18.00

In his preface, Motokawa states that "The purpose of this book is to present the major studies on vision performed in our laboratory during the past 25 years, and also to describe in some detail related studies in other laboratories."

The book is divided into 11 chapters. The first three include discussions of the anatomy and electrophysiology of the retina and visual pathways, and a discussion of electrophysiologic correlates of some aspects of pattern vision. Chapters 4 through 10 are devoted to a detailed discussion of techniques, results, and interpretation of experiments utilizing electrical stimulation of the eye. Topics under discussion include induction, color vision, optical illusions, movement, and stereoscopic vision. Chapter 11 concludes with a number of models simulating various aspects of spatial and temporal visual function.

The book is physically attractive and well laid out. There is a 22-page reference section, but only a scant two-page subject index, which is not very useful. The author assumes that the reader has considerable knowledge of both vision and physiology. The book provides a comprehensive review of the utilization of the electrical phosphene to gain insight as to the functioning of the visual system, and will be of value to researchers specializing in visual function. It is not, however, a suitable teaching text.

Joel Pokorny

---

THE PHARMACOLOGICAL BASIS OF THERAPEUTICS, 4th ed. Edited by Louis S. Goodman and Alfred Gilman. Toronto, MacMillan, 1971. Clothbound, 1794 pages, table of contents, index, 184 black and white figures. $25.00

It is 30 years since the publication of the first edition of this textbook, the "blue bible" of pharmacology. In the first two editions, the contents were provided solely by the two authors. In the third edition, published in the mid-1960's, it became, for the first time, a multi-authored work. The present fourth edition has undergone an updating of every chapter with respect to the mechanism of action, rational use of older therapeutic agents, and the addition of important new drug entities. The organization of the material in this text is similar to that of previous editions. Those who have read this book previously will find themselves on familiar ground.

This 1794-page volume tries to correlate pharmacology with related medical sciences, gives considerable attention to advances in medicine and interpretation of pharmacologic effects and actions leading to or influencing these advances. There has been a great effort made to help the reader evaluate promotional claims in published literature of new therapeutic agents. Many therapeutic agents that are in active use in each field are reported, with attempts made to reduce confusion, culling out those which are not well established, safe, and effective drugs.

There are many ways in which this tremendous compilation of data can be useful to the ophthalmologist. It provides fundamental knowledge of the action of agents which are employed by the ophthalmologist regularly or on rare occasions. He will have no difficulty understanding the mechanism of action of old and new agents, of comparing their chances for efficacy and toxicity. The specific fundamentals, essential for the proper use of any of these agents in all branches of ophthalmic therapeutics, are clearly defined.

The field of pharmacology has expanded rapidly in the past several decades, with remarkable advances in the various methods of testing for efficacy and toxicity. It is a Herculean task, and the two original authors, along with their fellow contributors, have brought order in a practical way into the therapeutic jungle.

BECKER-SHAFFER'S DIAGNOSIS AND THERAPY OF THE GLAUCOMAS, 3rd ed. By Allan E. Kolker and John Hetherington, Jr. St. Louis, C. V. Mosby, 1970. Clothbound, table of contents, index, 495 pages. 383 black and white figures and six color plates. $25.00

The third and latest edition of this superb text has maintained the original purpose of the first: "to make available in one volume the current thinking on the pathogenesis, diagnosis and management of the glaucomas." The format of the current edition is the same as the second. First, there is a section on classification of the glaucomas. This is followed by a section on gonioscopy and one on tonometry and tonography. A fourth section deals with ophthalmoscopy and perimetry and includes a description of static perimetry. Sections on diagnosis and therapy, followed by separate chapters on medical and surgical techniques, complete a succinct but comprehensive review of the subject matter. An appendix includes examples of gonioscopic views, tables for tonometry and tonography, and examples of tonograms.

In a subject so complex, with ramifications that touch almost every specialty area of ophthalmology, it would be difficult for any reader not to find some areas of disagreement. These turn out to be of a minor nature when one considers the overall excellence of the volume. This book is a must for the office, library, and laboratory of every ophthalmologist. Together with lectures on glaucoma by Chandler and Grant, it forms the outstanding pair of textual contributions from this country on the subject of glaucoma.

Marvin L. Sears

CLINICAL ASPECTS OF AUTONOMIC PHARMACOLOGY. By Paul Turner. Clothbound, 169 pages, table of contents, two indexes, 36 black and white figures, $7.50

The subject of autonomic activity and its relationship to the pathogenesis and treatment of disease has been revolutionized by two series of events which occurred in the past 10 years. The first has been an increase on understanding of transmitters, or their release and uptake. The second has been the introduction of compounds with relatively specific receptor blocking activity. The result of these new types of information has resulted in a change in thinking on autonomic pharmacology and has influenced the investi-

gations and treatment of many diseases.

The present text is an attempt to outline current concepts of autonomic pharmacology and its relationship to clinical methods in a manner which will be of value to both undergraduate and postgraduate clinical students.

The text is small, consisting of 169 pages. In an effort to reduce the volume of the text, the authors have deliberately written in an authoritative way without giving references for each statement of fact. However, each of the six chapters into which this book is divided is followed by selected references, usually to review articles which have appeared in the two or three years prior to the publication of this text.

In the introduction the authors review the physiology and pharmacology of the entire autonomic system. In the second and third chapters they specifically go into details of the actions of the parasympathometic and sympathometic drugs. Autonomic blockade is considered in one chapter. Autonomic activity in healthy man in a separate chapter and the autonomic activity and blockade in disease in another. In each of these the ocular effects are carefully considered. However, there are some omissions. For example, the ocular effects of noradrenalin are omitted as are those of isoprenalin and dopamine. At one point the author states that phenylephrine is an unsatisfactory mydriatic. In considering thymoxamine (Opilon), the author discusses his own work demonstrating its alpha blocking activity in man by local instillation into the cul-de-sac. These studies were done in 1968. However, he fails to mention the observations of Pau in 1955 in which he demonstrated thymoxamine to be a potent ocular adrenergic blocking agent and noted that this agent could block some of the actions of adrenalin as well as those of noradrenalin (Klin. Mbl. Augenheilk. 126:171, 1955).

The section on the autonomic activity and blockade in glaucoma is brief and does not present all of the information available in the literature. There are many discussions in this text which deal with ocularly oriented disorders—e.g., myasthenia gravis, familial dysautonomia, depression syndromes and anxiety states, Parkinson's disease, hyperthyroidism, and neurological alterations in pupillary function.

In addition, there are many diseases about which ophthalmologists are frequently consulted, such as pheochromocytomas, essential hypertension, cardiovascular system alterations, disturbances of the gastrointestinal and urinary tracts, and endocrine disorders other than diabetes and hyperthyroidism, and migraine. Ophthalmologists use these drugs probably more than or as much as any other specialty physicians. They will find a great deal of fundamental information included in this small text. It is possible that many ophthalmologists are not familiar with the diagnostic procedure known as the Loewi's test for acute pancreatitis which is discussed briefly. It is a test in which 0.10% solution of adrenalin, normally ineffective, is said to cause mydriasis. The pharmacologic basis of this test is not known.

At the present time, there are very few comprehensive reviews covering this entire and rapidly developing subject, but this text makes a noble effort.

Irving H. Leopold

# ABSTRACT DEPARTMENT

EDITED BY DAVID SHOCH, M.D.

## ANNALES D'OCULISTIQUE

TREATMENT OF ABNORMAL RETINAL CORRESPONDENCE WITH PRISMS. (French) Adelstein, F. E. and Cupper, C. (University Ophthalmology Clinic Giessen, West Germany), Ann. Ocul. 203:445-457, May, 1970.

Seventy-eight children with ARC and strabismus completed treatment with surgical over-correction and/or correcting prisms Forty-seven of these eventually needed no prism, and 18 needed only weak prism in their glasses. (2 figures, 12 tables)—Kenneth Hovland

TREATMENT OF ACCIDENTAL PERFORATION OF THE HOST CORNEA IN LAMELLAR KERATOPLASTY. (French) Olteanu, M., Boeras, F. and Ciurea, V. (Central Military Hospital, Bucharest, Roumania), Ann. Ocul. 203:459-467, May, 1970.

Nine cases of lamellar keratoplasty (out of 847) developed accidental perforation of the host cornea during surgery. Several methods of closure were employed, including a new technique of piecing together corneal grafts. Favorable results were obtained in eight of the nine cases. (7 figures, 14 references)—Kenneth Hovland

MEDICAL TREATMENT OF ENDOCRINE EXOPHTHALMOS. (French) Lavergne, G. and Winand, R. (University Ophthalmology Clinic, Liege, Belgium), Ann. Ocul. 203: 469-472, May, 1970.

Using 80 mg of prednisolone per day, six of eight patients with severe endocrine exophthalmos were improved rapidly. The authors felt this was due to the immuno-suppressive action of the prednisolone. (8 references)—Kenneth Hovland

THE BATTERED CHILD SYNDROME OF SILVERMAN. OCULAR SIGNS. (French) Aron, J. J., Marx, M. F., Blank, R. D. and Luce, R. (Universitaire Necker-Enfants Malades), Ann. Ocul. 203:533-546, June, 1970.

This syndrome consists of multiple fractures of the long bones, combined with sequelae of subdural hematoma and scars in the skin and mucous membranes of the nose and mouth. Concurrent ocular signs are old chorioretinal lesions, heavily pigmented and retinal detachments. Eighteen case histories are reported in detail. All of them demonstrate severe ocular abnormalities. This syndrome has been related to neglect and disregard of infants and small children and has been described as the battered child syndrome. However, this theory could not be substantiated in all the patients discussed. As several children belong to the same family the possibility of a familial disposition to similar bone and eye changes should be considered. The etiology, therefore, is not established with certainty. (6 figures, 1 table, 11 references)—Alice Deutsch

RECOVERY FROM A PRIMARY ORBITAL NEUROBLASTOMA. (French) Firat, T. (Clinique d'Ophthalmologie, Ankara, Turkey), Ann. Ocul. 203:579-583, June, 1970.

Primary orbital neuroblastomas are very rare. Their origin probably is the ciliary ganglion. A bilateral neuroblastoma occurred in a 2½-year-old boy. He was treated by chemotherapy and radiotherapy. The chemotherapy consisted of Endoxan which was given IV for ten consecutive days, 100 mg the first day and 50 mg during the following nine days; 3600 r of x-ray were applied. The local tumor masses disappeared gradually. (2 figures, 9 references)—Alice Deutsch

ABNORMALITIES OF LOCATION AND DIVISION OF THE CENTRAL RETINAL ARTERY ON THE PAPILLA. (French) Bonamour, G. (Clinique Ophthalmologique de l'Hopital de la Croix-Rousse, Lyon, France), Ann. Ocul. 203:639-649, July, 1970.

Variations of the branching and direction of the central retinal artery on the papilla include protrusion into the vitreous; trifurcation; formation of a cross, star, or "parrot's ladder";

and nasal or inferior direction. With congenital malformations of these vessels, one should suspect further malformations of other internal carotid branches. (13 figures)—Kenneth Hovland

CRYOTHERAPY IN A CASE OF OCULAR ACNE ROSACEA. (French) Michail, S. (Strada Izvor, 90 Sector 6, Bucharest 5, Romania), Ann. Ocul. 203:669-672, July, 1970.

A 50-year-old patient with acne rosacea keratoconjunctivitis was treated successfully with cryotherapy at −70° C for 10 to 60 seconds and subconjunctival hydrocortisone.—Kenneth Hovland

OCULAR ANOMALIES OF THE PHENOTYPE DR (RING-CHROMOSOME D). (French) Saraux, H. Rethore, M. O., Aussanaire, M., Dhermy, P., Joly, C., Le Loch, J., Praud, E. and Lejenne, J. (Travail du Service d'Ophthalmologie de l'Hopital Trousseau), Ann. Ocul. 203:737-748, Aug., 1970.

The main ocular symptoms were microphthalmia and colobomatous cysts with cartilage formation between the retinal layers close to the optic nerve entrance below. The superior segment of the fundus was nearly normal. There was not any hyperplasia of the primary vitreous, persistance of the hyaloid artery or hyperplastic retinal dysplasia. The ocular abnormalities of this genetic defect therefore do not resemble those connected with the common signs of the typical trisomy 13. While the typical trisomy 13 shows a proliferation of the primary vitreous as well as the immature retina the ocular changes of the ring-chromosome 13 anomaly depends on a lagging invagination of the retinal layer of the primitive ocular vesicle just below the optic nerve entrance, at the location of the final closure of the fetal cleft. Other congenital anomalies found in this infant were hypertelorism, a prominent nasofrontal mass, large ears with a deep helix, agenesis of the thumbs and partial fusion of other fingers. Those findings are compared with the findings of 15 other cases of DR ring-chromosome; seven of these had ocular involvements. (11 figures, 18 references)—Alice Deutsch

OPTIC NEURITIS CAUSED BY DISULFIRAM. (French) Saraux, H. and Biais, B. (2 square Albain, 16 Paris), Ann. Ocul. 203: 769-774, Aug., 1970.

Disulfiram is used for the rehabilitation of alcoholics. It can produce a retrobulbar neuritis with a much larger central scotoma than the one observed with alcohol-tobacco toxicity. Improvement usually starts about one month after the drug is discontinued. (2 figures, 6 references)—Alice R. Deutsch

THE TREATMENT OF THE GONJEROT-SJOGREN SYNDROME. (French) Bonnet, M. (Clinique d'Ophthalmologique, Hopital de la Croix-Rousse), Ann. Ocul. 203:775-783, Aug., 1970.

Many of the classical treatments are effective and should still be used. This includes solutions of artificial tears and occlusion of the lacrimal puncta. In severe cases hydroxychloroquine has been used with subjective and objective improvement. Daily doses of 600 to 800 mg are given for twenty days each month up to three months. After this the doses are reduced to 400 mg. Careful evaluation of visual functions and fundus inspections are necessary if this medication is used. Assuming that the changes in the lacrimal glands are basically inflammatory injections of soluble corticosteroids are suggested, hoping that at least during the early stages the inflammation would abate and sclerosis be prevented. Two injections are given each week for one month, later one injection per week for three weeks, followed by one injection every two weeks and finally one injection a month. The results of this latter treatment were good in selected cases. (12 references)—Alice Deutsch

## ARCHIV FÜR KLINISCHE UND EXPERIMENTELLE OPHTHALMOLOGIE

INFLUENCE OF 5-ETHYL-2-DEOXYURIDIN (EDU) ON THE REGENERATION OF THE EXPERIMENTALLY DAMAGED CORNEA. (German) Gauri, K. K., Malorny, G. and Rhiem, E. (Universitaets Augenklinik, 2000 Hamburg, Germany), Arch. Klin. Exp. Ophth. 179:287-293, 1970.

The regeneration of the rabbit cornea damaged by electrocautery was tested. The first group was treated with 0.5% EDU, the second

with 0.5% thymidin the third with 0.1% IDU and the fourth group with 0.9% NaCl solution. These solutions were injected subconjunctivally twice daily and dropped into the conjunctival sac four times daily. The corneas treated with EDU and thymidine solutions did not stain anymore on the fifth day in contrast to the corneas treated with IDU solution, which inhibits the regeneration of the corneal cells. (2 figures, 1 table, 15 references)—Walter Segall

A LIGHT- AND ELECTRONMICROSCOPIC STUDY OF AGE CHANGES IN THE HUMAN EYE. (German) van der Zypen, E. (Anatomisches Institut der Universitaet, 3550 Marburg a.d.Lahn, Germany), Arch. Klin. Exp. Ophth. 179:332-357, 1970.

Age changes begin between the twentieth and thirtieth year of life. In the beginning a marked increase in connective tissue can be seen; the electronmicroscope shows a fine granular amorphous mass which forces the muscle bundles apart. The circular muscle layer is affected first. After age 45 connective tissue pervades even the individual muscle bundles. At the age of 50 lipofuscin becomes deposited in the muscle cell. In old age the granular amorphous substance becomes replaced by coarse bundles of collagen fibers. The basement membrane of blood vessels in the ciliary body becomes stretched and degenerative changes occur in the endothelial cells. (2 tables, 35 references)—Walter Segall

COMPARATIVE EXPERIMENTAL INVESTIGATIONS OF THE RUPTURE RESISTANCE OF THE SCLERA AFTER APPLICATION OF ELECTROCOAGULATION CRYOTHERMY. (German) Matthaeus, W. and Dietze, H. (Augenklinik der med. Akademie, 8019 Dresden, DDR), Arch. Klin. Exp. Ophth. 179: 358-365, 1970.

The resistance of the sclera to rupture after electrocoagulation is reduced by about 60%. No reduction of the rupture resistance, however, resulted after cryothermy. (5 figures, I table, 26 references)—Walter Segall

## ARCHIVES OF NEUROLOGY

OPHTHALMOPLEGIA IN ACUTE POLYNEURITIS. Gibberd, F. B. (Department of Neurology, Westminster Hospital, London), Arch. Neurol. 23:161-164, Aug., 1970.

Six patients had acute polyneuritis and ophthalmoplegia. Two had complete internal and external ophthalmoplegia, two had complete external ophthalmoplegia but normal pupils, one had a partial external ophthalmoplegia and complete internal ophthalmoplegia, and one had partial internal and external ophthalmoplegia. It is concluded that the pupillary reaction can be lost during acute polyneuritis. (26 references)—Author's abstract

## ARCHIVES OF OPHTHALMOLOGY

INHERITANCE OF FUCHS' ENDOTHELIAL DYSTROPHY. Cross, H. E., Maumenee, A. E. and Cantolino, S. J .(Wilmer Institute, Johns Hopkins Hospital, Baltimore), Arch. Ophth. 85:268-272, Mar., 1971.

Two pedigrees contain seven individuals with documented Fuchs' endothelial dystrophy. A review of all previously reported familial cases reveals one pedigree with sufficient useful data for genetic analysis. Study of these three pedigrees together with segregation analysis suggests an autosomal dominant mutation as the most likely etiology, although alternative etiologies cannot be ruled out for other cases. An apparent female predilection for this disorder is present in the two reported sibships, which is similar to previously reported cases, but reduced penetrance of the gene cannot be documented. (3 figures, 8 references)—Authors' abstract

CONCOMITANT MEDIAL WALL FRACTURE AND BLOWOUT FRACTURE OF THE ORBIT. Dodick, J. M., Littleton, J. T. and Sod, L. M. (Manhattan Eye, Ear and Throat Hospital, 210 E. 64th St., New York 10021), Arch. Ophth. 85:273-276, Mar., 1971.

Medial wall fractures of the orbit should be considered a frequent component of the entity termed blowout fracture. Fracture of the medial wall without fracture of the floor did not occur in this series. Hypocycloidal tomography affords the best radiologic technique for diag-

nosing orbital fractures. (7 figures, 9 references)—Authors' abstract

SECONDARY AMYLOIDOSIS IN OCULAR LEPROSY. Rodrigues, M. and Zimmerman, L. E. (Armed Forces Institute of Pathology, Washington, D.C. 20305), Arch. Ophth. 85:277-279, Mar., 1971.

Deposits of amyloid were found in three eyes obtained postmortem from leprosy patients who had died in uremia from renal amyloidosis. We believe this may be the first report of ocular involvement in secondary amyloidosis associated with leprosy. (6 figures, 4 references)—Authors' abstract

"HOLES" IN BRUCH'S MEMBRANE. Friedman, E. and Strongin, M. (Boston University School of Medicine, Boston), Arch. Ophth. 85:280-282, Mar., 1971.

In a recent paper, "holes" were allegedly described in Bruch's membrane, and there has been speculation by the authors and others as to their significance. Utilizing both conventional histologic cross sections and flat preparations of the choroid, we find no evidence for the existence of such holes. Rather, it is clear that these apparent holes seen in flat preparations of the choroid are, in actuality, the lumina of the arterioles and venules supplying the choriocapillaris seen "end-on." (4 figures, 4 references)—Authors' abstract

HYDROPHILIC CONTACT LENSES IN CORNEAL DISEASE. Leibowitz, H. M. and Rosenthal, P. (University Hospital, 750 Harrison Ave., Boston), Arch. Ophth. 85:283-285, Mar., 1971.

A series of six patients illustrates that a hydrophilic contact lens may be fitted upon an edematous corneal epithelium containing bullae. The lens is well tolerated and may be worn continuously for prolonged periods without adverse effects. The lens produces a rapid and dramatic relief of pain and the accompanying symptoms of chronic bullous keratopathy. The lens itself produces no significant improvement in the clinical pathology of the epithelium, and symptomatic relief is directly dependent upon the lens remaining in place on the diseased cornea. (1 table, 3 references)—Authors' abstract

THE RECOVERY PHASE AFTER OCULAR HYPOTENSION INDUCED BY COMPRESSION. Schimek, R. A., Cooksey, J. C., Landreneau, M. and Steigner, J. B. (Oschsner Clinic, New Orleans, La. 70121), Arch. Ophth. 85:288-294, Mar., 1971.

As compression of the eye is often routine before intraocular surgery to help prevent vitreous loss, the duration of the resultant ocular hypotension is of clinical importance. Experimental and clinical studies after five minutes of compression of the eye demonstrated a homeostatic tendency for the untreated normal eye to recover most of its volume loss in 10 to 15 minutes. Continuation of pressure on the eye during early phases of intraocular surgery before the chamber is opened results in a more profound hypotension, but an increased episcleral bleeding tendency has been noted. Osmotic agents seem to increase the degrees and duration of ocular hypotension from compression. (8 figures, 4 tables, 8 references)—Authors' abstract

INTRAOCULAR INVOLVEMENT IN BURKITT'S LYMPHOMA. Karp, L. A., Zimmerman, L. E. and Payne, T. (Armed Forces Institute of Pathology, Washington, D.C.), Arch. Ophth. 85:295-298, Mar., 1971.

Burkitt's lymphoma, which is a poorly differentiated lymphocytic lymphoma with unique epidemiologic features and a characteristic clinical and histologic pattern, is the most common malignant tumor among children in tropical Africa. While the tumor frequently involves the orbit, it is not generally expected to involve the globe. The unique feature of, and sole reason for, recording the present case is the massive intraocular involvement. (5 figures, 25 references)—Joel G. Sacks

THE RUNNING INTERLOCKING SUTURE IN CATARACT SURGERY. Ryan, S. J. and Maumenee, A. (Wilmer Institute, Johns Hopkins University, Baltimore), Arch. Ophth. 85:302-303, Mar., 1971.

Utilizing the operating microscope, a limbal-based conjunctival flap is reflected, a corneal scleral groove created, and one or two sutures are preplaced. Following the opening of the eye, iridotomy, lens extraction, and filling the anterior chamber with air, the preplaced su-

ture is tied. A running interlocking 10-0 monofilament suture is then placed across the entire corneoscleral section, taking approximately 10 to 12 bites. (1 figure, 1 reference)—Joel G. Sacks

RETROBULBAR ADMINISTRATION OF STEROIDS IN HERPES SIMPLEX UVEITIS. Bohigian, G., Dawson, C. and Coleman, V. (University of California San Francisco Medical Center), Arch. Ophth. 85:320-328, Mar., 1971.

Efficacy of retrobulbar injections of dexamethasone on the von Szily model of herpes simplex chorio-retinitis was tested in rabbits. Herpesvirus hominis was injected into the anterior chamber of one eye of 45 rabbits. In each, a uveitis developed in the injected eye. In 36 animals a chorioretinitis appeared 7 to 12 days later in the uninoculated eye. Retrobulbar steroid or placebo therapy was begun in matched animals after clinical signs of the posterior chorioretinitis appeared. Eyes were examined daily by an observer not informed of the nature of the treatment. Clinical changes were correlated with photographs, viral titrations, and histologic examinations. A definite anti-inflammatory effect was observed during a short course of retrobulbar steroid therapy, although the final outcome was not altered. This short-term clinical improvement occurred without any significant increase in virus multiplication. (7 figures, 3 tables, 27 references)—Authors' abstract

THERAPY IN EXPERIMENTAL HYPHEMA. Masket, S., Best, M., Fisher, L. V., Kronenberg, S. M. and Galin, M. A. (Bird S. Coler Hospital, Welfare Island, New York 10017), Arch. Ophth. 85:329-333, Mar., 1971.

A radioactive assay technique was used to determine the rate of absorption of clotted and unclotted hyphemas in rabbits. Unclotted blood in the anterior chamber was absorbed at a significantly more rapid rate than clotted blood. Treatment of rabbits with clotted hyphemas with intravenous infusions of hyperosmotic urea and mannitol markedly enhanced blood resportion. Subconjunctival injections of methylprednisolone before clotting occurred resulted in poor clot formation and retraction, and thereby enhanced blood resorption. Subconjunctival injections of methylprednisolone after clot formation slightly decreased blood resorption rate. (5 figures, 20 references)—Authors' abstract

OCULAR DIATHERMY AND CRYOCOAGULATION. Miller, J. B. (1127 Wilshire Blvd., Los Angeles 90017), Arch. Ophth. 85: 339-349, Mar., 1971.

A comparison between diathermy and cryotherapy was made in lesions which were placed in single eyes of adult, albino rabbits. The effects on both the retinal and choroidal vessels were stressed. Moderate to heavy dosage was used. Cryoprobe application caused immediate retinal and choroidal hemorrhage which slowly resorbed during the first week. Diathermy caused a hemostatic, coagulative effect on the retinal vessels. Diathermy to the choroid caused initial hemorrhage and hyperemia which was distributed to a circumferential pattern around a central, avascular, coagulated area. Both diathermy and cryotherapy caused obliteration of the smaller retinal and choroidal vessels. Diathermy resulted in a more adherent and "stickier" early chorioretinal adhesion than cryotherapy. Heparin had little effect on the hemorrhagic tendency of either diathermy or cryotherapy. (17 figures, 1 table, 17 references)—Author's abstract

TOPICALLY APPLIED STEROIDS IN ACTIVE HERPES SIMPLEX KERATITIS. Takahashi, G. H., Leibowitz, H. M. and Kibrick, S. (University Hospital, 750 Harrison Ave., Boston 02118), Arch. Ophth. 85:350-354, Mar., 1971.

Topical administration of medrysone 1.0% produced a detrimental effect on active infection of the corneal epithelium by herpes simplex virus. Treatment with this drug resulted in a keratitis that was more severe in its clinical characteristics and ran a more prolonged course than the disease observed in control animals. A ten-day course of therapy also resulted in a prolongation of the period during which virus could be cultured from the eye. The undesirable effects produced by medrysone 1.0% were not as pronounced as those which followed administration of dexamethasone phosphate 0.1%. (4 tables, 11 references)—Authors' abstract

MULTILINE ARGON LASER. Behrendt, T. (Thomas Jefferson University, 1025

Walnut St., Philadelphia 19107), Arch. Ophth. 85:355-358, Mar., 1971.

Continuous argon and krypton gas laser sources are available commercially. By their nature they are bulky and relatively unmanageable in optical systems designed to focus on ocular tissues. By taking advantage of a simple geometric design of placing mirrors at diagonals of parallelograms, it is possible to provide maximum flexibility and minimum energy loss into such a system. The device is useful for producing microlesions in retinal vessels. (10 figures, 3 references)—Authors' abstract

TRANSIENT CORTICAL BLINDNESS AND CEREBELLAR ATAXIA ASSOCIATED WITH MUMPS. Davis, L. E., Harms, A. C. and Chin, T. D. Y. (Ecological Investigations Program, 2002 W. 39th St., Kansas City, Kansas 66103), Arch. Ophth. 85:366-368, Mar., 1971.

Visual impairment is an unusual complication of mumps and may be secondary to pathological conditions in several places along the optic pathway. Cortical blindness, however, is an extremely rare complication. A 25-year-old woman suddenly developed meningitis, cortical blindness, and cerebellar ataxia during an acute episode of parotitis associated with rise in mumps neutralizing antibodies. The patient recovered completely with only supportive care in six days. (1 figure, 10 references)—Authors' abstract

PIGMENTARY EPITHELIOPATHY AND ERYTHEMA NODOSUM. Van Buskirk, E. M., Lessell, S. and Friedman, E. (Boston University Medical Center, 80 E. Concord St., Boston 02118), Arch. Ophth. 85:369-372, Mar., 1971.

A young woman with erythema nodosum demonstrated the clinical and fluorescein angiographic findings of acute posterior multifocal placoid pigment epitheliopathy. The possibility of a relationship between the two disorders is raised. The fluorescein angiograms seemed suggestive of choroidal vascular disease rather than of a primary pigment epitheliopathy. (3 figures, 5 references)—Authors' abstract

## BRITISH MEDICAL JOURNAL

LASER IRIDOTOMY. Perkins, E. S. (Institute of Ophthalmology, London), Brit. Med. J. 1:580-581, 1970.

A ruby laser has been used to produce a permeable lesion in the iris to establish a communication between the anterior and posterior chambers. In a preliminary study in nine patients the technique gave satisfactory results in the prophylactic treatment of four cases of incipient closed-angle glaucoma and of two cases of iris bombe following uveitis. (4 references)—Authors' abstract

MIOSIS DURING L-DOPA THERAPY. Spiers, A. S. D., Calne, D. B. and Fayers, P. M. (University College Hospital, London W.C.1.), Brit. Med. J. 2:639-640, 1970.

The pupillary diameter of 11 patients with Parkinson's disease was significantly decreased four hours after ingestion of L-dopa. It is suggested that this miosis may be caused by diminished noradrenaline output at sympathetic nerve endings, or alternatively by an action on the central nervous system. (1 figure, 19 references)—Authors' abstract

## CANADIAN JOURNAL OF OPHTHALMOLOGY

COATS' DISEASE, DIAGNOSIS AND TREATMENT. Harris, G. S. (Department of Ophthalmology, University of British Columbia, 2550 Willow Street, Vancouver, 9, Canada), Canad. J. Ophth. 5:311-320, Oct., 1970.

Twenty-three patients with Coats' disease were studied. The presence of the abnormal retinal vessels is an important point in distinguishing this condition from retinoblastoma. About half the patients were felt to be treatable and of these, more than half had their disease cured or arrested. Destruction of the anomalous vessels is necessary and this usually can be most readily accomplished with the photocoagulator. If the anomalous vessels are elevated by a serous detachment, a posterior sclerotomy must be performed first. The insertion of a scleral buckle during this procedure is sometimes the most effective way of securing effective photocoagulation. Once the anomalous vessels are destroyed, the subretinal

exudates and serous fluid disappear. Once fibrosis, pigment hyperplasia or hemorrhage have occurred, the condition is not reversible and treatment can only be directed at delimiting the extent of the disease. (11 figures, 5 tables, 12 references)—R. Theodore Goldberg

HEMORRHAGE ON THE DISC—A SIGN OF ACUTE ISCHEMIC OPTIC NEUROPATHY IN CHRONIC SIMPLE GLAUCOMA. Begg, I. S., Drance, S. M. and Sweeney, V. P. (Department of Opthalmology, University of British Columbia, Vancouver 9, British Columbia, Canada), Canad. J. Ophth. 5: 321-330, Oct., 1970.

Four patients with chronic open-angle glaucoma developed a hemorrhage on a sector of the disc accompanied by the occurrence of a corresponding absolute scotoma in the Bjerrum area, which probably represented an acute ischemic change at the optic nerve head. This ischemic optic neuropathy was symptomless, discrete, recurrent, sometimes bilateral, and produced a progression of field loss. It was probably associated with small vessel disease and occurred at levels of intraocular pressure which were normal or just above normal, and with or without adverse perfusion pressure at the optic nerve head. (11 figures, 9 references)—R. Theodore Goldberg

CONGENITAL FIBROSIS SYNDROME. Crawford, J. S. (Department of Ophthalmology, The Hospital for Sick Children, 555 University Avenue, Toronto 101, Ontario, Canada), Canad. J. Ophth. 5:331-336, Oct. 1970.

Sixteen patients with congenital fibrosis of all the extraocular muscles and the levator muscle, are reviewed. There is frequently a family history with autosomal dominant inheritance. All 16 held the head tilted backward with the chin elevated and all had bilateral hypotropia with eyes fixed in a downward position 20 to 30 degrees below the horizontal. Eleven patients showed jerky convergent movements on attempted upward gaze. In most cases, vertical muscle surgery on the recti did not elevate the eyes enough, and the author recommends a 6 mm recession of the inferior rectus and resection of the superior rectus to obtain best results. Eleven of 16 patients had fascia lata suspension operations for ptosis despite the absence of Bell's phenomenon. The lids were raised above the pupils, but not as high as in those cases where a Bell's phenomenon was present. Surgery can offer cosmetic improvement and symptomatic relief from fatiguing head positions. (6 figures)—R. Theodore Goldberg

SEVERE APLASTIC ANEMIA AS A COMPLICATION OF ACETAZOLAMIDE THERAPY. Rentiers, P. K., Johnston, A. C. and Buskard, N. (Department of Ophthalmology, University of British Columbia, 2550 Willow Street, Vancouver 9, British Columbia, Canada), Canad. J. Ophth. 5:337-342, Oct., 1970.

A patient with chronic open-angle glaucoma who was treated with Diamox for seven months, developed severe aplastic anemia. The ophthalmologist should be alert to the symptoms and signs of aplastic anemia, which are weakness, pallor, hemorrhages, ecchymoses, and a decreased resistance to infections. The peripheral blood shows depression of red and white blood cells and platelets. The marrow is fatty and hypocellular. During this patient's severely anemic period, the relative ischemia of the optic nerve head allowed further nerve fiber bundle infarction to occur despite normal intraocular pressures. (5 figures, 2 references) —R. Theodore Goldberg

PEDUNCULATED MALIGNANT MELANOMA OF CONJUNCTIVA. Watson, A. G., Campbell, J. S., Tolnai, G. and Hill, D. P. (Dept. of Ophthalmology, Ottawa General Hospital, Ottawa, Canada), Canad. J. Ophth. 5:386-391, Oct., 1970.

There is a predilection of precancerous melanosis and junctional nevi for the limbic and caruncular areas. Pedunculation suggests a good prognosis generally and extensive local excision of such lesions may be indicated in exceptional cases where there is pedunculation and no sign of spread of the neoplasm. (6 figures, 22 references)—R. Theodore Goldberg

## JAPANESE JOURNAL OF OPHTHALMOLOGY

ELECTRON MICROSCOPIC OBSERVATIONS ON REACTIONS OF RETINAL MULLER CELLS UNDER PATHOLOGICAL CONDITION. Uga, S.

and Katsume, K. (Department of Ophthalmology, Kyushu University, Fukuoka), Jap. J. Ophth. 13:223-236, Oct-Dec., 1970.

Under certain conditions Muller cell processes may penetrate the inner limiting membrane and grow into the vitreous. The Muller cells may also phagocytose disintegrated retinal cells. (15 figures, 26 references)—Paul A. Hein, Jr.

ULTRASTRUCTURAL OBSERVATION ON THE CORNEA OF HURLER SYNDROME. Matsuda, H., Satke, Y. and Katsumata, H. (Department of Ophthalmology, Hokkaido University School of Medicine, Sapporo), Jap. J. Ophth. 14:237-246, Oct-Dec., 1970.

The cellular elements of the cornea of a patient with Hurler's syndrome showed vacuoles containing substances apparently secreted through clefts in the cell membrane. These vacuoles are felt to be specific for Hurler's syndrome. (8 figures, 3 tables, 19 references) —Paul A. Hein, Jr.

FALSE OR EXAGGERATED NARROWNESS OF RETINAL ARTERIOLES IN HYPERTENSIVES—COMPARATIVE STUDY OF COLOR AND FLUORESCEIN FUNDUS PICTURE IN HYPERTENSIVES. Matsumoto, K. (Department of Ophthalmology, Surugadai, Nihon University Hospital, Tokyo), Jap. J. Ophth. 14:263-268, Oct.-Dec., 1970.

The irregularity of the retinal arterioles in hypertensives is reduced or eliminated when these arterioles are studied by fluorescein angiography. This is thought to be the result of perivascular retinal cloudiness. (6 figures, 6 tables, 3 references)—Paul A. Hein, Jr.

## INVESTIGATIVE OPHTHALMOLOGY

ULTRASTRUCTURE OF "TUBULAR BODY" IN THE ENDOTHELIAL CELLS OF THE OCULAR BLOOD VESSELS. Matsuda H. and Sugiura, S. (Department of Ophthalmology, Hokkaide University School of Medicine, Sappor, Japan), Invest. Ophth. 9:919-925, Dec., 1970.

Characteristic tubular bodies were detected with great regularity in the endothelial cells of the blood vessels of human eyes, normal and pathologic, as well as in growing vessels in rabbit corneas. These bodies in the mature form are shaped like a cylindrical rod with an internal tubular structure, bounded by a limiting membrane of unit membrane type. It is interesting that they are numerous in some instances of Behcet's disease. (11 figures, 5 references)—Authors' abstract

EXPERIMENTAL MYOPIA IN RABBITS. Tokoro, T. (Department of Ophthalmology, Washington University School of Medicine, 660 S. Euclid, St. Louis, Mo.), Invest. Ophth. 9:926-934, Dec., 1970.

About 1 diopter (D) myopic change was induced experimentally in rabbit eyes by raising the body temperature and increasing the intraocular pressure with a specially designed suction cup. The myopic changes only took place when the body temperature was 41 to 43°C, intraocular pressure was above 40 mm Hg, and topical atropine was given. Eyes subjected to repeated high pressure after the initial experiment exhibited greater changes. It seemed that imbalance between the intraocular pressure and elastic properties of the eye coat produced myopia. (5 figures, 13 references)—Author's abstract

OCULAR RIGIDITY AND DECAY CURVES ANALYZED BY TWO NONLINEAR SYSTEMS. Lyon, C., McEwen, W. K. and Shepherd, M. D. (Francis I. Proctor Foundation for Research in Ophthalmology and the Department of Ophthalmology, University of California Medical Center, San Francisco, Calif.), Invest. Ophth. 9:935-945, Dec., 1970.

A mathematical approximation technique has been used for the analysis of pressure-volume and decay curves to see which concept of the mechanical properties of the coats of the eye is the more valid: Friedenwald's concept that the outer coats are nonlinear elastic or a recent concept that the outer coats are nonlinear viscoelastic. With such an approach we can analyze equally well by both systems the pressure-volume curves, but not the decay curves. From a single eye two decay curves may be obtained, their positions depending on whether the eye is kept at an elevated pressure

for a long or a short time. These decay curves cannot be analyzed or matched without conceding that the outer coats of the eye are viscoelastic. By means of pressure-volume and decay curves, it is thus possible to obtain quantitative data on the fundamental nonlinear viscoelastic properties of the enucleated human eye. (12 figures, 5 tables, 11 references)—Thomas M. Aaberg

CORTICOSTEROID PROVOCATIVE TESTING. LeBlanc, R. P. Stewart, R. H. and Becker, B. (Department of Ophthalmology, Washington University School of Medicine, St. Louis, Mo.), Invest. Ophth. 9: 946-948, Dec., 1970.

Topical corticosteroid provocative testing for three to eight weeks was carried out on three groups of patients in order to evaluate effects on aqueous dynamics and visual fields. All changes were reversible and no long-term effects were noted. (1 table, 14 references)—Authors' abstract

EFFECTS OF HYDROXYPROPYL METHYLCELLULOSE AND POLYVINYL ALCOHOL ON INTRAOCULAR PENETRATION OF TOPICAL FLUORESCEIN IN MAN. Waltman, S. R. and Patrowicz, T. C. (Department of Ophthalmology, University of Florida, Gainesville, Fla.), Invest. Ophth. 9:966-970, Dec., 1970.

A slit lamp fluorophotometer was used to measure penetration of topical 2% fluorescein, in various vehicles, into human eyes. The technique provides a sensitive method for measuring attained fluorescein concentrations in the anterior segment of the eye. One-half per cent hydroxypropyl methylcellulose significantly increased the penetration of the drug as compared to penetration with 1.4% polyvinyl alcohol or aqueous solutions. Doubling the concentration of fluorescein in the vehicles doubled the attained intraocular concentrations. Very little of the applied drug penetrated into the anterior segment. (2 figures, 4 tables, 11 references)—Authors' abstract

ARGON LASER PHOTOTHERAPY OF PSEUDOMONAS CORNEAL ULCERS. Fromer, C. and L'Esperance, F. (Department of Ophthalmology, Columbia University, New York, N.Y.), Invest. Ophth. 10:1-8, Jan., 1971.

A new technique with the use of argon laser irradiation of Pseudomonas organisms stained with fluorescein-tagged antibody has proved beneficial in the treatment of these particular corneal ulcers in rabbits. Eleven of thirteen ulcers became negative by culture after laser phototherapy. This specific phototherapy introduces a concept that may have significance in future clinical studies. (4 figures, 1 table, 19 references)—Thomas M. Aaberg

ELECTRON MICROSCOPIC STUDIES ON FUCHS' COMBINED DYSTROPHY I. POSTERIOR PORTION OF THE CORNEA. Iwamoto, T. and DeVoe, A. G. (Department of Ophthalmology, Columbia University, 635 W. 165th St. New York, N. Y.), Invest. Ophth. 10:9-28, Jan., 1971.

Seven corneal buttons of typical Fuchs' combined dystrophy were studied with the electron microscope. Descemet's membrane was markedly thickened in six cases and showed various structural alterations. Five different regions could regularly be distinguished in the pathologic Descemet's membrane in all cases. From anterior to posterior they were (1) "anterior banded region" with 1,000 A-banded pattern, (2) "non-banded region," without clear banding (these regions are seen in normal corneas); (3) "posterior banded region" filled with 1,000 A-banded material ("warts" are formed by its partial backward protrusions); (4) "border region" composed of groups of "thin fibrils," "long-spacing bundles" of 1,000 A periodicity with two types of banded pattern, and "basement membrane-like material"; and (5) "fibrillar region" which consists of "basement membrane-like material" and collagen fibrils. (32 figures, 47 references)—Thomas M. Asberg

ELECTRON MICROSCOPIC STUDIES ON FUCHS' COMBINED DYSTROPHY II. ANTERIOR PORTION OF THE CORNEA. Iwamoto, T. and DeVoe, A. G. (Department of Ophthalmology, Columbia University, 635 W. 165th St., New York, N.Y.), Invest. Ophth. 10:29-40, Jan., 1971.

Anterior portions of the central corneas of Fuchs' combined dystrophy were studied with

the electron microscope. The epithelium showed various grades of cellular edema, mostly in the basal layer sometimes coalescing to form subepithelial bullae. Alterations of the subepithelial region paralleled or followed the epithelial changes. Active fibroblasts and collagen fibrils formed large subepithelial masses of connective tissue. Alterations of Bowman's layer and stroma were less marked, although some changes were seen in the stroma as compared with normal controls. All this indicates that the changes in the anterior cornea in Fuchs' dystrophy are secondary to the involvement of the posterior portions. (29 figures, 19 references)—Thomas M. Aaberg

OUTER SEGMENT PRODUCTION AND REMOVAL IN THE DEGENERATION RETINA OF THE DYSTROPHIC RAT. Herron, Jr., W. L., Riegel, B. W. and Rubin, M. L. (Department of Ophthalmology, College of Medicine, University of Florida, Gainesville, Fla.), Invest. Ophth. 10:54-63, Jan., 1971.

The pigment epithelium of the dystrophic rat, as studied by autoradiography, shows an inability to remove its rod outer segment material. By 36 days of age, photoreceptor outer segment production in the dystrophic rat gradually ceases, although uptake of amino acids by the inner segment still appears normal. The first outer segment material which the developing dystrophic rat produces is still adjacent to the pigment epithelium 120 days later. Subsequently produced outer segment material is removed first apparently, suggesting that the removal of this material may be through the inner retina. (5 figures, 2 tables, 4 references) —Thomas M. Aaberg

ELECTRON MICROSCOPIC STUDY OF HEREDITARY CORNEAL EDEMA. Kanai, A., Waltman, S., Polack, F. M. and Kaufman, H. E. (Department of Ophthalmology, College of Medicine, University of Florida and the Veterans Administration Hospital, Gainesville, Fla.), Invest. Ophth. 10: 89-99, Feb., 1971.

Hereditary corneal edema, a previously undescribed corneal dystrophy thought to be transmitted as a dominant trait, was present in five family members. Electron microscopic studies of a corneal button from one member who had penetrating keratoplasty showed absence of the epithelial basement membrane, large fibril-free "lakes" in the middle and posterior stroma, irregular undulating Descemet's layer and an abnormal 2 to 3 cell layer replacing the endothelium. (14 figures, 12 references—Thomas M. Aaberg

EXPERIMENTAL REHYDRATION OF CRYOPRESERVED CORNEAL TISSUE. Edelhauser, H. F., Van Horn, D. L., Gallun, A. B. and Schultz, R. O. (Departments of Physiology and Ophthalmology, Medical College of Wisconsin), Invest. Ophth. 10:100-107, Feb., 1971.

Changes in total water and electrolyte content were measured in corneas following cryopreservation and following experimental rehydration of the cryopreserved-thawed tissue in an albumin-NaCl solution, Kinsey medium, or in vivo in aqueous humor. During the cryopreservation procedure the corneal tissue becomes dehydrated and loses intracellular potassium and sodium. Experimental rehydration of the cryopreserved tissue in Kinsey medium restores the Na+ and water content to control values, but corneal K+ remains decreased. Corneas rehydrated in albumin-NaCl regained only the normal water content; whereas, corneas rehydrated in vivo in aqueous humor regained the normal water content and sodium concentration over a two-hour period, while corneal potassium showed a slight increase throughout the two-hour period. (5 figures, 4 tables, 13 references)—Authors' abstract

CORNEAL EXPOSURE. SODIUM CONCENTRATION IN AQUEOUS AND LENS CHANGES. Bronson, L. J. and Lazar, M. (Department of Ophthalmology, Mount Sinai School of Medicine, City University of New York, New York, N.Y.), Invest. Ophth. 10:144-146, Feb., 1971.

In this experiment, changes in the colligative properties of hamster aqueous were measured as related to corneal exposure and the development of lens opacity. A rise of sodium concentration of aqueous was found to parallel the appearance and progression of lens opacity, indicating the sodium exerted on osmotic effect on the lens. This is consistent with the speculated relationship between corneal exposure and reversible cataracts. (1 figure, 7 references)—Thomas M. Aaberg

CATION CHANGES IN THE LENS AND AQUEOUS DURING THE INDUCTION OF ACUTE REVERSIBLE LENS OPACITY IN THE HAMSTER. Peterson, L. H. (John E. Weeks Institute for Advancement of Ophthalmology, University of Oregon Medical School), Invest. Ophth. 10:147-150, Feb., 1971.

The induction of acute reversible lens opacities in the Syrian hamster following corneal exposure and phenylephrine mydriasis is accompanied by an increase in the sodium and potassium concentration and a decrease in the water content of the lens. There is a simultaneous increase in sodium concentration in the aqueous humor. Final analysis of the effect of various drugs on these lens opacities should reveal that the potentiation of cataracts is proportional to the effect on evaporation of the cornea or aqueous production or both. (2 tables, 10 references)—Authors' abstract

## KLINISCHE MONATSBLATTER FÜR AUGENHEILKUNDE

INDICATION FOR IRRADIATION THERAPY IN OPHTHALMOLOGY. (German) Haye, C. and Calle, R. (23 bis., Avenue Niel, Paris 17 e, France), Klin. Mbl. Augenh. 156: 761-770, June, 1970.

Lid epitheliomas, retinoblastomas and radiosensitive tumors of the orbit (lymphoid tumors) should be irradiated after tumor diagnosis through biopsy. Epitheliomas: small, superficial lesions (up to 1.5 cm in diameter and 0.5 cm in thickness) receive contact irradiation (a total of 4800 r cutaneous dose in 10 to 12 sessions). Middle-sized tumors are conventionally irradiated with total doses of 4600 to 6000 r/field over 5 to 6 weeks. Extensive lesions receive 6500 to 8000 r beta-irradiation (betatron) over 6 to 7 weeks. Healing occurs in 75% of these cases. Retinoblastomas: When enucleation reveals optic nerve invasion, beta irradiation is indicated. In smaller tumors (less than 4 prism diopters prominence and less than ⅓ of the fundus involved) chemotherapy in combination with beta-irradiation cures about 80% of the patients. Orbital tumors: Lymphocytic tumors, lymphosarcomas and reticulosarcomas should be treated with 3000 to 5000 r conventional irradiation; the regional lymph nodes with cobalt irradiation. Complications involving the radiosensitive structures of the eye are rare, when all available precautions are strictly observed. (3 figures, 1 reference)—Helmut Buettner

RETINAL ADHESION AFTER CRYOSURGICAL APPLICATION. (German) Lincoff, H., O'Connor, P. and Kreissig, I. (New York, N.Y., 10022/USA, 440 East 57. Street; 53 Bonn, Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 156: 771-783, June, 1970.

The strength of the cryosurgical adhesion varies directly with the strength of application (200 to 1850 mg adhesive force). However the adhesive strength of a diathermy lesion does not relate to the strength of application. The range of its adhesive strength is approximately the same after cryopexy. The retinal adhesion due to the thermal damage occurs when Müller cell cytoplasm infiltrates newly formed pigment epithelium or Bruch's membrane. (11 figures, 5 references)—Helmut Buettner

PHOTO-COAGULATION OF RETINAL LESIONS AFTER PERFORATING INJURIES. (German) Ullerich, K. and Kammann, J. (46 Dortmund, Beurhausstrasse 40, Krankenanstalten Augenklinik, West-Germany), Klin. Mbl. Augenh. 156:783-807, June, 1970.

The prognosis of perforating injuries of the eye is especially poor when the vitreous cavity has been opened and the retina has been damaged. The prognosis is adversely affected by the occurrence of a retinal detachment. The detachment usually arises from a retinal break produced by the foreign body or the surgeon when attempting its extraction, traumatically induced vitreous traction or shrinkage of superficial retinal scars. In order to prevent these posttraumatic retinal detachments, 42 out of 372 patients with perforating injuries and involvement of the posterior parts of the eye received photocoagulation treatment of the posterior pole lesions. It is important, to limit photocoagulation to the smallest necessary intensity and area, in order to avoid retinoschisis, retinal breaks or shrinkage of the retinal surface. Forty out of these 42 patients showed, 29 months later, a favorable anatomical and

functional result. (4 figures, 2 tables, 21 references)—Helmut Buettner

COMPUTER APPLICATION IN CLINICAL ELECTRORETINOGRAPHY. (German) Schmidt, B. and Straub, W. (355 Marburg/Lahn, Univ. Augenklinik West-Germany), Klin. Mbl. Augenh. 156:808-820, June, 1970.

Small ERG potentials, for example in cases of retinitis pigmentosa or when lid margin electrodes have to be used (uncooperative children, corneal diseases) can not be recorded with the regular set-up. In such cases, by using a computer, which averages the data of repeated recordings, a diagnostic ERG can be obtained. The computer ERGs of normal children and adults with special regard to the range of the a- and b-wave amplitudes and their latencies are reported. The authors present the ERG data in cases of RLF, vitelliform cyst of the macula, microphthalmus with congenital cataract, retinal degeneration, corneal ulcer and symblepheron. (7 figures, 6 tables, 13 references)—Helmut Buettner

DISTURBANCES OF VISUAL SENSATIONS IN BI-TEMPORAL HEMIANOPSIA AND DISPLACEMENT OF THE VISUAL AXES. (German) Nachtigäller, H. and Hoyt, W. F. (46 Dortmund, Beurhausstr. 40 Augenklinik; U. C. Medical Center, Moffit, Parnassus San Francisco, Calif. 94122), Klin. Mbl. Augenh. 156: 821-836, June, 1970.

The authors describe some sensory phenomena in bitemporal hemianopsia which are explained by the existence of a cuneiform field behind the point of fixation from which no picture objects can be recognized. These phenomena become manifest through a displacement of the visual axes towards each other. The two intact nasal halves of the visual field which in the binocular visual act in orthophoria meet in the vertical line running through the point of fixation, are separated, partially placed above each other or displaced vertically at the deviation of the visual axes into convergence or in vertical direction. Thus surprising sensory phenomena arise which are discussed in detail (extinction of objects, middle field diplopia, vertical shifts of images, shortening and prolongation effects). (17 figures, 4 references)—Authors' abstract

OCULAR NEUROMYOTONY. (German) Ricker, K. and Mertens, H. G. (87 Würzburg, Neurol. Univ. Klinik, West-Germany), Klin. Mbl. Augenh. 156:837-842, June, 1970.

Hypersensitivity and spontaneous potential formation due to pathologic changes in motor nerve membranes are called "parabiosis." This condition is well known in skeletal muscles, but has not yet been described as occurring in ocular muscles. A 42-year-old female complained about sudden and repeated occurrence of a short-lasting convergent strabismus of the left eye with diplopia. EMG examination revealed a pathologic activity of the peripheral neurogenic type, causing a spasm of the internal rectus muscle. Since other etiological factors (brain stem lesion, basal aneurysm, thyroid problem, orbital myositis) could be excluded and a membrane stabilizing medication (carbamazepine) made the disturbance disappear immediately, the authors call this a case of ocular neuromyotony. (3 figures, 6 references)—Helmut Buettner

CONCENTRATION DYNAMICS OF TETRACYCLINE IN THE HUMAN AQUEOUS HUMOR AFTER ORAL ADMINISTRATION. (German) Knothe, H., Moog, E., Vogel, F. and Fabricius, K. (6 Frankfurt a. M., Paul-Ehrlich-Str. 40, Hygiene Inst. d. Univ. and 23 Kiel, Hehewischstr. 2 Univ. Augenklinik, West-Germany), Klin. Mbl. Augenh. 156: 843-850, June, 1970.

One hundred and fifty-six patients with cataract received, at different times before surgery, one or several oral doses of 500 mg tetracycline. At the start of the operation, both serum and aqueous humor were withdrawn and their tetracycline content determined in the agar-plate diffusion test. In comparison to the values reported in the literature, the elimination of tetracycline from the serum is somewhat retarded, which might be due to the high average age of our patients (72 years). After equalization by diffusion the aqueous humor level amounts to only 16 to 17% of the serum level or, if put in relation to the non-protein-bound portion of tetracycline in the serum, to 24% ± 2.5 of the plasma water level. After three doses of 500 mg tetracycline at intervals of eight hours, levels of up to 1.2 μg/ml are reached in the aqueous humor. In the case of an intraocular inflammation with reduced blood-aqueous-barrier, effective aqueous humor concentrations of between 3 and 5 μg/ml

can be expected because of the slight affinity of tetracycline to the serum protein when given in the aforementioned dosage. In the treatment of intraocular bacterial infections tetracycline itself should be given preference instead of its derivatives pyrrolidino-methyl-tetracycline and demethylchlortetracycline. (2 figures, 2 tables, 24 references)—Authors' abstract

COLOBOMA OF IRIS AND CHOROID IN XYY-SYNDROME. (German) Schwinger, E. and Wiebusch, D. (53 Bonn, Stiftsplatz 12, Univ. Inst. f. Gerichtl. Med.; 53 Bonn-Venusberg, Univ. Augenkl. Bonn, West-Germany), Klin. Mbl. Augenh. 156:873-877, June, 1970.

Ocular malformations can be related to chromosomal aberrations such as a luxated lens in 47 XYY-syndrome. The authors report another ocular defect, which might have been caused by this chromosomal aberration. Cytogenetic investigations in a 19-year-old man with a large coloboma of the iris and the choroid revealed a 47 XYY-karyotype. The patient also had above average height, psychic and social problems (prison inmate) and gonadal atrophy, features known to occur in 47 XYY chromosome aberrations. (2 figures, 23 references)—Helmut Buettner

## NEUROLOGY

EPISODIC BLINDNESS AS A LATE EFFECT OF HEAD TRAUMA. Kooi, K. A. (Electro-encephalography Laboratory, University of Michigan Medical Center, Ann Arbor), Neurology 20:569-573, June, 1970.

Three patients who had episodic blindness as a major complaint some years following head trauma were shown to have significant deviations in the responsivity of the visual system to series of photic stimuli. It was postulated the symptom represented an inhibitory visual seizure. (3 figures, 10 references)—Joel G. Sacks

INTERNUCLEAR OPHTHALMOPLEGIA AS AN EARLY SIGN OF BRAINSTEM TUMORS. Cogan, D. G. and Wray, S. H. (Howe Laboratory, Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston), Neurology 20:629-633, July, 1970.

Six patients with tumors of the brainstem are described in whom internuclear ophthalmoplegia was a prominent feature. This syndrome is an unusual feature of tumors and may lead to confusion with demyelinative disease. (2 figures)—Authors' abstract

## NEW ENGLAND JOURNAL OF MEDICINE

TRANSIENT CORTICAL BLINDNESS: STILL AN "OVERLOOKED" SYNDROME? Carmola, J. R. and Harris, B. S. (Dartmouth Affiliated Hospitals), New England J. Med. 282:1325, June, 1970.

Three cases of transient cortical blindness following head injury are described out of only 267 neurosurgical patients seen in an emergency room. The paucity of clinical reports and further investigation of this entity suggest that this is an "overlooked" syndrome. (4 references)—Joel G. Sacks

TAY-SACHS DISEASE: DETECTION OF HETEROZYGOTES AND HOMOZYGOTES BY SERUM HEXOSAMINIDASE ASSAY. O'Brien, J. S., Okada, S., Chen, A. and Fillerup, D. L. (Department of Neurosciences, School of Medicine, University of California, San Diego), New England J. Med. 283:15-20, July, 1970.

A fluorometric method showed the activity of hexosaminidase A to be markedly deficient in serum specimens from nine patients with Tay-Sachs disease. Parents (obligate heterozygotes) of children with Tay-Sachs disease had levels of hexosaminidase A that were intermediate between those found in affected children and those in control groups. No overlap was found between values for this enzyme in serums from heterozygotes, healthy controls and homozygotes. (6 figures, 2 tables, 5 references)—Joel G. Sacks

## OPHTHALMIC RESEARCH

OCULAR SIDE-EFFECTS OF LONG-TERM IMMUNOSUPPRESSIVE THERAPY IN RECIPIENTS OF CADAVER KIDNEY TRANSPLANTS.

Zaruba, R. K. and Scheitlin, W. (University of Zurich, Kantonsspital Zurich), Ophth. Res. 1:21-30, 1970.

This is a report of an ophthalmologic survey of 28 bilaterally nephrectomized patients with a unilateral cadaver kidney transplant, kept under a continuous immunosuppressive therapy for up to 48 months. Two types of cataracts were delineated: anterior subepithelial and posterior subcapsular cataracts, brought about by the corticosteroid treatment, and "Glaukomflecken"—like, subepithelial spots, possibly induced by a transient failure of the kidney transplant. (4 figures, 5 tables, 15 references)—Authors' abstract

THE RELATIONSHIP BETWEEN ERG AND VER. van Lith, G. H. and Henkes, H. E. (Eye Clinic, Medical Faculty, Rotterdam), Ophth. Res. 1:40-47, 1970.

From a comparison between local cone-ERG and VERs, elicited with disc and ring stimuli, it appeared, that the local cone ERG is highest in the macular region, because it is only dependent on the number of cones stimulated. The VER, too, is mainly determined by the central retinal area. Apart from the high cone density in the macular region this is also due to the fact, that the contribution of the central cones is higher than that of the peripheral cones. This is caused partly through the convergence of the extra-foveal cones in the ganglion cells, partly through the localization of the retinal projection in the area striata. (4 figures, 17 references)—Authors' abstract

ULTRASTRUCTURAL CHANGES IN THE RAT PHOTORECEPTOR INNER SEGMENT DURING EXPERIMENTAL CHLOROQUINE RETINOPATHY. Solze, D. A. and McConnel, D. G. (Ohio State University, Columbus, Ohio), Ophth. Res. 1:140-148, 1970.

Hooded rats were given chloroquine phosphate (Aralen) over an eight month period during which regular indirect ophthalmoscopic examinations were performed. When retinal or anterior ocular changes were observed in poisoned rats, retinas were prepared for electron microscopy. Significant ultrastructural changes were localized in the inner segments of the receptor cells, where mitochondrial swelling, disappearance of the ciliary process and disorganization of the endoplasmic reticulum were observed. Observations were consistent with previous clinical, light microscopic and electroretinographic findings. (3 figures, 1 table, 27 references)—Authors' abstract

RESPONSE OF THE MOUSE LENS TO HIGH CONCENTRATIONS OF GLUCOSE OR GALACTOSE. Kuck, Jr., J. F. R. (Emory University, Atlanta, Ga.), Ophth. Res. 1:166-174, 1970.

In vitro studies show that the mouse lens exposed to elevated concentrations of glucose or galactose does not develop the changes which affect the rat lens under similar conditions. The young mouse lens (CFW strain) is resistant to the cataractogenic effect of a galactose diet or alloxan diabetes. This species difference appears to reside in the lens itself since both sugars can accumulate in the mouse lens to reach levels comparable to those found in the rat lens exhibiting significant changes. (9 tables, 12 references)—Authors' abstract

THE EFFECT OF CHANGES IN ARTERIAL BLOOD PRESSURE ON THE RATE OF AQUEOUS HUMOUR FORMATION IN A PRIMATE. Bill, A. (Institute of Pharmacology, Uppsala, Sweden), Ophth. Res. 1:193-200, 1970.

The rate of aqueous humour formation in vervet monkeys was determined with a dilution method during stepwise reductions in mean arterial blood pressure produced by bleeding the animals. The mean rate of aqueous humour formation at a mean arterial blood pressure of 119 ± 7 mm Hg was 2.64 ± 0.22$\mu$ 1/min (n = 11). Bleeding the animals to a pressure of 70 to 90 mm Hg had little effect on the rate of aqueous formation. Further reductions in mean arterial blood pressure usually decreased aqueous formation markedly. Interruption of the sympathetic supply to the eye under study had no appreciable effect on the relationship between rate of aqueous humour formation and mean arterial blood pressure. (3 figures, 20 references)—Author's abstract

STATISTICAL INVESTIGATIONS OF INTRAOCULAR PRESSURE WITH GOLDMANN'S APPLANATION TONOMETER. Bechrakis, E. (University of Bonn, Germany), Ophth. Res. 1:211-219, 1970.

On the basis of 1,235 anamnestically healthy eyes, the author shows that intraocular pressure after transformation is of normal loga-

rithmic distribution with a high degree of probability and is not bimodal, at least not in the pressure range between 6 and 32 mm Hg. For this reason a division into "glaucoma" and "non-glaucoma" solely on the basis of intraocular pressure without additional information is not permissible. (5 figures, 2 tables, 9 references)—Authors' abstract

BILATERAL LACRIMAL GLAND ENLARGEMENT ASSOCIATED WITH A DIFFUSE GAMMA GLOBULIN ELEVATION. Yanoff, M., Nix, R. and Arvan, D. (University of Pennsylvania, Philadelphia), Ophth. Res. 1:245-253, 1970.

A patient with PAS-positive intranuclear plasma cell inclusions in the lacrimal gland is reported. Immunoelectrophoresis showed a diffuse elevation of the IgG and IgA fractions but a normal IgM fraction. No abnormal proteins (M-components) were found. (5 figures, 12 references)—Authors' abstract

## OPHTHALMOLOGICA

THE HYPERPYREXIA SYNDROME AS COMPLICATION AFTER INTRAOCULAR OPERATIONS IN INFANTS. (German) Kintzel, H.-W. and Graupner, K. (Departments of Ophthalmology and Pediatrics, the Academy of Medicine "Carl Gustav Carus," Dresden, Germany), Ophthalmologica 160: 385-390, 1970.

In four infants with congenital cataracts, uncomplicated linear lens-extractions under halothane-nitrous oxide anesthesia were followed by fatal hyperpyrexia. Pre-existing brain damage, related in etiology to the cataracts, is assumed to be a predisposing factor. Hourly temperature readings after the operation and prompt use of antipyretics if the temperature rises 1°C above normal are recommended. (6 references)—Peter C. Kronfeld

GLAUCOMA AND DIABETES. (German) Hauff, D. (Eye Clinics of the Humboldt University in Berlin and of the County Hospital Berlin-Friedrichshain), Ophthalmologica 160:391-397, 1970.

In a series of 962 cases of primary glaucoma the prevalence of diabetes was 13%, that is, considerably higher than in unselected (general) populations with corresponding age distribution. (4 figures, 2 tables, 24 references)—Peter C. Kronfeld

ANTERIOR VITREOUS CHANGES FOLLOWING CATARACT EXTRACTION BY CRYO-SURGERY. Joyce, M. and Sollom, A. W. (The Wolverhampton and Midland Counties Eye Infirmary), Ophthalmologica 160:398-402, 1970.

The authors' material consisted of 100 eyes on which uncomplicated lens extractions by a standardized cryo-technique had been performed during the previous three years. The term anterior hyaloid membrane is used for the interface at which a change in optical density can be seen between aqueous and vitreous. In 70 of the 100 eyes one or more holes were found in the anterior hyaloid membrane; 32 cases had developed localized and 17 cases general spreading of vitreous into the anterior chamber. The vision was demonstrably disturbed only in the cases of general spreading of the vitreous.

The percentage of holes in anterior hyaloid with consequent protrusion of vitreous was much higher than in other reported series where cataracts were extracted by other methods. For this reason the authors consider it possible that we may see increased instances of postoperative complications following cryo-extractions. (5 references)—Peter C. Kronfeld

THE EFFECT OF ANTI-INFLAMMATORY DRUGS, CORTICOSTEROIDS AND TANDEARIL, UPON THE INTRAOCULAR PRESSURE. (French) Younessian, S. and Psilas, K. (University Eye Clinic Geneva, Switzerland), Ophthalmologica 160:403-408, 1970.

In a series of 11 glaucoma suspects one eye was treated with 0.5% prednisolone t.i.d. and the other with a 10% ointment of Tandearil (oxyphenbutazone) b.i.d. During a test period of three weeks the corticosteroid produced statistically significant rises in pressure and drops in outflow facility while the Tandearil-treated eyes showed no significant change in aqueous-dynamics. The latter observation was confirmed in nine eyes with overt primary open-angle glaucoma in which the Tandearil-ointment was added to the pressure-normalizing medication. Cases of uveitis in which ocular

hypertension had developed under the influence of topical corticosteroids, responded very well to topical Tandearil ointment, in terms of pressure as well as in terms of ocular inflammation. (2 tables, 8 references)—Peter C. Kronfeld

DIFFERENTIAL MACULAR ILLUMINATION TESTS. Paul, S. D. and Singh, K. M. (Department of Ophthalmology, Postgraduate Institute of Medical Education and Research, Chandigarh, India), Ophthalmologica 160:409-420, 1970.

The test consists of measurements of the recovery of the visual acuity following a standardized amount of mild macular dazzle. As originally proposed by Baillart, white light was used for illumination of the macula. The authors of the present paper added dazzling and recovery measurements through red and green filters. They now present findings in 124 controls and in 170 cases of macular lesions. In early macular degeneration or early angiospastic maculopathy the response with the red filter is more delayed than that with the green filter; the reverse order is found in late macular degenerations or healed angiospastic maculopathy. The differential macular illumination test allows recognition of macular degeneration when the ophthalmoscopic appearance of the macula is still normal. (8 tables, 5 references)—Peter C. Kronfeld

REGARDING THE TECHNIQUE OF EYE EXAMINATIONS FOR STRABISMUS IN INFANTS AND SMALL CHILDREN. (German) Šeba, J. (The Polyclinic of the County Institute for Community Health, Rychnow and Knežňou, Czechoslovakia), Ophthalmologica 160: 421-429, 1970.

On the basis of extensive experience of eye examinations of newborns and small children the author has extended and refined Brückner's transillumination test which was designed to give answers to the questions: 1) Is strabismus present, and 2) Is there a danger of amblyopia? Between 1962 and 1964 the present author used his modification of the test for the examination of 1592 small children with ages ranging from four months to two and a half years. In 126 of these children the test revealed the presence of strabismus or of refractive conditions likely to lead to amblyopia. In the course of routine pre-school eye examinations the status of the entire population of 1592 children became known again. Of the children in whom the original test had been negative, eight had developed strabismus (between the ages of three to five years) and nine showed a mild degree of amblyopia due to an anisometropia which had not been present or had not been detected at the first examination. The author's method apparently yields the largest number of children at risk. (7 references)—Peter C. Kronfeld

## SCIENCE

TESTING THE VISION OF CATARACT PATIENTS BY MEANS OF LASER-GENERATED INTERFERENCE FRINGES. Green, D. G. (Dept. of Ophthalmology, University of Michigan, Ann Arbor), Science 168:1240-1242, 1970.

The fineness of the laser-generated interference fringe that the cataract patient can detect gives an indication of the potential for postoperative improvement in vision. (1 figure, 5 references)—Joel G. Sacks

CATARACTS PRODUCED IN RATS BY YOGURT. Richter, C. P. and Duke, J. R. (Psychobiology Laboratory and Wilmer Eye Clinic, Johns Hopkins Hospital, Baltimore, Md.), Science 168:1372-1374, 1970.

Rats kept on an exclusive diet of yogurt avidly ate the yogurt, grew at a normal rate, were normally active, mated, conceived, and gave birth to normal, healthy litters. However, all of the rats developed cataracts. The cataracts appear to be the same as those produced by diets with a high content of galactose. (3 figures, 9 references)—Joel G. Sacks

## SOUTHERN MEDICAL JOURNAL

MANAGEMENT OF OCULAR ADNEXAL AND MOTILITY PROBLEMS ASSOCIATED WITH MIDFACIAL FRACTURES. McCord, Jr., C. D. (Department of Ophthalmology, Emory University School of Medicine, Atlanta, Ga.), Southern Med. J. 63:842-848, July, 1970.

The clinical course of 41 patients who suffered consecutive fractures to the mid-facial area is reviewed. Double vision is the most

# NEWS ITEMS

EDITED BY THOMAS CHALKLEY, M.D.
*700 North Michigan Avenue, Chicago, Illinois 60611*

For adequate publicity, notices of postgraduate courses, meetings and lectures must be received *at least* three months prior to the date of occurrence.

### IMPLANT CLUB TO MEET IN BUDAPEST

The Second meeting of the Intra-Ocular Implant Club will be held in Budapest, at the conclusion of the European Ophthalmological Congress, on April 22, 1972. The morning session will be devoted to intracameral lens implants and the afternoon to intracorneal prostheses. Short opening papers will be read by members of the club. Any ophthalmologist who wishes to attend will be welcome. Inquiries should be addressed to Mr. Peter Choyce, F.R.C.S., Secretary, Intra-Ocular Implant Club, 45 Wimpole Street, London, W1M 7 DG, England.

### PEDIATRIC COURSE: AMERICAN UNIVERSITY OF BEIRUT

The department of ophthalmology of the American University medical center, Beirut, Lebanon, is offering a course on pediatric ophthalmology December 3-4, 1971. Guest speakers will be Jules François and Gunter K. von Noorden.

Additional information may be obtained from Camille S. Matta, M.D., Chairman, Department of Ophthalmology, School of Medicine, American University, Beirut, Lebanon.

### SYMPOSIUM: PATHOLOGIC EFFECTS OF LIGHT ON THE RETINA

On September 19, 1971, a joint meeting of the Association for Research in Vision and Ophthalmology and the American Academy of Ophthalmology and Otolaryngology will be held in Las Vegas, Nevada, convention city. The participants and their topics are as follows:

Introduction, Lorenz E. Zimmerman (Washington, D.C.), moderator; Solar retinopathy in man: Clinical features, course, and recovery: Robert Penner, (Chula Vista, California); Photic maculopathy in rhesus monkeys: Clinical features, course, and recovery: Mark D. M. Ts'o (Washington, D.C.); Foveomacular retinitis, an important problem in military medicine: Clinical features and course: Bernard R. Blais (San Diego, California); Foveomacular retinitis: Evidence that sun gazing is causative: Budd Appleton (Washington, D.C.); Effects of prolonged exposure of rabbit retina to low intensity light: Theodore Lawwill (Louisville, Kentucky); Damage to primate retina produced by low intensity light: Toichiro Kuwabara (Boston, Massachusetts); Relationship of vitamin A deficiency to damaging effects of low intensity light: Werner K. Noell (Buffalo, New York); Experimental and therapeutic aspects of photic damage to retina: Eliot L. Berson (Boston, Massachusetts); Summary and suggestions for further research, clinical and experimental: Frank W. Newell (Chicago, Illinois).

### ATLANTIC SECTION: ASSOCIATION FOR RESEARCH IN VISION AND OPHTHALMOLOGY

The Atlantic section of the Association for Research in Vision and Ophthalmology will hold their 1971 meeting at the Fontainebleau Hotel, Miami Beach, Florida, November 1-3, 1971.

Abstracts of papers are to be submitted by September 1, 1971, to Douglas R. Anderson, M.D., Bascom Palmer Eye Institute, 1638 N.W. 10th Avenue, Miami, Florida 33152. Advance registration is requested.

### OFFICERS ELECTED: AMERICAN OPHTHALMOLOGICAL SOCIETY

At the recent meeting of the American Ophthalmological Society held at the Homestead, Hot Springs, Virginia, May 24-26, 1971, the following officers were elected: President, Trygve Gundersen; Vice-President, Arthur G. DeVoe; Secretary-Treasurer, Samuel D. McPherson, Jr.; Editor of Transactions, Clement McCulloch; Council, William F Hughes, Jr.

### MEDICAL ASSISTANCE PROGRAM

The Medical assistance program (MAP) of Wheaton, Illinois, provides medical and surgical supplies to many hundreds of mission hospitals in more than 80 developing nations of the world. Close to 100 pharmaceutical and surgical supply firms donate their products for overseas use. They have shipped medical supplies worth more than $80 million to about 1000 medical missionaries. Those who are interested in donating good used instruments and surgical equipment may write to MAP, Box 50, Wheaton, Illinois 60187, for further details. Would-be donors in the Chicago area may call Larry Dixon at 653-6010.

### SOFT LENS COURSE: UNIVERSITY OF FLORIDA

A practical course on soft contact lenses, sponsored by University of Florida, will be held January 26-29, 1972, immediately preceding the Florida Midwinter Seminar.

The course is designed to provide practical instruction in the selection, fitting, and use of all types of soft contact lenses. It will consist of lectures, round table discussions, demonstrations and workshops on fitting techniques. Faculty will in-

clude: J. Aquavella, J. Baldone, C. Black, V. Chiquiar Arias, G. Feldman, M. Friedberg, A. Gasset, J. Hartstein, H. Kaufman, M. Poster, W. Sampson, M. Uotila, and K. Whitman.

Registration fee is $100 for the seminar and $300 for the seminar and workshop. Attendance will be limited and the deadline for applications is December 1, 1971. For application forms and additional information please write to Antonio R. Gasset, M.D., Department of Ophthalmology, College of Medicine, University of Florida, Gainesville, Florida 32601.

### Two meetings: University of Iowa

The ocular microbiology and immunology group of the department of ophthalmology will meet on September 17, 1971, at the university.

An international symposium on ocular inflammatory disease will be held in Iowa City on November 3-4, 1971.

Further information in regard to either meeting may be obtained from Bruce Golden, M.D., University Hospitals, Department of Ophthalmology, University of Iowa, Iowa City, Iowa 52240.

### Postgraduate course: State University of New York

The department of ophthalmology of the State University of New York Upstate Medical Center in Syracuse will present its 22nd annual postgraduate course in ophthalmology at the Hotel Syracuse, December 3-4, 1971. Guest speakers will be Joseph S. Haas, of Chicago, Marshall M. Parks, of Washington, D.C., and David Paton, of Houston, Texas.

The fee is $35. Enrollment is limited to 90 persons. For further information, contact James L. McGraw, M.D., State University of New York Upstate Medical Center, 750 East Adams Street, Syracuse, New York 13210.

### Postgraduate conference: Estelle Doheny foundation

The Estelle Doheny Eye Foundation sponsors its annual postgraduate conference in Los Angeles, California, on Monday and Tuesday, October 18 and 19, 1971. The principal speakers will be Ramon Castroviejo and Frank W. Newell.

## Personals

### George T. Brooks

Biologist George T. Brooks has been appointed Associate Director for Extramural Programs of the National Eye Institute (NEI) by Institute Director, Carl Kupfer.

Dr. Brooks was formerly Deputy Director of the Division of Research Grants, National Institute of Health. In his new position, he directs the scientific and administrative management of NEI's research and training grants programs. He will also be responsible for conducting a continuous review of Extramural Program content and will serve as a principal advisor to the NEI Director in planning and administering Institute programs, policies, and operating procedures.

Born in Okmulgee, Oklahoma, Dr. Brooks did undergraduate and graduate work at the University of Kansas. After receiving his Ph.D. degree in entomology in 1949, he became associate professor of biology at Southern University in 1949, and in 1951 was appointed acting head of the biology department. The next year, Dr. Brooks joined the International Cooperation Administration (forerunner of the Agency for International Development) as a research specialist in entomology, and was assigned to advise the Government of Nepal in establishing a plant protection service and malarial control program.

Beginning a series of assignments with the Department of Agriculture's Regional Insect Control Project in 1957, Dr. Brooks served in Pakistan, Lebanon, and Iran, assisting and advising the governments of the Middle East, North and East Africa, and South Asian countries in the control of locusts and other insect pests, and aided in the administration of U.S. technical assistance programs related to these efforts. As part of these activities, he served as the chief consultant for organizing the first Pan Africa seminar on insect control services.

Dr. Brooks came to NIH in 1962 as a Grants Associate. He was appointed Training Consultant to the National Institute of Child Health and Human Development, NIH, in 1963, and in 1965 became Director of the Hematology Grants Program within the National Institute of Arthritis and Metabolic Diseases.

In 1966, Dr. Brooks became Deputy Chief of NIH's Latin American Office and was appointed Chief of the office in 1968. He became Deputy Director of the NIH Division of Research Grants in 1969.

For achievement in the field of biology, Dr. Brooks received the Phi Sigma award of the University of Kansas in 1947. He was nominated in 1954 for the Arthur Fleming Award to honor outstanding young men in the Federal Government.

Dr. Brooks lives in Washington, D.C., is married, and has two children.

### Jin Kinoshita

Jin H. Kinoshita, Ph.D., has been promoted to tenure status as professor of biochemical ophthalmology at Harvard Medical School.

# THE AMERICAN SOCIETY OF OPHTHALMIC PLASTIC AND RECONSTRUCTIVE SURGERY

2nd Annual Scientific Session

# SOFT CONTACT LENSES

*A Practical Course Sponsored by University of Florida to be held January 26-29, 1972 in Gainesville, Florida*

(Immediately preceding the Florida Midwinter Seminar)

The course is designed to provide practical instruction in the selection, fitting and use of all types of soft contact lenses. It will consist of lectures, roundtable discussions, demonstrations and workshops on fitting techniques. An outstanding faculty will include:

J. Aquavella
J. Baldone
C. Black
V. Chiquiar Arias
G. Feldman
M. Friedberg
A. Gasset
J. Hartstein
H. Kaufman
S. Mishima
M. Poster
W. Sampson
M. Uotila
K. Whitham

Registration fee will be $100 for the seminar or $300 for the seminar and workshop. Attendance will be limited and the deadline for applications is December 1, 1971. For application forms and additional information please write:

Antonio R. Gasset, M.D.
Department of Ophthalmology
University of Florida
College of Medicine
Gainesville, Florida 32601

# ANNUAL POSTGRADUATE CONFERENCE

## ESTELLE DOHENY EYE FOUNDATION

Los Angeles, California

October 18, 19, 1971

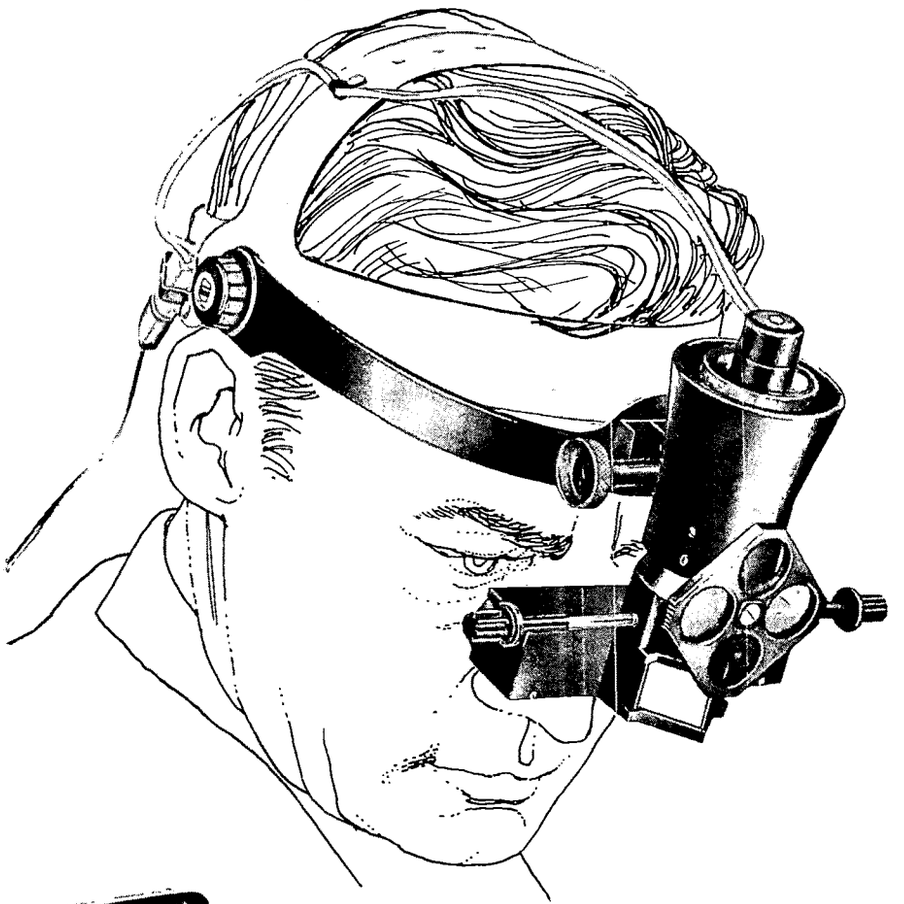
The program will be devoted to clinical applications of eye pathology, selected topics in the management of the diabetic, current concepts of pathogenesis and treatment of corneal disease, and new techniques in ocular surgery.

*PRINCIPAL GUEST SPEAKERS*

Ramon Castroviejo
Frank Newell

*GUEST FACULTY*

Samuel P. Bessman
Jerry F. Donin
J. William Greenhut
Wolf Z. Guggenheim
Richard P. Kratz
Arthur Oberman
Vincent di Raimondo
Nancy E. Warner



*ESTELLE DOHENY EYE FOUNDATION FACULTY*

A. Ray Irvine, Jr.
Dharmendra V. Arya
Robert E. Levine
Jean Mannagh
Anthony B. Nesburn
Ralph S. Riffenburg
Alan A. Snyder
T. Rodman Wood
Zolton Yuhasz

Registration Fee: $75.00. Residents, Interns and Fellows $25.00. Fee includes luncheon both days; cocktails, and banquet reservations for registrant and guest. Please register prior to September 1, 1971.

Further information may be obtained by writing to Robert E. Levine, M.D. or T. Rodman Wood, M.D., Program Chairmen, Estelle Doheny Eye Foundation, 272 South Lake Street, Los Angeles, California, 90057.

# The Fison indirect ophthalmoscope is an integrated, versatile, system

The Fison binocular ophthalmoscope offers as standard many attachments usually considered as extras; plus the unique 'bi-mirror' which allows consultation with or instruction of two extra observers, able to view the fundus simultaneously from left and right. The high intensity light source is venturi-section cooled for maximum wearer comfort while the newly-designed vision system combines optical stability with minimum weight. Fully stereoscopic viewing through automatically-aligning lenses in an adjustable P.D. system gives optimum depth perception. The integral but detachable filter wheel is supplied fitted with cobalt and red-free filters; provision is made for incorporation of special colour filters for specific study and research work. The tough, smart carrying case has a fitted, removable transformer, accessory compartment and pocket for detachment charts and case notes.

**KEELER OPTICAL PRODUCTS INC · 456 PARKWAY, BROOMALL, PA. 19008**

for your contact lens patients—when you insist they use AR-EX the only ***truly*** hypo-allergenic eye make-up.

**Prescribe "AR-EX" and increase patient acceptance of contact lenses by helping to eliminate irritation caused by ordinary eye make-up.**

AR-EX Hypo-allergenic Eye Make-up is completely free of perfume, lanolin, soap, gums, bismuth compounds and nylon or rayon floc.

The only ***truly*** Hypo-allergenic Eye Make-up.

## Supplemento

En esta sección se publicaran algunos de los trabajos presentados en el VII Congreso ad-interin de la Asociación Panamericana de Oftalmología, reunido en Bogotá del 31 de enero al 5 de febrero de 1971.

Las publicaciones se haran en 4 números consecutivos de la Revista, distribuyéndose los temas en la siguiente forma:

Número 1:
PATOLOGIA DE LA RETINA.

Numero 2:
GLAUCOMA Y CATARATA.

Numero 3:
CORNEA Y ESTRABISMO.

Numero 4:
TEMAS VARIOS.

Los trabajos serán publicados en el idioma natal del autor con resúmenes al final en Español e Inglés.

SUSCRIPCIONES:

Suscripción anual (4 números) $ 60.00 (Moneda colombiana).
Suscripción anual para el Exterior $ U.S. 5.00

## THE UNIVERSITY OF TEXAS MEDICAL SCHOOL AT HOUSTON BASIC SCIENCE COURSE IN OPHTHALMOLOGY

**January 3 through February 25, 1972**

**Texas Medical Center, Houston, Texas**

This course consists of 270 hours of lectures and demonstrations by an experienced faculty of forty ophthalmologists and basic scientists. It is directed toward the requirements of residents and prospective residents in ophthalmology.

The curriculum includes:

| | |
|---|---|
| Anatomy | Pharmacology |
| Physiology | Optics |
| Pathology | Refraction |
| Biochemistry | Glaucoma |
| Neuro-ophthalmology | Motility |
| Embryology and Genetics | Visual Fields |
| Microbiology | External Disease |
| Medical Ophthalmology | Surgery |

Tuition is $600.00. For further information and application forms please write to Whitney G. Sampson, M.D., Coordinator of Basic Science Programs, Department of Ophthalmology, The University of Texas Medical School, 530 West 20th Street, Houston, Texas 77008.

The medi-FLOW device is available either in a 6-pack or single unit through your usual source of ophthalmic supplies.

## *medi-FLOW*™

battle-proved in Viet Nam* . . . now amplifying the armamentarium of civilian ophthalmology.

The medi-FLOW device delivers controlled medication to the cornea and conjunctiva either rapidly or slowly, as you desire.

It is a uniquely designed clear plastic scleral lens with a polyethylene tube and Luer-lock adaptor for attaching either a syringe or I.V. set. The lens incidentally protects the cornea from eyelid trauma, reduces discomfort rapidly, and aids in the prevention of symblepharon formation—all outstandingly valuable assets of medi-FLOW.

# Apollo Space Flight Veteran: Methulose, for dry eyes!

Methulose artificial tears lubricate sensitive ocular tissues to provide comfortable, soothing relief from eye dryness and irritation without blurring vision. Little wonder it is a big item on Apollo flights where dry eyes could present serious problems.

Meanwhile, back on earth, Methulose might be the simple solution to the dry-eye problems of many of your patients. A non-irritating buffered aqueous solution containing Methylcellulose U.S.P. preserved with Benzalkonium Chloride 1:25,000, it is available in 15cc and 30cc direct application plastic containers. Write for a generous supply of 5cc starter samples.

**PROFESSIONAL PHARMACAL CO., INC.**

## There's no biting sting with "comfort strength" Epifrin ½%, 1%

Epifrin® (l-epinephrine) has long offered the most economical, convenient l-epinephrine available to glaucoma patients. Now, with "comfort strength" Epifrin ½% and 1%, the biting sting is gone too! Evaluate our "comfort strengths" with your glaucoma patients. Have them compare the comfort of EPIFRIN ½% with any other l-epinephrine. You'll find there is no significant difference in patient acceptance. There is growing documentation of the efficacy of these lower concentrations. (1, 2) Lower concentrations also mean reduced side effects and no blurring or impaired vision. Now the economy and convenience of "comfort strength" Epifrin® ½% and 1% make a lot more sense.

**References:** 1. Kronfeld, P.C.: Invest. Ophth. 3258 (June) 1964. 2. Harris, L. S., Galin, M.A.; and Lerner, R.: Annals of Oph. 219 (June) 1970. **Prescribing Information:** Contains: levo-epinephrine (as the HC1)...2%, 1%, ½%. with benzalkonium chloride, sodium metabisulfite, disodium edetate, and purified water. **Indications:** Chronic simple glaucoma. **Contraindications:** Should not be used in patients who have had an attack of narrow angle glaucoma since dilation of the pupil may trigger an acute attack. **Warnings:** Undesirable side reactions may include: eye pain or ache, browache, headache, conjunctival hyperemia, and allergic lid reactions. Adrenachrome deposits in the conjunctiva and cornea after prolonged epinephrine therapy have been reported. Epinephrine has been reported to produce macular edema in some aphakic patients. **Precautions:** Should be used with caution in patients with a narrow angle since dilation of the pupil may trigger an acute attack of glaucoma. **Dosage:** The usual dosage is one drop in the affected eye(s) once or twice daily. However, the dosage should be adjusted to meet the needs of the individual patient. **Note:** Protect from excessive light and heat. If the solution discolors or a precipitate forms it should be discarded. **How Supplied:** 0.5% and 1.0% strengths in 15 cc plastic dropper bottles. 2% in 5 cc and 15 cc plastic dropper bottles. On prescription only.

**Epifrin** (l-epinephrine)

# ADD NIGHT TO DAY

Isopto Carbachol 3%
controls
diurnal variation
without
risking lens opacities

**One drop of Isopto® Carbachol 3% keeps IOP down for 8 hours.** Administer it at bedtime and control IOP through the early morning hours—without the side effects of the more potent cholinesterase inhibitor. Consider Isopto Carbachol, also, for extended IOP control *during the day,* in cases where the patient no longer responds to pilocarpine.

One recent study* in glaucoma patients showed Isopto Carbachol 3% effective for a full 8 hours. A single instillation of the solution was administered in one eye; the fellow eye served as a control. IOP in the treated eye was still significantly lower than the control at 8 hours. Use it for assured all night glaucoma control.

**Variation in IOP after instillation of a single dose of Carbachol 3%**

An increase in the log value corresponds to a drug induced fall in IOP

Mean Log = Baseline outflow pressure treated eye / Baseline outflow pressure control × Outflow pressure control eye at same time after instillation as treated eye / Outflow pressure treated eye at same time after instillation as control eye.

*Drance, S. M. and Flindall, R. J.; Canad. J. of Ophth. *1*:#4:292-296, Oct. 1966

**Contraindicated** in presence of corneal abrasion or when constriction is undesirable, as in acute iritis. **Precaution & Side Effects:** Avoid overdose. Transient ciliary and conjunctival injection, headache and ciliary spasm with resultant temporary decrease of visual acuity may occur. Systemic symptoms of cholinesterase inhibitors may occur even when epithelium is intact. **Available:** Isopto Carbachol 0.75%, 1.5%, 2.25%, 3%. **Supplied** in 15cc and 30cc Drop-Tainer® Dispensers. Rx only.

**All Strengths now in Economy Packages—30cc.**

## THE PRECISION MICROSCOPE THAT'S AS MANEUVERABLE AS YOU ARE

Your delicate movements during surgery require you to **move about freely.** So you've passed up table or floor mounted microscopes to retain your mobility.

Now, the XONIX STEREOSCOPE* — the quality binocular microscope **you control like a loupe.** To bring a subject into focus, you merely move your head. A glance below the oculars gives you an unobstructed, unmagnified view of the field. **Your hands are completely free** — no fiddling with adjustments during surgery.

**Self-contained coaxial light system** pinpoints the subject with 1500 foot-candles of **cool illumination,** which you'll find particularly useful when operating in cavities.

Interchangeable oculars provide various magnifications, such as 6X, with exceptional optical clarity and resolution. The optical system was **computer-designed** specifically for this instrument.

Comfortable headpiece is **chamois-lined** to absorb moisture and **foam-padded** to provide a soft cushion. You can even wear the XONIX STEREOSCOPE **with your regular glasses** without sacrificing field size.

**THE XONIX STEREOSCOPE — DESIGNED FOR THE SURGEON WHO WANTS THE SAME MANEUVERABILITY WITH HIS MICROSCOPE AS HE HAS WITH HIS HANDS.**

## General

Address manuscripts and other scientific communications to Frank W. Newell, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Manuscripts must be original material submitted solely to the American Journal of Ophthalmology. Two original typed copies must be submitted. The entire manuscript, including case reports, footnotes and references, must be typed in double space, with wide margins, on 8½ by 11-inch heavy white bond paper. See Suggestions to Authors (Am. J. Ophth. **70**: Advertising pages 85–88, December, 1970).

Author's proofs must be corrected and returned within 48 hours to Manuscript Editor, 160 East Grand Avenue, Chicago, Illinois 60611.

Fifty reprints of each article will be supplied to the senior author without charge. Additional reprints may be obtained from Ophthalmic Publishing Company, 160 East Grand Avenue, Chicago, Illinois 60611, if ordered at the time proofs are returned.

Address news items and society proceedings to Thomas Chalkley, M.D., 700 North Michigan Avenue, Chicago, Illinois 60611.

Exchange copies of medical journals should be sent to David Shoch, M.D., 160 East Grand Avenue, Chicago, Illinois 60611.

Subscriptions, requests for single issues, notices of changes of addresses, advertising and other communications should be sent to 160 East Grand Avenue, Chicago, Illinois 60611.

Change of address notices must be received at least 60 days in advance and must include both old and new addresses.

Claims for copies lost in the mail must be received within 60 days from the date of issue.

Advertisement insertion orders and copy must be received before the first day of the preceding month for which the advertisement is scheduled.

# PROJECTOR COMMAND

## REMOTE CONTROL SYSTEM

Remote control attachment mounted on AO Project-O-Chart projector

Remote control panel provides convenient finger-tip control

Offers many advantages over manual operation of a projector. The projector attachment is housed in durable plastic. Measuring 3¾" x 5¾" x 3¾", it is easily mounted on the left side of the AO Project-O-Chart projector.

All action is provided by direct gear drive from three quiet, geared-down motors, without the use of flexible shafts. Remote Control Panel is connected to the projector attachment by an eight strand electrical cable. In attractive metal box with brushed aluminum face, it contains three activating switches and an on-off switch.

Designed for easy installation. A "do it yourself" kit is provided containing all necessary tools and complete, easy-to-follow instructions.

**HV5106**—Projector Command remote control system, with "do it yourself" kit. . . . .$315.00

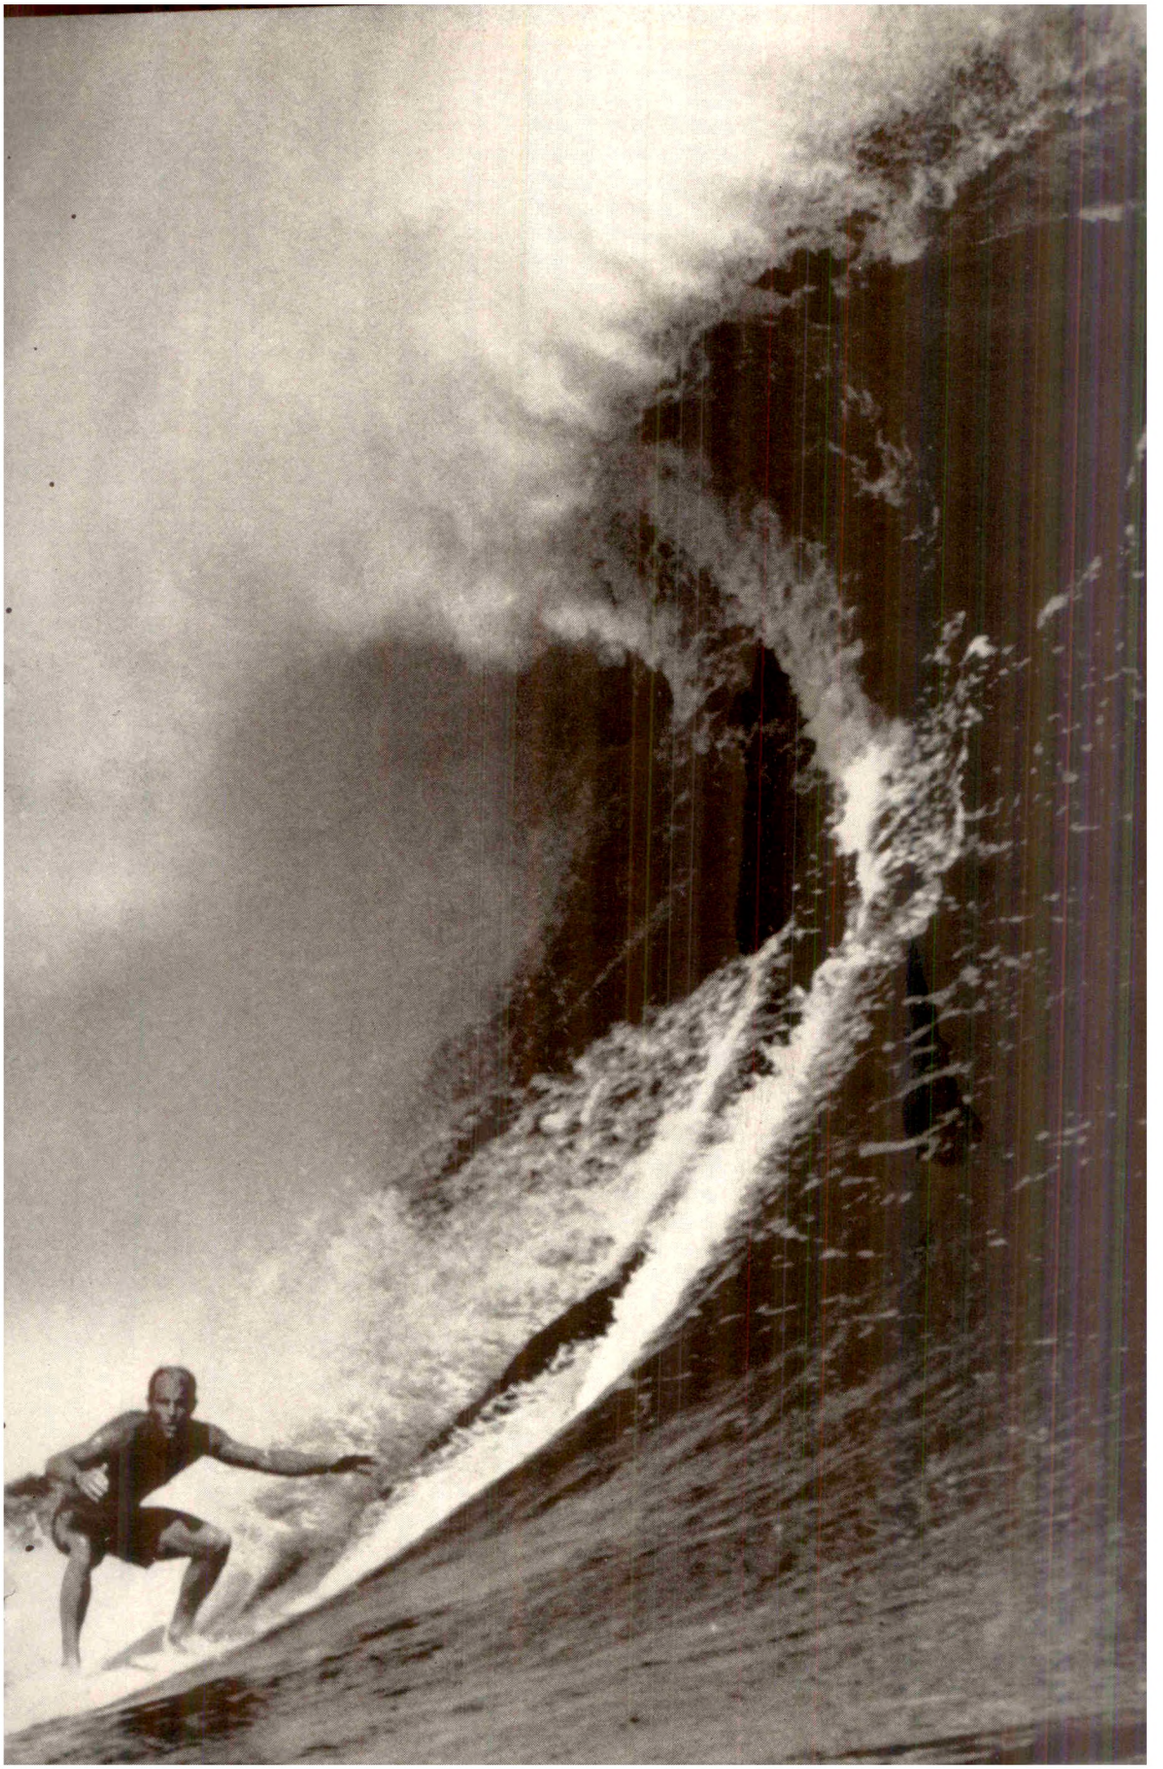
Redness and burning can't be wiped out with a beach towel. Surfside eyes need Vasocon-A. Long-lasting vasoconstrictor-decongestant, antihistamine. Reduces conjunctival hyperemia in minor eye irritations and ocular allergies. Relieves burning and itching. Vasocon-A. Keeps eyes in the swim.

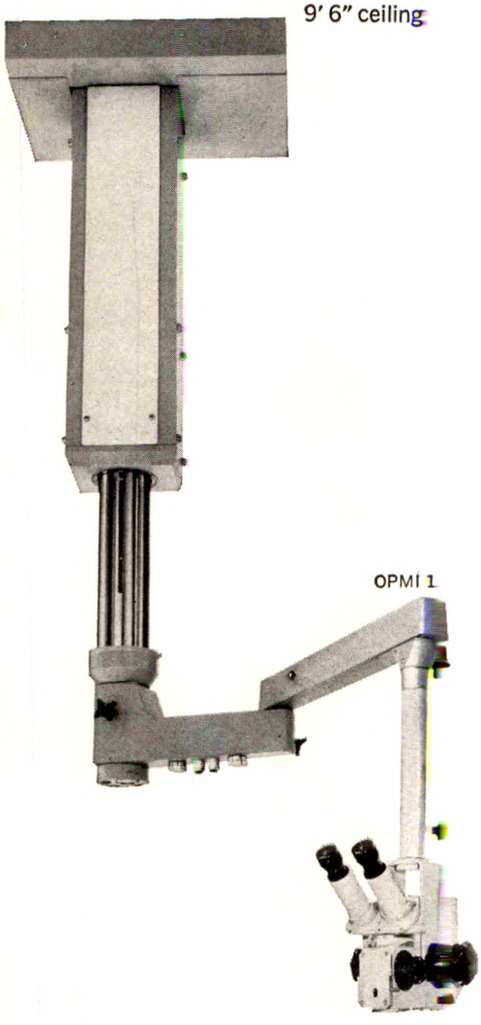
CAUTION: Federal law prohibits dispensing without prescription. See package insert before prescribing.

COMPOSITION: Naphazoline HCL, 0.05%; antazoline phosphate, 0.5%; boric acid, 1.2%; sodium carbonate anhydrous; sodium chloride; phenylmercuric acetate (preservative) 0.002%.



SIDE EFFECTS: Except for transitory stinging, side effects have rarely been encountered.

CONTRAINDICATIONS: Should not be used by patients with narrow angle glaucoma. If irritation persists or increases, patient should be advised to discontinue use and return to physician.



SUPPLIED: 15 cc plastic dropper-tip vials.

9′ 6″ ceiling

OPMI 1

OPMI 2

OPMI 3

Now any of the seven great Zeiss Operation Microscopes can be suspended from the ceiling of the operating room, providing an unmatched combination of the world's finest optics and the utmost in convenience.

The versatile and precision-engineered Zeiss Electro-Hydraulic Ceiling Suspension System is the device that makes it possible. Since Zeiss operation microscopes are the standards for microsurgery in operating rooms worldwide, the Zeiss engineers have been able to draw upon the broadest base of experience in designing a system to meet both the requirements of the surgeon and the practicalities of the hospital. Let's consider some of the main features of the system—leaving the best for last.

1. Adaptability to any operating room height Standard equipment for ceilings 9′6″ up to 13′; cus

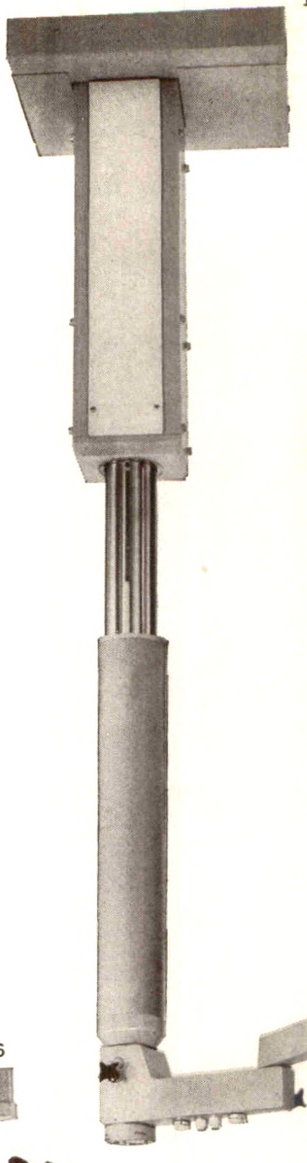
# 7-UP

**OPMI 1**

The microscope that has been used in the development of most currently employed microsurgical procedures. Magnifications from 2.5X to 50X; working distances from 4″ to 16″; direct, internal, shadow-free illumination. Still, motion picture, and television cameras can be attached.

**OPMI 2**

Fully motorized. *Zoom* magnification operated by foot or hand remote control panels. OpMi 2 provides a stereo image of unequalled brightness and edge-to-edge sharpness with continuous magnification. All photographic attachments available.



**OPMI 3 after Barraquer**

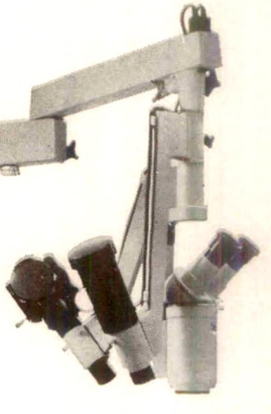
Designed exclusively for ophthalmological surgery, OpMi 3 is the easiest-to-operate microscope made. The exclusive 150/200mm tele-lens provides an unmatched depth of focus and flatness of field. All attachments available, including a special assistant's stereo-microscope with optics of the same high quality as the main one.

**OPMI 4**

A specialized instru-

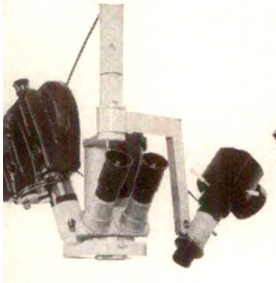
13′ceiling or higher

ɔm fittings for higher ceilings. (See illustration.)



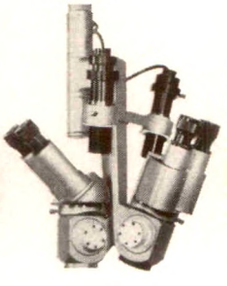
2. Telescoping action through a range of 21″ 530mm) to permit surgical fields to be cleared fully ɲd freed when the microscope is not in use.

3. Two telescoping speeds—one for rapid po-itioning of the microscope along the vertical axis ɲd one for precise positioning. Speeds can be set nywhere up to 30mm/sec.

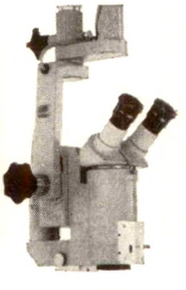


4. Automatic electro-hydraulic control by ither hand or foot control panels or both simultane-usly.

5. And, most important, the system is fully ompatible with any of the seven great Zeiss opera-on microscopes you may presently own or with any ɔu may add in the future. This feature alone means nequalled versatility. A brief review of the instru-ɲents will prove it.



OPMI 7



OPMI 4

OPMI 5

OPMI 6

ɲent for taking 16mm mo-ion pictures during eye urgery. Adaptable for Urban, Beaulieu or Bolex 16mm movie cameras. ipecial cine objective for ɲigh-resolution close-up ɯork.

**OPMI 5 after Harms**

A double microscope hat provides simultaneous ɔinocular observation in he positions most conven-ent to the tasks at hand—side-by-side, opposite, or anywhere in between. Illumination from two homogeneous illuminators.

**OPMI 6**

A new, versatile operating microscope with coaxial illumination, motorized *zoom* optics and motorized fine focusing. Especially compatible to the requirements of hospitals where the Ear, Nose and Throat Dept. and the Ophthalmology Dept. must both use the same instrument.

**OPMI 7**

A new instrument designed specifically for ophthalmic microsurgery. The vertical microscope body has a built-in *zoom* magnification system with a ratio of 1:5. In addition to all the regular Zeiss accessories, several special ones are available, including an assistant's microscope and a scanning prism.

Cryophake®
Firm grip
with a
light touch

# Cryophake®

Sterile/Disposable Cryoextractor

Developed by R. David Sudarsky, M. D.

## for a firm grip with a light touch

### All the advantages of cryoextraction with Cryophake

Reduces incidence of capsule rupture[1-5]
Facilitates intracapsular extraction[2,3,4,5]
Reduces likelihood of vitreous loss[1,2,5]
Reduces trauma and postoperative complications[1-5]
Permits a wide variety of surgical techniques[3]

### All these surgical benefits with Cryophake

Selective defrosting . . . accidental adhesions easily freed without loosening bond on lens
Ready for immediate use, self contained, easily activated
Compact, hand-contoured design for 'in use' comfort
Lightweight and maneuverable
Small tip for maximum visualization
Pre-sterilized to minimize chance of infection
Disposable and inexpensive

**Cryophake** . . . for all your cataract surgery

SURGICAL PRODUCTS DIVISION, ALCON LABORATORIES, INC.

# in post-operative retinal or cataract surgery

## Murocoll Phenylephrine, Scopolamine and Prednisolone (Murocoll Product #2c)

**FORMULA:** Sterile ophthalmic solution containing Phenylephrine Hydrochloride 10%, Scopolamine Hydrobromide 0.3% and Prednisolone 0.2%; preservatives chlorobutanol 0.5%; sodium bisulfite; polysorbate 20 and distilled water as inactive ingredients.

**CLINICAL INDICATIONS:** Used in intraocular inflammation such as uveitis and iritis, where it is desirable to maintain dilation, rest ciliary body as well as to decrease inflammation with post-operative retinal or cataract surgery.

**CONTRAINDICATIONS:** (a) Acute herpes simplex, vaccinia, varicella, and most other viral diseases of the cornea and conjunctiva. (b) Tuberculosis. (c) Fungal diseases. (d) Acute purulent untreated infections which, like other diseases caused by microorganisms, may be masked or enhanced by the presence of the steroid. (e) Purulent conjunctivitis and purulent blepharitis. Individuals with hypersensitivity to belladonna alkaloids.

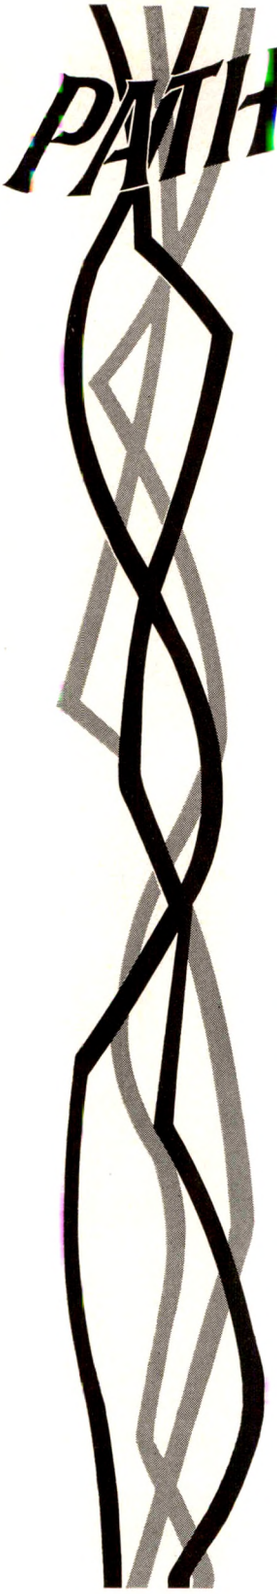
**PRECAUTIONS:** (a) Extended use of topical steriod therapy may cause increased intraocular pressure in certain individuals. It is advisable that intraocular pressure be checked frequently. (b) In those diseases causing thinning of the cornea, perforation has been known to have occurred with the use of topical steroids.

**CAUTION:** Should be used with caution in patients with narrow chamber angles.

**DOSAGE:** One or two drops in eye three or four times daily until all signs of intraocular inflammation are absent.

Use of this combination reduces the number of instillations that would be required if separate agents were prescribed, and materially reduces the cost of therapy.

**AVAILABLE:** 7.5 cc glass bottle with plastic dropper on prescription only.



**Complete ophthalmologic formulary available on request**

Muro preparations are available to all community pharmacists and hospitals through their drug service wholesaler.

## Keep pace with your rapidly expanding specialty . . .

*New!* **CURRENT CONCEPTS IN DYSLEXIA,** *by Jack Hartstein, B.S., M.D.; with 10 contributors.* The *first and only* book to deal with so many specific areas of dyslexia, this timely new reference provides an in-depth delineation of this disorder. It thoroughly describes the concepts and procedures used in educating and treating children with dyslexia, as well as the approaches used by the disciplines involved, including opposing views. The ophthalmologist's responsibilities are fully examined, including diagnostic tests, evaluation of the patient, and duties as a member of the interdisciplinary team. Actual case histories demonstrate the importance of the ophthalmologist's role and show how all disciplines interrelate in evaluating the patient.

**November, 1971. Approx. 224 pages, 34 illustrations. About $12.00.**

*New 2nd Edition!* **THE OPHTHALMIC ASSISTANT, Fundamentals and Clinical Practice,** *by Harold S. Stein, M.D., M.Sc.(Ophth.), F.R.C.S.(C); and Bernard J. Slatt, M.D., F.R.C.S.(C).* Increase office efficiency and upgrade the quality of patient care by providing your assistants with this clearly written explanation of ophthalmic procedures and treatments. This helpful reference is the *only* book written specifically for the assistant's needs and level of knowledge. In this up-to-date new edition, a new chapter describes the hospital ophthalmic assistant's role.

**September, 1971. Approx. 448 pages, 754 illustrations. About $22.50.**

*New 2nd Edition!* **EYE SYMPTOMS IN BRAIN TUMORS,** *by Alfred Huber, M.D. Edited and new material translated by Frederick C. Blodi, M.D.* In this extensive revision of *the* definitive over-all evaluation of ocular signs and symptoms of brain tumors, the noted ophthalmologist and neurologist Dr. Alfred Huber has thoroughly updated all material to reflect recent advances. Newly revised and updated in light of current progress in this area, this comprehensive presentation describes methods for neuro-ophthalmologic examination and evaluates symptoms of general and localizing significance. Many new illustrations demonstrate normal and abnormal fluorescein angiographic patterns.

**July, 1971. 392 pages, 233 illustrations. $32.50.**

*New!* **SYMPOSIUM ON HORIZONTAL OCULAR DEVIATIONS,** *edited by Donelson R. Manley, M.D.; with 15 contributors.* Dealing in depth with diagnosis and management of both esodeviations and exodeviations, this authoritative new reference presents the most current information available in book form. Fifteen distinguished ophthalmologists discuss clinically oriented topics such as classification, vertical deviations associated with exodeviations, and A and V patterns in horizontal deviations. A panel discussion concludes this practical report.

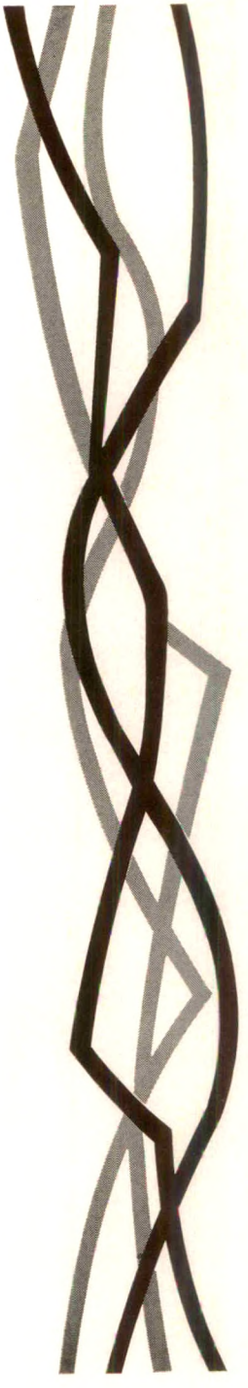
**July, 1971. 251 pages, 169 illustrations. $26.50.**

# *timely new Mosby books present the latest advances!*

*New 3rd Edition!* **THE VISUAL FIELDS: A Textbook and Atlas of Clinical Perimetry,** *by David O. Harrington, A.B., M.D., F.A.C.S.* A clinical guide to current perimetric techniques, this graphic presentation describes and demonstrates the examination of the visual fields and interpretation of defects. This carefully revised new edition includes information on recent advances in perimetric instruments, and a completely rewritten chapter on diseases of the retina. Many new illustrations and 9 vivid color plates highlight this helpful reference.

**June, 1971. 412 pages, 341 illustrations and 9 color plates. $21.50.**

*New 3rd Edition!* **SYNOPSIS OF OPHTHALMOLOGY,** *by William H. Havener, B.A., M.D., M.S.(Ophth.).* This authoritative revision of a popular synopsis presents current diagnosis and management of eye diseases concisely, yet in enough detail to provide a useful working reference. Three totally new chapters stress the diagnostic importance of the ophthalmoscope, demonstrate its application in macular disease, and discuss evaluation of reduced vision. A greatly expanded chapter on ocular therapy succinctly describes commonly used medications.

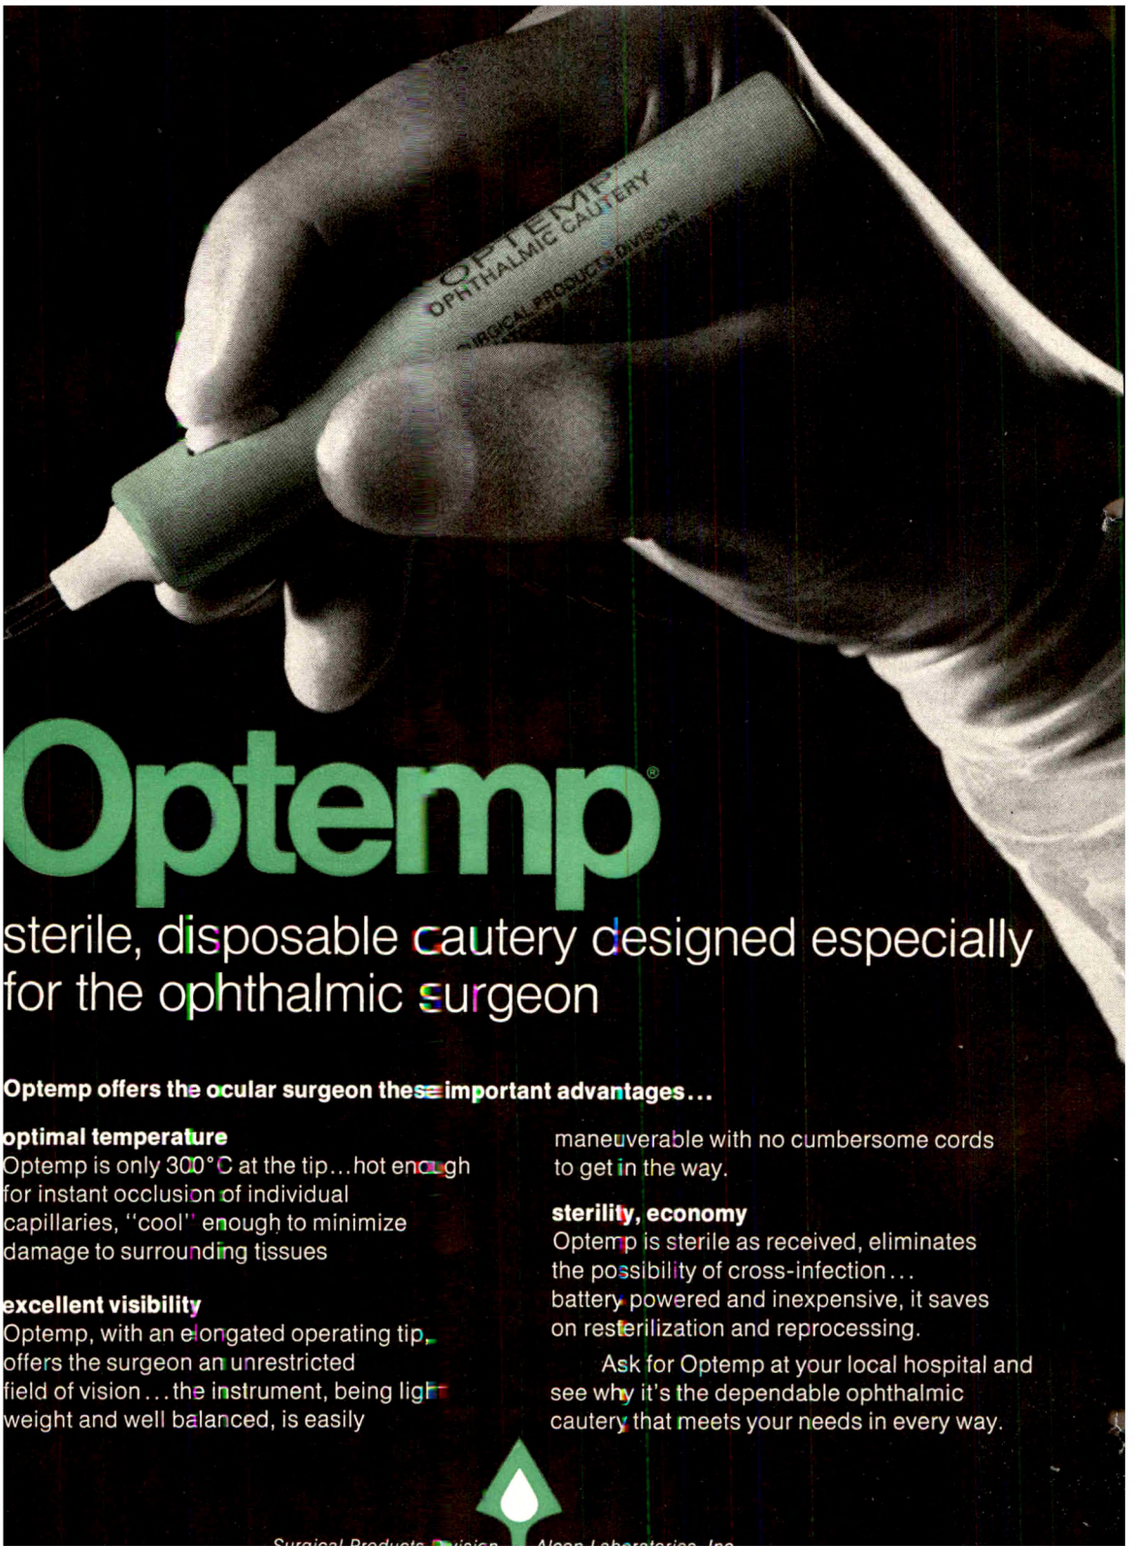


**September, 1971. Approx. 456 pages, 355 illustrations. About $12.50.**

*New!* **THE LACRIMAL SYSTEM: Proceedings of the First International Symposium,** *edited by Everett R. Veirs, M.D.; with 14 contributors.* A complete record of the significant symposium in which world-renowned authorities discussed the latest advances in the nasolacrimal field, this unique new book offers effective guidance in techniques for diagnosing and treating lacrimal disorders. It provides full information on such timely topics as: diagnosis, classification and treatment of lacrimal gland tumors; techniques for reconstructing the totally obstructed lacrimal drainage system; repair of the freshly lacerated canaliculus; and improved techniques for external dacryocystorhinostomy. In addition, controversial aspects are clearly discussed.

**October, 1971. Approx. 224 pages, 166 illustrations. About $22.50.**

*New!* **THE FIRST CONGRESS OF THE INTERNATIONAL STRABISMOLOGICAL ASSOCIATION,** *edited by Peter Fells, M.A., M.D., B.Chir., D.O.; with 41 contributors.* Forty-one specialists from many countries pool their theoretical knowledge and clinical experience to examine a wide variety of recent advances in concepts and techniques. Twenty papers and three symposia report authoritative views on such topics as early operations for strabismus, amblyopia and motility problems, an improved method of charting diplopia, and occlusion therapy.



**May, 1971. 328 pages, illustrated. $29.50.**

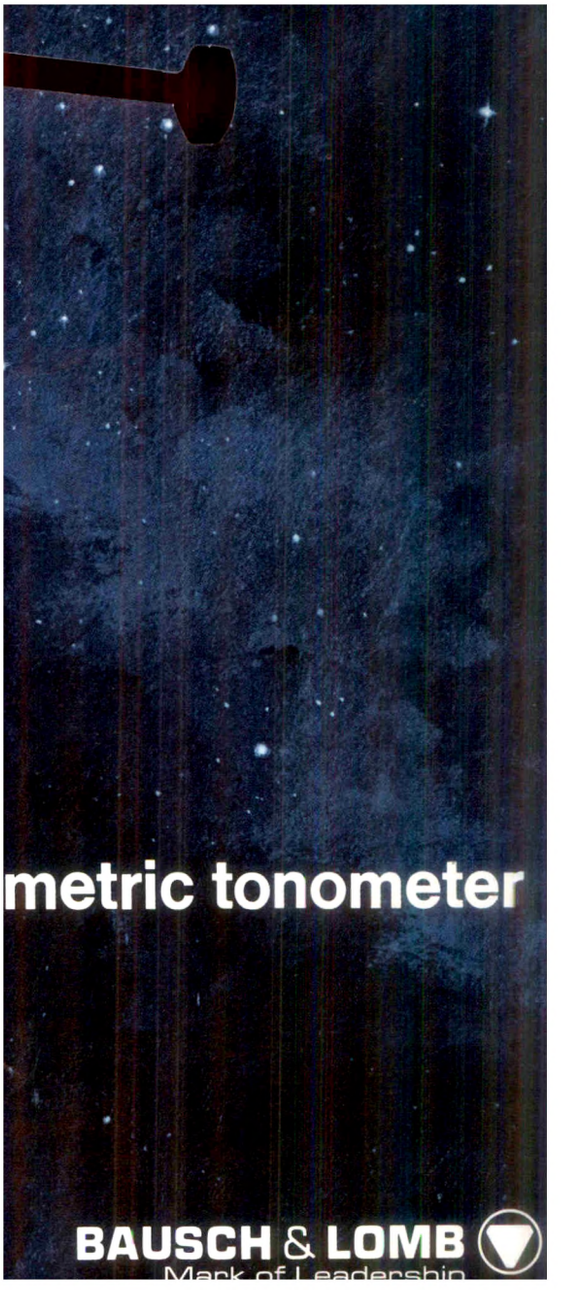
# Optemp®

## sterile, disposable cautery designed especially for the ophthalmic surgeon

**Optemp offers the ocular surgeon these important advantages...**



**optimal temperature**
Optemp is only 300°C at the tip...hot enough for instant occlusion of individual capillaries, "cool" enough to minimize damage to surrounding tissues

**excellent visibility**
Optemp, with an elongated operating tip, offers the surgeon an unrestricted field of vision...the instrument, being light weight and well balanced, is easily maneuverable with no cumbersome cords to get in the way.

**sterility, economy**
Optemp is sterile as received, eliminates the possibility of cross-infection... battery powered and inexpensive, it saves on resterilization and reprocessing.

Ask for Optemp at your local hospital and see why it's the dependable ophthalmic cautery that meets your needs in every way.
